Figures 2 and 3 show that the theoretical curves of V_{tot} are in good agreement with the experimental results over the whole frequency range. According to Eq. (8), when f is small, the constant term C'^2_{na} is dominant in V_{tot}, and the estimated values of V_{tot} are therefore larger than those given by the $f^{0.5}$ line at the same f. As f increases, the term $C'^2_{\text{dm}}f$ becomes dominant over C'^2_{na}, therefore V_{tot} increases with f approximately as $f^{0.5}$. It is known that the velocity v of domain walls is proportional to the resistivity, and inversely proportional to the saturation magnetization M_s.[7] Therefore a material with a lower M_s such as nickel tends to have a larger v than one with a higher M_s such as steel. The existence of a strong central peak in most of the MAE profiles from Ni suggest that non-180° walls in Ni move faster and are more easily unpinned than in steel, giving rise to more MAE in low fields. Thus in nickel domain wall motion plays a dominant role in the generation of MAE over nearly the whole frequency range. This assumption is supported by the MAE profiles obtained at different values of f, in which only a sharp peak around the coercivity can be found. Therefore the $f^{0.5}$ variation fits well with the experimental results except for $f<2$ Hz. In steel, M_s is large and non-180° walls are less mobile, and the wall nucleation process therefore makes a larger contribution than the wall motion process to the generation of MAE (r is larger than in nickel) especially when $f<10$ Hz. There is a greater discrepancy between the $f^{0.5}$ curve and the experimental results for $f<10$ Hz. The predicted V_{tot} curve, which has taken both wall motion and wall nucleation-annihilation into consideration, however, shows good agreement with the experimental results even in the low frequency range. As f increases, the contribution of the domain wall motion to the MAE signal increases, and the $C'^2_{\text{dm}}f$ term becomes more important, as also indicated by the overall increase of the MAE signal. At very high frequencies, the MAE signals due to the nucleation-annihilation and the wall motion processes tend to merge into a single, broad peak. As a result, the amplitude of the MAE signal is now mainly dominated by wall motion, and the MAE becomes a linear function of $f^{0.5}$.

V. CONCLUSIONS

It has been shown that the MAE signal increases with f and is a linear function of $f^{0.5}$ if non-180° domain wall motion is the major source of MAE. This happens in nickel over a wide range of frequencies, because nickel has a low M_s, the domain walls can easily be unpinned and have a larger velocity. On the other hand, in materials with large M_s such as steel, domain walls have a lower velocity, and the MAE output is mainly due to the domain wall nucleation-annihilation processes. However, as frequency increases, the wall velocity also increases, and both wall motion and wall nucleation-annihilation contribute to the MAE.

180° domain wall with the coordinate dependent azimuthal angle of magnetization

V. L. Sobolev,[a] C. T. Teh, and H. L. Huang
Department of Physics, National Taiwan University, Taipei 10764, Taiwan, Republic of China

Structure of 180° one-dimensional domain wall (DW) in a uniaxial ferromagnet in the presence of an external magnetic field arbitrarily oriented with respect to the DW has been investigated. Solutions of the system of equations which describe the behavior of the magnetic moment inside the DW in the case when the magnetization azimuthal angle is dependent upon the coordinate normal to the DW have been obtained and influence of magnetic field on the structure of the DW analyzed. Dependences of the effective widths of the distributions of both the polar and azimuthal angles of magnetization across the DW proper have been obtained. The effective width due to the azimuthal angle variation along the DW normal was found to increase with increasing transverse field.
 [S0021-8979(96)76508-2]

I. INTRODUCTION

Structure of the 180° DW in a uniaxial ferromagnet under the influence of external magnetic field normal to the anisotropy axis (the transverse field) has been already analyzed in a number of papers[1–7] (see Ref. 2 for a review). As a rule, one usually describes the structure of the one-dimensional DW based on the assumption that the azimuthal angle of the magnetization does not depend on the coordinate normal to the DW plane.[2] The only successful attempt which has taken into account the coordinate dependence of the azimuthal angle of magnetization was given in Ref. 8. This paper treated the case of the one-dimensional DW moving at a low velocity.

It was recently shown that new types of one-dimensional solutions of the system of equations for the polar and azimuthal angles of the magnetization $\mathbf{M}=M\{\sin\vartheta\cos\varphi, \sin\vartheta\sin\varphi, \cos\vartheta\}$ which describes the distribution of magnetic moment inside the DW can be obtained in the case when the transverse field is arbitrarily oriented with respect to the DW plane.[6] This new solution for the magnetization azimuthal angle is a function of the transverse field and of the coordinate normal to the plane of the DW. The solution was shown to yield lower value of the DW energy in comparison with the one in which the value of the azimuthal angle was assumed to be constant inside the DW.[6]

The purpose of the present paper is devoted to a detailed further analysis of the structural dependence of the new solutions of both the polar and azimuthal angle of the magnetization inside the one-dimensional DW. The dependence of the new solution on both the coordinate normal to the DW plane and the external field normal to the anisotropy axis arbitrarily oriented with respect to the DW plane will be thoroughly investigated.

II. EQUATIONS AND METHOD OF SOLUTION

Consider a uniaxial ferromagnet with the anisotropy axis oriented along the z axis of the coordinate frame. For convenience the DW is assumed to be pinned throughout the investigation and the wall plane is chosen to coincide with the $x-z$ plane. The orientation of the external field normal to the anisotropy axis is described by the azimuthal angle ψ_H of the field with respect to the x axis $\mathbf{H}=h(\cos\psi_H, \sin\psi_H, 0)$. In the frames of the uniaxial ferromagnet model we shall consider the so-called uncharged domain walls. The last means that the demagnetization part of the DW energy density can be written as follows:[2]

$$w_m=2\pi M^2\Delta_B(\sin\vartheta\sin\varphi-\mu)^2. \tag{1}$$

Here $4\pi M$ is the saturation magnetization; $\Delta_B=\sqrt{A/K}$ is the Bloch wall width parameter; K is the uniaxial anisotropy constant, A is the exchange stiffness constant, the parameter μ in (1) is determined by the value of the normal component of the magnetization which exists inside domains in the presence of the transverse field, that is, $\mu=\sin\vartheta_0\sin\psi_H$, where ϑ_0 is the magnetization polar angle inside the domain.

The dimensionless energy density for the DW in a uniaxial ferromagnet may be written as follows:[1,2]

$$w_{\mathrm{DW}}=\frac{\omega_{\mathrm{DW}}}{\sqrt{AK}}=\int d\xi\{\vartheta'^2+\varphi'^2\sin^2\vartheta+\sin^2\vartheta + \epsilon(\sin\vartheta\sin\varphi-\mu)^2-2h\sin)\vartheta\cos(\varphi-\psi_H)\}, \tag{2}$$

where $\xi=y/\Delta_B;\vartheta'\equiv d\vartheta/d\xi,\varphi'\equiv d\varphi/d\xi;\epsilon=Q^{-1}$; the material quality factor $Q=H_K/4\pi M(H_K=2K/M);h=H/H_K$ is the reduced transverse field.

The system of equations from which the distribution of the magnetization inside the DW may be obtained has the form[1–3]

$$\vartheta''-\sin\vartheta\cos\vartheta(1+\varphi'^2+\epsilon\sin^2\varphi + \epsilon\mu\cos\vartheta\sin\varphi+\sin\vartheta_0\cos\vartheta\cos(\varphi-\psi_H)=0, \tag{3}$$

$$(\sin^2\vartheta\varphi')'-\epsilon(\sin\vartheta\sin\varphi-\mu)\sin\vartheta\cos\varphi - \sin\vartheta_0\sin\vartheta\sin(\varphi-\psi_H)=0. \tag{4}$$

The polar angle of the magnetization inside quit is determined by the relation $\sin\vartheta_0=h$, a condition which has been

 0021-8979/96/79(8)/6060/3/$10.00

properly taken care of in writing down Eqs. (3) and (4). The boundary conditions for the solutions describing the variation of the angles inside the DW have been chosen as follows:

$$\vartheta(\xi)=\vartheta(\xi;h,\psi_H)=\begin{cases}\vartheta_0, & \xi\to-\infty\\ \pi-\vartheta_0, & \xi\to+\infty\end{cases};$$

$$\vartheta'(\xi;h,\chi_H)\to 0, \quad \text{at} \quad \xi\to\pm\infty,$$

$$\varphi(\xi)=\varphi(\xi;h,\psi_H)=\psi_H, \quad \xi\to\pm\infty;$$

$$\varphi'(\xi;h,\psi_H)\to 0, \quad \text{at} \quad \xi\to\pm\infty. \tag{5}$$

The system of Eqs. (3) and (4) along with the boundary conditions (5) has been solved numerically using the adaptive Runge–Kutta–Fehlberg method.[9] The interval of the variation of the coordinate ξ was chosen to be equal to $-15\leqslant\xi\leqslant 15$. The step of the ξ variation was adjusted automatically. We have obtained the set of dependences for $\vartheta(\xi)$ and $\varphi(\xi)$ for several orientation values of the azimuthal angle of the external field ψ_H=30°, 35°, 40°, 45°, 50°, 60°, 70°, 80°, and 90° and for several values of the reduced transverse field h=0.01, 0.05, 0.1, 0.2, and 0.25. The characteristic value of the material quality factor Q was chosen to be equal to Q=2.0 for easy convenience of making comparison with the results obtained in Refs. 6 and 7 where a slightly different method of numerical solution of the system of Eqs. (3) and (4) has been used.

III. ANALYSIS OF RESULTS

The dependence of the azimuthal angle of magnetization on the coordinate normal to the DW, ξ, has the following form: $\varphi(\xi;h,\psi_H)=\psi_H-\psi(\xi;h,\psi_H)$, where $\psi(\xi;h,\psi_H)\to 0$ at $\xi\to\pm\infty$. Such a form of dependence may be easily understood as follows. The external magnetic field applied at an angle ψ_H with respect to the DW plane produces a deviation in the orientation of the magnetization inside the DW which in turn leads to an increase of the demagnetization energy. The type of solution for the azimuthal angle $\varphi(\xi;h,\psi_H)=\psi_H-\psi(\xi;h,\psi_H)$ provides, first, the fulfillment of the condition that the DW is uncharged and, second, it diminishes the increase of the energy of the DW. This is the reason why the energy of the DW with the coordinate dependent azimuthal angle is always lower than the energy of the DW with the constant azimuthal angle $\varphi=\psi_H$.[6] The dependence $\varphi(\xi;h,\psi_H)$ for the case of ψ_H=30° for several values of transverse field h is given in Fig. 1. Clearly, it is seen that the maximum value of deviation of the magnetization inside the DW from the orientation of the transverse field located at the center of the DW decreases with increasing transverse field. The dependences of $\varphi(\xi)$ for other orientations of the transverse field are similar to the ones given in Fig. 1. The only difference is that at ψ_H=90° the function $\psi(\xi;h,\psi_H)$ becomes identically equal to zero at h=0.225.[6] This circumstance is a reflection of the fact that a phase transition from the quasi-Bloch wall to the Néel one has taken place at the value of the reduced field h=0.225 when the latter is oriented along the normal to the DW.[2,6]

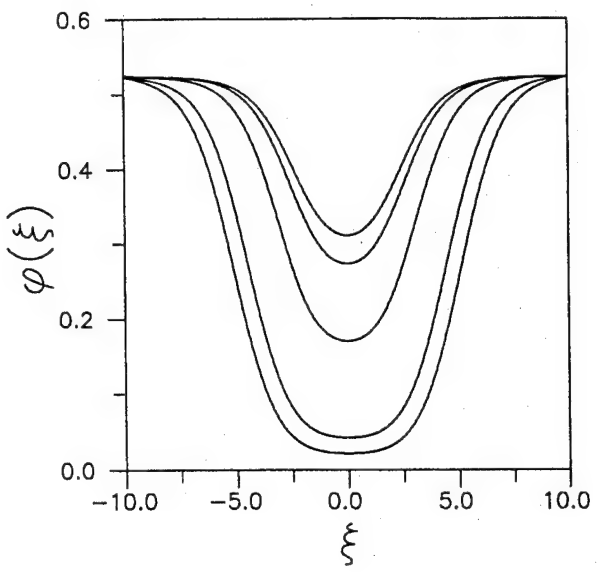

FIG. 1. Variation of the magnetization azimuthal angle $\varphi(\xi)$ along the coordinate ξ normal to the DW plane at ψ_H=30° and h=0.01, 0.02, 0.1, 0.2, and 0.25 (from bottom to top).

Using the definition of the effective DW width of the distribution of the magnetization angle inside the DW as given in Ref. 10, we have analyzed the transverse field dependences of the effective widths of the distributions of both the polar and azimuthal angles of the magnetization for our solutions of the system of Eqs. (3) and (4). The effective width of the distribution of the azimuthal angle of the magnetization, $\Delta_\varphi(h,\psi_H)$, was found to decrease with increasing transverse field in the region of the reduced fields $0<h\leqslant 0.4\div 0.5$ and then it increases, and tends to infinity as $h\to 1$ when the remagnetization of the sample takes place and it becomes homogeneously magnetized. The transverse field dependences of the effective width of the magnetization azimuthal angle distributions, $\Delta_\varphi(h,\psi_H)$, for several orientations of the transverse field are given in Fig. 2. Note that the curve for ψ_H=90° is truncated at h=0.225 as remarked above.

It is interesting to compare the transverse field dependences of the effective widths of the distributions of the polar and azimuthal angles inside the DW. Our analysis of the polar angle distributions inside the DW for different orientations of the transverse field showed that this distribution depends weakly on the transverse field orientation.[7] Another result obtained in Ref. 7 was that the numerical solutions of the system of Eqs. (3) and (4) for the polar magnetization angle do not deviate much from the dependence of

$$\sin\vartheta(\xi)=\sin\vartheta_0+\frac{\cos^2\vartheta_0}{\cosh u+\sin\vartheta_0}.$$

Note that the above expression represents the analytical solution of the system obtained under the approximation $\varphi=\psi_H$ inside the DW.[2] In this expression $u=\xi\cos\vartheta_0\sqrt{1+\epsilon\sin^2\psi_H}$. According to Ref. 10, the effective width $\Delta_\vartheta(h)$ of the polar angle distribution described by the above formula is determined by the expression

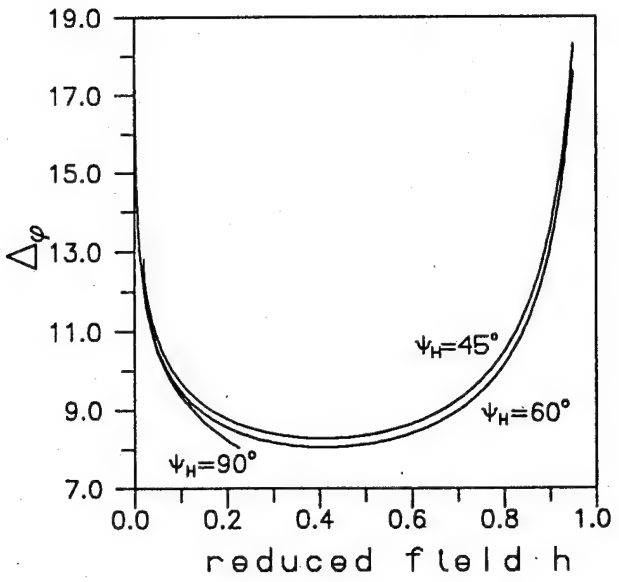

FIG. 2. The transverse field dependences of the effective width of the distribution of the azimuthal magnetization angle inside the DW, $\Delta_\varphi(h)$, for the orientations of the transverse field ψ_H=45°, 60°, and 90°.

$$\Delta_\vartheta(h)=\pi\Delta_B[\cos\vartheta_0\sqrt{1+\epsilon\sin^2\psi_H}]^{-1}. \quad (6)$$

It is easy to see from (6) that $\Delta_\vartheta(h)$, increases monotonically with increasing reduced transverse field and, tends to infinity as h approaches to unity. The transverse field dependences of the numerically obtained effective width of the polar angle distribution and the one calculated directly from formula (6) are presented in Fig. 3. One can easily see from this figure that the analytical expression (6) gives a little bit larger values of the effective width in the region of small values of the transverse field but approaches the numerical results when the values of the transverse field approaches unity.

Comparing the dependences given in Figs. 2 and 3, it is clear that the dependence of the effective width of the azimuthal magnetization angle $\Delta_\varphi(h)$, is different from that of polar angle, $\Delta_\vartheta(h)$, and that the absolute value of the effective width for the azimuthal angle distribution is always greater than that of the polar angle.

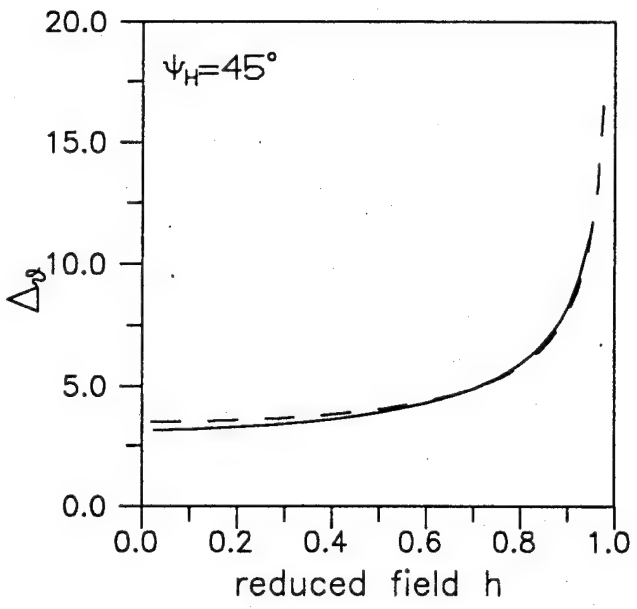

FIG. 3. Comparison of the dependence of the effective widths of the distribution of the polar angles, $\Delta_\vartheta(h)$, on the transverse field h at ψ_H=45°. Solid line: numerical result obtained from solving the system of Eqs. (3) and (4); dashed line: analytical result obtained directly from (6).

Magnetic force microscopy (MFM) is a powerful technique that has gained wide acceptance in the imaging of magnetization patterns. However, MFM images are "raw" images, and they are not necessarily identical to the original images of the magnetization patterns. In an attempt to investigate the relationship between the raw images and the magnetization patterns, we present a theoretical analysis of the MFM images through numerical computations. In this way, we show the dependence of the images on both the orientation of the probe's magnetic moment and the interaction between the probe moment and the sample magnetic fields. For a pure sinusoidal magnetization pattern, a vertical orientation of the MFM probe's magnetic moment will yield images that follow the magnetic charge density distribution, while a horizontal orientation of the probe will yield MFM images that follow the magnetization patterns themselves. We investigate the deviation from this correlation between the images and the magnetization distribution when magnetization patterns are not purely sinusoidal. Computations are performed for periodic patterns with linear and arctangent transitions. To model the interaction of the tip with the sample's magnetic fields, we model the tip as a Stoner–Wohlfarth particle. This allows us to investigate how the tip–sample interaction may distort the MFM image. Our modeling suggests that in general there is no direct correlation between the raw MFM image and the actual magnetization distribution. This makes a strong case for the implementation of image reconstruction techniques. [S0021-8979(96)61008-8]

Magnetic force microscope study of domain wall structures in magnetite

Taras G. Pokhil and Bruce M. Moskowitz
Institute for Rock Magnetism, University of Minnesota, Minneapolis, Minnesota 55455

Domain walls (DW) in a small multidomain grain (≈20 μm) of magnetite (Fe_3O_4) exhibiting a planar domain pattern were studied using a magnetic force microscope (MFM). Most walls were subdivided with one or two Bloch lines and all walls displayed asymmetric MFM responses. Domain walls were observed to have small offsets either at the location of Bloch lines or at other locations without Bloch lines. The experimental data were described by a model in which (1) the easy axis of magnetization is not exactly parallel to the grain surface but is slightly inclined, and (2) there is also some plane dividing the grain in two parts with slightly different inclined easy axis directions. The inclined easy axis produces asymmetric spin distributions across the DW and wall offsets occur to reduce the surface magnetostatic energy of the wall. © *1996 American Institute of Physics.* [S0021-8979(96)54908-7]

I. INTRODUCTION

The internal structure of domain walls (DW) between two domains with antiparallel magnetization has been intensively investigated both experimentally and theoretically.[1–11] A variety of micromagnetic structures of domain walls in thin films and bulk materials have been observed and predicted including (1) domain walls with asymmetric spin distributions across the wall due to Néel-like structures called Néel caps terminating interior Block walls at surfaces, and (2) vortex-like spin distributions in Bloch lines separating opposite polarity wall segments.[1–5] High spatial resolution imaging of micromagnetic structures using magnetic force microscopy provides experimental data on the structure of domain walls which can be used to test predictions of micromagnetic models.[8–10]

Magnetite is a ferrimagnetic oxide that occurs as a trace mineral in continental and ocean rocks. The magnetic memory in rocks of the ancient geomagnetic field is carried by the remanent magnetization of magnetite particles less than 50 μm in size.[12] The term pseudo-single domain (PSD) describes magnetic behavior that is intermediate between classical single domain (SD) and multidomain (MD) behavior and is usually attributed to particles containing just a few (<10) domains. The physics of PSD behavior plays a central role in paleomagnetism because most magnetic oxide grains in rocks are too large to be in an equilibrium SD state (<0.1 μm) and contain domains, yet can carry geologically stable remanence. In this paper we present results of a magnetic force microscope (MFM) study of domain wall structures in a small grain of magnetite containing a few domains.

II. EXPERIMENTAL METHODS

Small grains (5–50 μm) of magnetite (Fe_3O_4), randomly oriented and dispersed in nonmagnetic matrix, were produced by the glass-ceramic method.[13] The sample was mounted in epoxy and mechanically polished with diamond compounds. Amorphous silica solution was used as a final polish to obtain a smooth surface and to reduce the strained surface layer produced during the initial mechanical polishing.[14] The bulk coercive force of the sample was 15 Oe.

Magnetic force images were obtained with a Nanoscope III scanning probe microscope. The microscope was operated in the "tapping/lift" scanning mode,[15] which combines constant interaction and constant height modes, to separate topographic and magnetic signals. The scanned probes were batch fabricated Si cantilevers with pyramidal tips coated with a CoCr film alloy.[15] All MFM data shown in this paper were collected with the tip magnetized approximately perpendicular to the sample surface (z direction), making the MFM sensitive to the second derivative of the z component of sample stray field. To exclude any influence of the MFM tip on the sample micromagnetic structure, images were taken with various tip-sample orientations and tip-sample separations. Under these experimental conditions we did not observe any noticeable modifications of micromagnetic features during MFM scanning. All MFM images presented in this paper were obtained with tip sample separation of 50 nm and tip vibration amplitude of 20–30 nm. The drive frequency of cantilever was chosen above the resonance frequency of the cantilever near the point of maximum gradient of the cantilever resonance curve.

III. RESULTS

We concentrated our MFM study on a 20 μm grain exhibiting a simple planar domain structure. Although the crystallographic orientation of the grain surface was unknown, the simple domain pattern suggested that the direction of magnetization within the domains was approximately parallel to the surface of the grain. Domain walls in this grain were approximately parallel to each other with domain spacing of 2–3 μm (Fig. 1). The FWHMs of the MFM response profiles across the walls were about 200 nm which is slightly wider than the theoretical Bloch wall width in bulk magnetite (100–150 nm),[16] but similar to MFM results obtained for a large single crystal of magnetite.[10] Surface broadening of the DW can result from the self-demagnetizing field acting on the DW near the grain surface resulting in, for instance, a Néel cap. However, some broadening of the MFM response is expected due to the integrated effect over the tip. Some walls were subdivided into alternating chirality segments separated by Bloch lines. The smallest observed distance between Bloch lines was ≈1 μm.

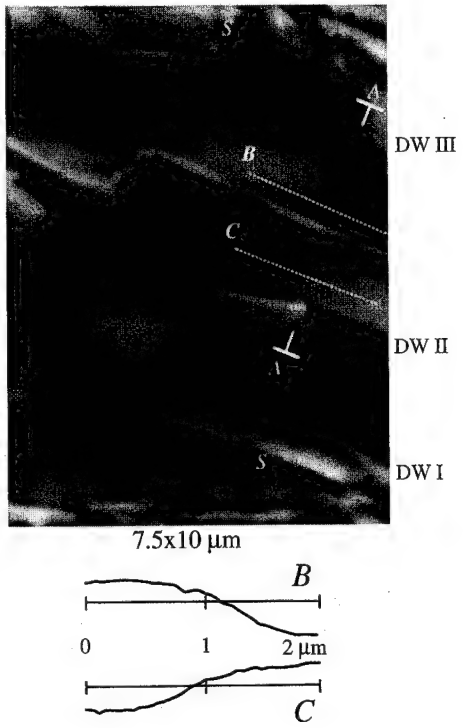

FIG. 1. MFM image of domain walls in a magnetite grain and MFM response profiles along the domains at lines *B* and *C*. Features marked as *S* are stray fields from scratches.

We found several interesting spin features associated with domain walls. Small offsets of the DW were observed in some walls at the location of Bloch lines [Fig. 2(c)], whereas other walls had offsets without an accompanying Bloch line [Fig. 2(a)]. The size of these offsets varied between 30 and 50 nm. The MFM response profiles across these walls were asymmetric. Moreover, the MFM profiles *A* taken on one side of DW offset point can be transformed into profiles *B* taken on the opposite side of the offset using axially symmetric [Figs. 2(a) and 2(b)] or centrally symmetric transformations [Fig. 2(c)]. We also observed a change of the MFM response within the domains. For example, in Fig. 1, the MFM response changes when the MFM tip crosses line *A-A* and the sign of the change is opposite in neighboring domains resulting in checkerboard contrast pattern. This is seen more clearly in Fig. 2 which shows higher-resolution image scans of the walls labeled DW I, DW II, and DW III in Fig. 1. Here, there is a change in the MFM response within the domains across the wall offset associated with DW III [Fig. 2(a)] and the Bloch line in DW II [Fig. 2(b)], but no change in MFM response associated with the offset at the location of the Bloch line in DW I [Fig. 2(c)].

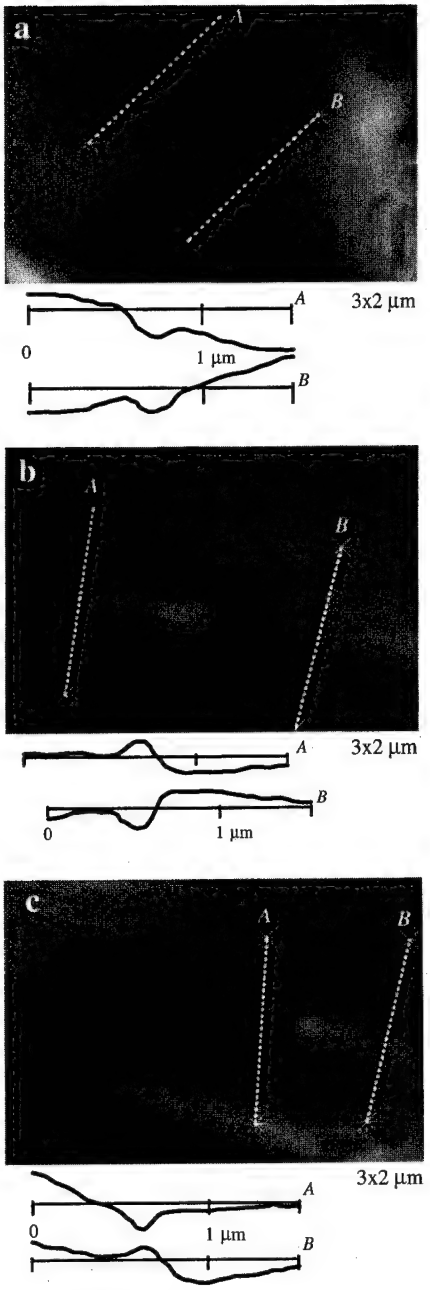

FIG. 2. MFM images of three walls in Fig. 1, DW I, DW II, and DW III and MFM response profiles across the domain walls at lines *A* and *B*. The size of all images is 3×2 μm. (a) DW without a Bloch line; easy axis of magnetization has different directions on different sides of the DW offset point, (b) DW with a Bloch line; easy axis has different directions on different sides of the Bloch line. (c) DW with a Bloch line; easy axis has the same direction on different sides of the Bloch lines.

IV. DISCUSSION

To explain our experimental data (DW offsets and asymmetric MFM profiles), we proposed the following simple model depicted in Figs. 3 and 4. We assumed that (1) the easy axis of magnetization is not in the plane of the grain surface but is slightly inclined and that the direction of magnetization inside the domains is parallel to the easy axis; and (2) a plane intersecting the domain walls divides the grain in two parts with slightly different inclined easy axis directions (Fig. 4). Under these conditions, the magnetization in each domain will have a small component perpendicular to the surface. Within the same domain, this component is directed out of (into) the surface on one side of the dividing plane and directed into (out of) the surface on the opposite side of the plane. The inclined easy axis relative to the sample surface produces the observed asymmetric spin distribution across the DW. This hypothesis is consistent with the observed change of MFM response within the domains (i.e., the

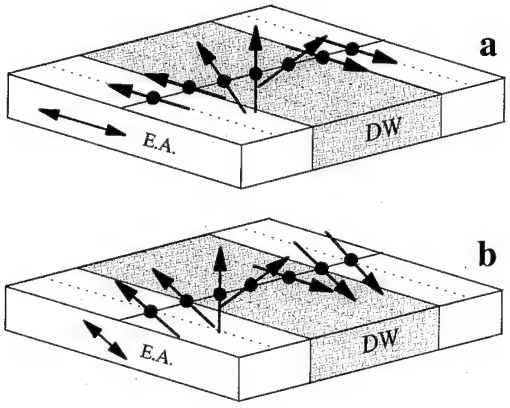

FIG. 3. Distribution of magnetic moments across a Bloch domain wall where (a) the easy axis is in the plane of the surface; and (b) the easy axis makes a small angle with the surface. The MFM response across the wall would be symmetric for (a) and asymmetric for (b).

checkerboard pattern in Fig. 1). Such a change of easy axis direction can result from residual surface stress, or from the formation of subgrain or twin boundaries during crystallization which divides the grain in two parts with slightly different crystallographic orientations.

Spin distributions across a Bloch wall when the easy axes are in plane or inclined are presented in Figs. 3(a) and 3(b), respectively. For the DW shown in Fig. 3(b), the area of the wall with magnetization perpendicular to the surface is shifted toward one side of the wall, while near the other side of the wall, there is an area in which the direction of magnetization is parallel to the surface. The magnetostatic energy of a DW crossing an area where the easy axis changes direction is reduced if the DW is offset and "in-plane" spins in the DW on both sides of this area follow the magnetization in the adjacent domains [Fig. 4(a)]. The stray field distribution above the DW on both sides of wall offset point would be asymmetric as shown in Fig. 4(a). These model field distributions are qualitatively similar to the MFM response profiles in Fig. 2(a). Similarly, it follows that (1) a DW offset is magnetostatically favorable at the location of Bloch line when the easy axis is inclined, but does not change its direction at the Bloch line [Fig. 4(c)]; and (2) no DW offset should occur at the location of a Bloch line if it happens to be located in the plane where the easy axis changes direction [Fig. 4(b)]. The MFM images of domain walls with Bloch lines in Figs. 2(b) and 2(c) agree with this simple interpretation. This model also explains the symmetry relationships exhibited by the MFM response profiles on opposite sides of offset points (Fig. 2). Using the model and measured wall offsets, the angle of the inclined magnetization within the domains with respect to the surface of the grain was calculated to be approximately 20°.

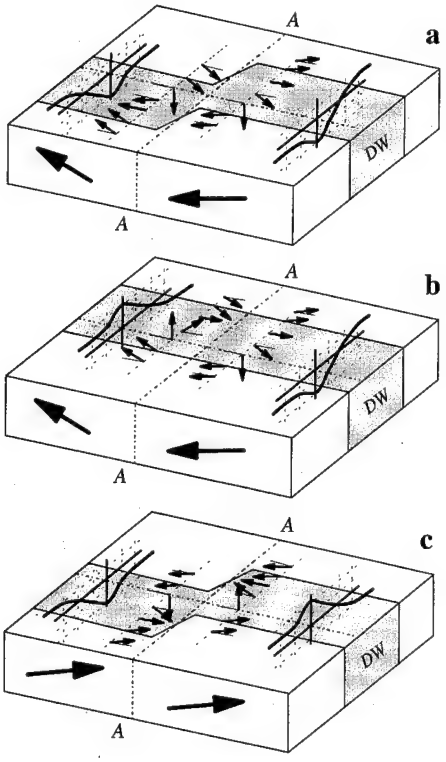

FIG. 4. Schematic drawing of an asymmetric Bloch DW. In (a) the DW has an offset but no Bloch line. The easy axis of magnetization has different directions on different sides of the DW offset point. In (b) the DW has a Bloch line but no offset. The easy axis has different directions on different sides of the Bloch line. In (c) the DW has both a Bloch line and an offset. The easy axis has the same direction on different sides of the Bloch line.

A scanning microscope using a magnetoresistive head as the sensing element

R. O'Barr, M. Lederman,[a] and S. Schultz
Department of Physics and Center for Magnetic Recording Research, University of California, San Diego, 9500 Gilman Drive, LaJolla, California 92093-0319

We have built a scanning probe microscope where a magnetoresistive (MR) head is used as the sensing element. The sensor region of the MR head is about 5 μm wide and 30 nm thick giving high resolution in one direction and poor resolution in the other. As MR heads with smaller cross-track dimensions are developed, submicron resolution in this direction should also be realizable. The MR head is mounted on a piezoelectric bimorph and vibrated perpendicular to the plane of the sample, and the ac voltage output of the head is detected with a lock-in amplifier. We have imaged pre-recorded bits as a function of scan height, and also imaged bits that were written using the write element of the same MR head. The typical voltage change through a transition is ~4 μV, two orders of magnitude smaller than signals generated on a spin stand. This is most likely due to the difficulty in setting the slider parallel to within submilliradian accuracy to the plane of the sample. Our positioning system does not have this capability at this time. With modifications in the positioning stage, this device should provide a valuable tool for investigating the recording and playback processes, and for characterizing media and heads at ever decreasing track widths, bit separations, and flying heights. © *1996 American Institute of Physics.* [S0021-8979(96)55008-1]

I. INTRODUCTION/MOTIVATION

In recent years, a variety of scanning probe microscopes have been developed.[1] These instruments have the common feature of a probe that is raster scanned in close proximity to the surface of a sample. Magnetic force microscopy (MFM) is one form of scanning probe microscopy useful for obtaining spatially resolved information of the magnetic forces or force gradients acting on a magnetic tip as it is passed over magnetic patterns.[2] We have implemented another form of scanning probe microscopy which can be used to directly image magnetic flux patterns. We have used a magnetoresistive (MR) head as the probe which detects the vertical component of magnetic field passing through the MR sensor. The sensor region of present MR heads is typically a few microns wide and ~30 nm thick making such a device capable of imaging magnetic structures with high resolution in one dimension and with poor resolution in the other. As MR heads with smaller cross-track dimensions are developed, submicron resolution in this direction should also be achieved. One application for this device is as a diagnostic tool for characterizing magnetic media and conversely, using known magnetic field patterns to characterize the MR head itself. Since the playback signal generated by an MR head is fundamentally independent of the relative speed between the head and media,[3] diagnostics obtained by the scanning of an MR head over recorded bits should correspond directly with the MR signals in a spin stand or working disk drive device.

II. SETUP AND PROCEDURE

The apparatus used is a modification of a home-built MFM[4] where the magnetic probe (which in our case is usually an etched Ni wire) is replaced with an MR head. The suspension arm of the MR head is glued onto a piezoelectric bimorph (see Fig. 1). The illumination from an optical fiber (coupled to a laser diode) is positioned incident on the suspension arm in a location directly behind the MR element. By oscillating the bimorph perpendicular to the plane of the sample to be imaged, a time-dependent interference pattern is obtained, allowing one to monitor the oscillation of the MR head. The MR head was typically oscillated at a frequency, f=1.85 kHz, which corresponded to the resonant frequency of the bimorph, suspension, and slider assembly. The peak-to-peak vibration amplitude of the MR head perpendicular to the media was typically 50 nm. The sample was mounted on three mutually orthogonal piezoelectric block translators, which were mounted on a mechanical x,y,z positioning stage. The pitch and roll angles that the slider made with the sample were mechanically adjusted so that the slider was approximately parallel to the disk (to less than 1°). When the slider just makes contact with the disk, the amplitude of the interference pattern starts to damp out and then,

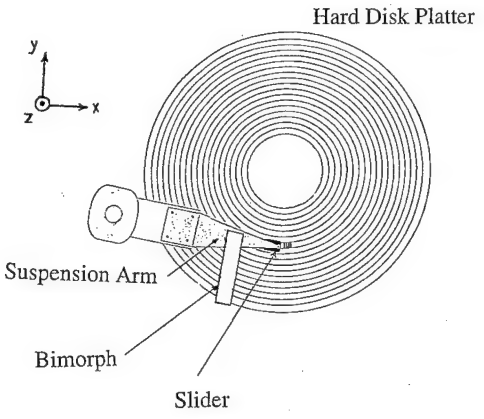

FIG. 1. The experimental setup. An ac voltage is applied to the bimorph causing the MR head to vibrate in the z direction. The sample is scanned in the xy plane.

when complete contact is made, disappears altogether. Contact was made with the sample at three points defining the sample plane. The sample was then backed away from the slider a fixed distance, and raster scanned in a plane parallel to the defined sample plane. The MR voltage was fed into a lock-in amplifier with the signal driving the bimorph used as the reference. The dc output of the lock-in was recorded as a function of the coordinate position of the head with respect to the plane of the disk.

III. IMAGING OF BITS

Bits were prerecorded on a commercial hard disk platter with transitions of alternating polarities. The recorded magnetization patterns were first imaged by MFM (Fig. 2). The bimorph with the MFM etched Ni tip was then removed and replaced with one having an MR head mounted on it. Figure 3 is an image obtained by scanning the MR head over bits written on the same disk (with the same head) as those imaged by MFM. Because the track width of the recorded bits are about twice that of the MR element, the signal is strongest in the central 5 μm of the track and falls off uniformly toward the edges of the track (see Fig. 4). We initially tried to image the recorded patterns without oscillating the MR

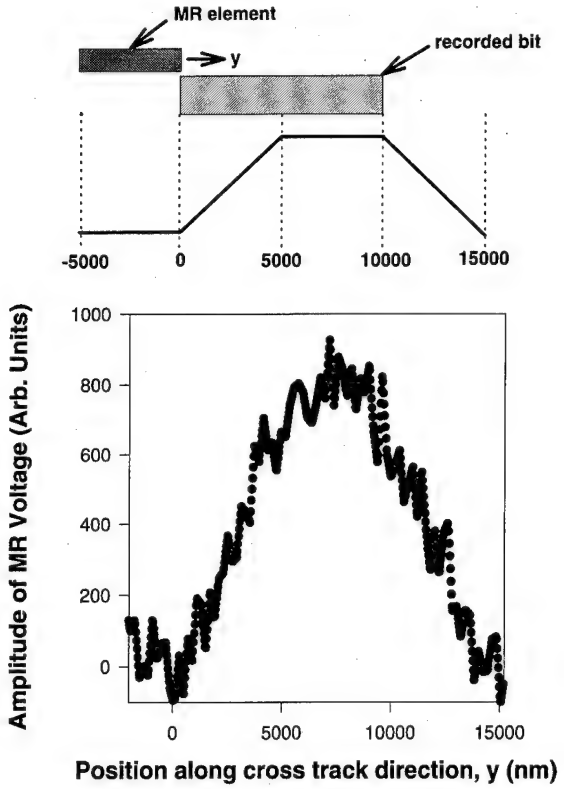

FIG. 4. Cross-track section taken through one of the bits in Fig. 3. The diagram above illustrates the expected MR voltage profile for an element width of 5 mμ and a track width of 10 mμ. Amplitude of MR voltage is given in arbitrary units.

head (i.e., without lock-in detection) but found insufficient signal to noise to detect the transitions. The peak-to-peak change in MR voltage amplitude between transitions of opposite polarity was approximately 4 μV when the slider was backed away ~100 nm from the hard disk platter and vibrated with a peak-to-peak amplitude of 50 nm. In Fig. 5, the data of MR voltage change as a function of d, the distance between the slider and disk is shown. The data give a good fit to the form expected for square wave recording,

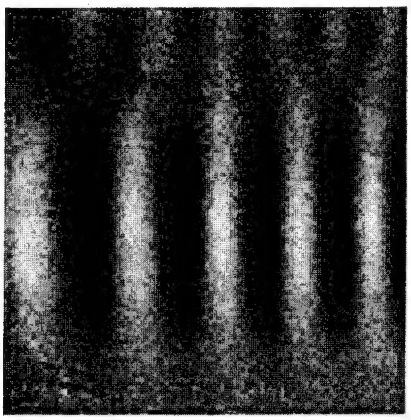

FIG. 3. Bits written on same disk as those in Fig. 2 with the same head but with somewhat lower frequency, as imaged by scanning an MR head. The MR head peak-to-peak amplitude of vibration is 50 nm and the slider-to-disk distance is 250 nm. Scan dimensions are 20×20 μm.

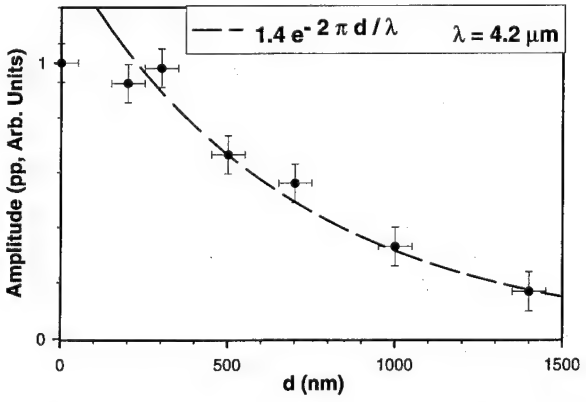

FIG. 5. Change in amplitude of MR head voltage between bits of opposite polarity vs distance to disk peak to peak. Amplitude of vibration of head: 50 nm, f=1.85 kHz. Data are fit to the wallace spacing loss formula, where λ=4.2 is the measured wavelength of the bits imaged.

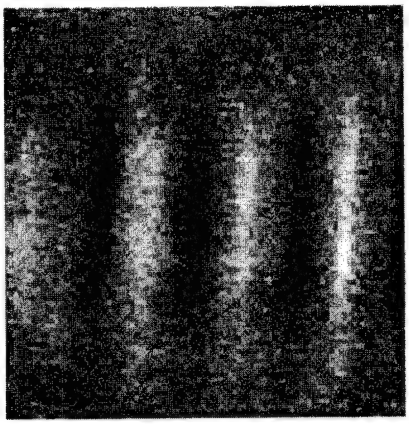

FIG. 6. Image of bits recorded with the write element of the MR head and subsequently imaged by scanning the MR read element. Slider was just in contact during the record process. Imaging was done with a slider to disk distance of 250 nm, pp. Amplitude of vibration of head 100 nm, f=1.85 kHz. Scan dimensions are 20×20 μm.

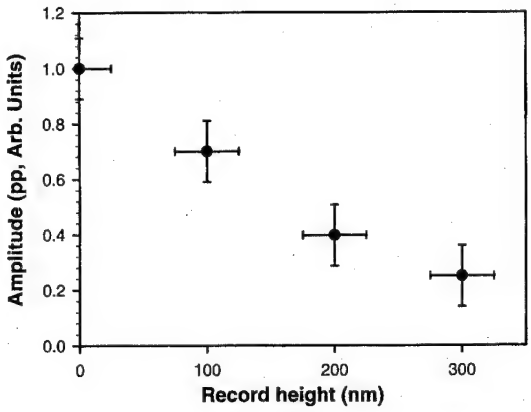

FIG. 7. Change in amplitude of MR head voltage between bits of opposite polarity vs record height. The slider to disk distance is 250 nm, peak-to-peak. Amplitude of vibration of head 100 nm, f=1.85 kHz.

$V=V_0\exp(-2\pi d/\lambda)$, where V_0 is the voltage at d_0, the distance from which d is measured.[5] We have used λ=4.2 μm (as measured from the data in Fig. 3).

IV. WRITING TRANSITIONS

The MR head has an inductive write element which we used to write bits on a nonrecorded region of the hard disk platter. The procedure for writing bits was as follows:

(a) The slider was approached to the platter until contact was made and then backed up a set distance away.

(b) A forward dc current of 40 mA was applied to the write head. The platter was then translated 2 μm in the recording direction.

(c) A reverse dc current of 40 mA was applied to the write head. The platter was then translated another 2 μm in the recording direction.

(d) Steps b and c were repeated several times. The current was then turned off.

Figure 6 shows an image taken of bits written with the slider just in contact with the disk. The scan was made with the slider backed up about 250 nm from the surface and with a peak-to-peak oscillation amplitude of ~100 nm. Bits were written at different recording heights and subsequently imaged at the same scan height of ~250 nm. The decrease in peak-to-peak change in MR voltage as a function of record height is given in Fig. 7.

V. CONCLUSION

We report the implementation of a scanning microscope using an MR head as the scanning probe. As previously mentioned, the signal was too weak to image bits without oscillating the MR head and using lock-in direction. In an actual disk drive, the aerodynamic design of the slider maintains it very nearly parallel to the disk with pitch and roll angles smaller than 100–200 μrad and 10 μrad, respectively. These angles are critical because if the pitch angle is only one degree when contact occurs, the MR sensitive element will still be backed almost a half micron away from the disk surface. This is because the MR element on this head is followed by a midshield (shared by the read and write elements), a write gap, a write pole, and an overcoat with a thickness of approximately 25 μm. The constraint on the roll angle is even more demanding since the slider rail has a width of a few tenths of millimeters with the MR element occupying only a small region near the center of the rail. In our initial setup, we only had coarse mechanical control over the pitch and roll angles. It is likely that the slider was not sufficiently well aligned with the disk and the MR element was always several hundreds of nanometers away from the disk even when one edge or corner of the slider was making contact with the disk. Once modifications permitting fine adjustments over the pitch and roll angles have been implemented, we should be able to align the slider more nearly parallel to the disk. This should allow for imaging without oscillating the MR head, and should generate peak-to-peak dc MR signals of a few hundred microvolts. These changes combined with an improved positioning stage (with feedback control and nm resolution) will provide a valuable tool for investigating the recording and playback processes, and for characterizing media and heads at ever decreasing track widths, bit separations, and flying heights.

Surface deformations and domains in Terfenol-D by scanning probe microscopy

A. P. Holden, D. G. Lord, and P. J. Grundy
Physics Department, Joule Laboratory, University of Salford, M5 4WT, United Kingdom

This paper reports the first direct measurements of the deformations in the surface of a ferromagnet caused by magnetostrictive lattice strains in neighboring magnetic domains. Observations of the {011} and {112} surfaces of twinned Terfenol-D ($Tb_{0.3}Dy_{0.7}Fe_2$) crystals by atomic force microscopy reveal the deformation domains previously imaged by optical microscopy and predicted by recent theory. The surface topography has been imaged in the remanent and ac demagnetized states and measurements of the deformation gradients have enabled the magnetostriction constant in the ⟨111⟩ direction to be estimated as 1.63×10^{-3} to within 8%. All theoretically predicted deformation domains have been observed and, in particular, the exact compatibility of such deformations across the growth twin boundaries is clearly revealed. The magnetic domains associated with the observed deformations are inferred from magnetic force microscopy observations which yield complex contrast patterns. © *1996 American Institute of Physics.* [S0021-8979(96)55108-8]

I. INTRODUCTION

The cubic Laves phase compound $Tb_{0.3}Dy_{0.7}Fe_2$ (Terfenol-D) exhibits a large magnetostriction to anisotropy ratio at room temperature, the anisotropic magnetostriction resulting in significant rhombohedral strain within magnetic domains when the magnetization is along the ⟨111⟩ easy axes. Material grown by a free-standing zone (FSZ) technique is known to solidify via a {211} dendritic growth front producing samples composed of dendritic plates which often contain growth twins, the predominant plate and twin boundary plane being the {111} orthogonal to the growth front.[1,2]

The interactions between the magnetic domain structure and both the crystallographic defects and the sample surfaces have been the subject of a number of investigations using x-ray topography,[2] optical differential interference contrast (DIC) microscopy,[3] magnetic colloid,[4] and Lorentz transmission electron microscopy (TEM).[2,5] Such studied have all indicated complex surface domain structures and associated surface deformations which have recently been the subject of theoretical assessment.[6] The application of scanning probe microscopy (SPM) techniques to Terfenol-D surfaces has yielded direct measurements of the deformation gradients for particular domain configurations and data is presented here which has enabled evaluation of the magnetostrictive constant.

II. EXPERIMENT

Samples used in this investigation were obtained from 8-mm-diam rods prepared by Edge Technologies, Inc., by a FSZ technique. Surfaces parallel to the $(1\bar{1}0)$ plane, orthogonal to the $(11\bar{2})$ growth plane, and surface containing the $(11\bar{2})$ plane were spark eroded from the rods following alignment using the backreflection x-ray Laue technique. The surfaces were polished down to 0.25 μm diamond finish and then lapped with Syton. Atomic and magnetic force microscopy observations were carried out using a Dimension 3000 (Digital Instruments) SPM employing silicon cantilevers with tips coated with a CoCr film. All observations were carried out at ambient temperature with the tip magnetized normally to the specimen surface. The topography images were obtained in the "tapping" mode and the magnetic force gradient images (hereafter referred to as MFM images) were obtained by phase detection in the "interleave" mode using a typical lift height, above the topography, of either 20 or 30 nm.

III. RESULTS AND DISCUSSION

Figure 1 illustrates the typical topographic features observed from $(1\bar{1}0)$ surfaces of samples in a remanent state following field application along the $[11\bar{2}]$ growth axis direction. Such images show the chevron-like contrast associated with topography features interacting with the growth twin boundaries (TB) as previously observed by optical DIC microscopy.[3] The exact compatibility of the height changes across the twin boundaries is clearly shown. The nonuniformity of the deformations in the $[11\bar{2}]$ growth direction is thought to be associated with variation in the Tb/Dy ratio resulting in small changes in both anisotropy, and magnetostriction. Figure 2 shows a three-dimensional representation of these data where the angular nature of the deformations is clearly illustrated. An interpretation of the origin of this sur-

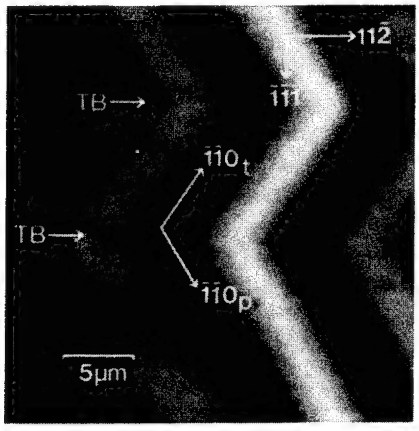

FIG. 1. AFM topographic (height) image of $(1\bar{1}0)$ surface showing surface deformations across two twin boundaries (TB).

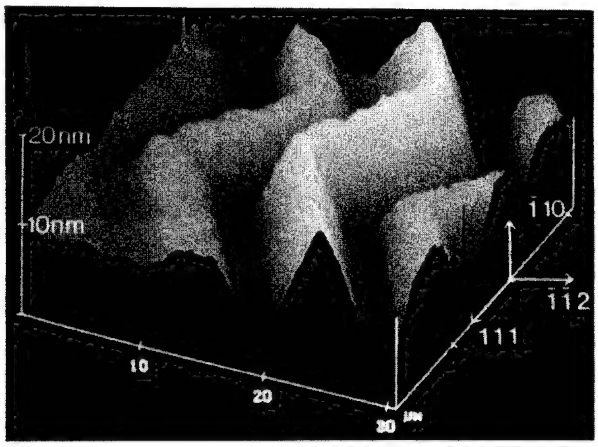

FIG. 2. Three-dimensional representation of Fig. 1 showing the angular deformations.

face relief, generated by internal stress relief at the crystal surfaces, is given in Fig. 3(a) where (001) 109° Bloch walls are shown intersecting the $(1\bar{1}0)$ surface. Such walls lie parallel to the $[\bar{1}\bar{1}0]$ direction in this surface and are consistent in their geometry to the deformation domains of the theory of James and Kinderlehrer.[6] Each domain will magnetostrictively strain along its $\langle 111\rangle$ direction as depicted in Fig. 3(a). The magnitude of this strain effect on the surface distortion α is shown in Fig. 3(b) assuming a two-dimensional simplified model. The deformation gradient α can be related to the magnetostriction coefficient such that $\lambda_{111}=\sqrt{2}\alpha/3$. Direct measurements of α have been made on a large number of such topographic images from several specimens, in both $(1\bar{1}0)$ and $(11\bar{2})$ surfaces by the analysis of sections of images such as that shown in Fig. 1. The typical height changes are of the order of 10 nm in 5 μm and estimates of λ_{111} from such data yield a value of 1.63×10^{-3} ($\sigma\sim8\%$) which agrees remarkably well with previous experimental and theoretical evaluations.[7]

Topographic and MFM images of the same area of a $(1\bar{1}0)$ surface across a double growth twin are shown in Fig. 4 and demonstrate the direct relationship between the magnetic and topographic features which is not unduly influenced by the surface scratches in this example. The fine

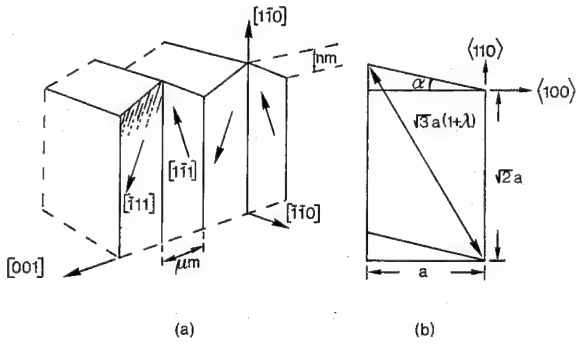

FIG. 3. (a) Magnetization distribution diagram to show origin of surface deformations and closure domains for (001) 109° Bloch walls, (b) simple distortion of a {110} section, where α represents deformation gradient.

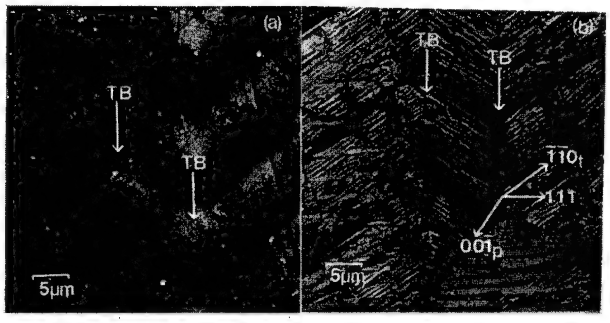

FIG. 4. (a) Topographic and (b) MFM images of a $(1\bar{1}0)$ surface across a double twin (TB). Magnetic contrast can be seen in $\langle 111\rangle$, $\langle 110\rangle$, and $\langle 001\rangle$ directions.

structure associated with the magnetic force gradient image is thought to be associated with closure domains and is symptomatic of the branching structures required to reduce magnetostatic energy. In general these fine structure features, which will not affect the surface distortion as shown in Fig. 3(a), have a separation of about 10% of the major deformation separations. Those lying parallel to the $\langle 110\rangle$ directions in the surface are considered to have {110} 109° Bloch character. Magnetic contrast can also be seen in $\langle 111\rangle$ and $\langle 001\rangle$ directions as predicted[7] and most configurations imply that the growth twin boundaries are associated with domain walls.[2,5] In the few regions of the surface which yield no surface topographical deformation, the MFM images reveal contrast which is considered to arise from in-plane easy axis domain configurations. An example of such contrast is shown in Fig. 5 from a $(1\bar{1}0)$ surface where the [111] and $[11\bar{1}]$ directions lie in the plane. The interpretation of such images however requires further experimental evidence concerning the magnetic state of the tip, since the directionality of the observed contrast will be dependent on the stray field distribution of both tip and sample.

Figure 6 shows the changes in MFM contrast in a $(11\bar{2})$ surface associated with ac field demagnetization of a sample in the in-plane [111] and $[\bar{1}10]$ directions. The surface deformations, and magnetic domain structure, both change consid-

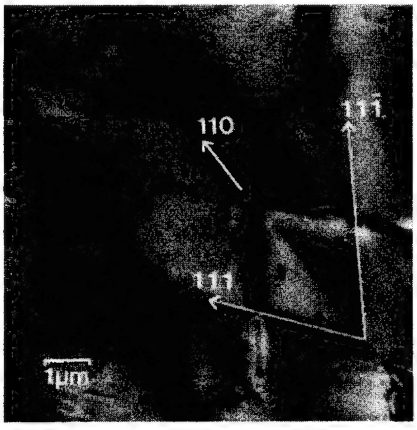

FIG. 5. MFM image from $(1\bar{1}0)$ surface from a region showing no topographic deformation indicating possible in-plane (001) 109° and (112) 180° walls.

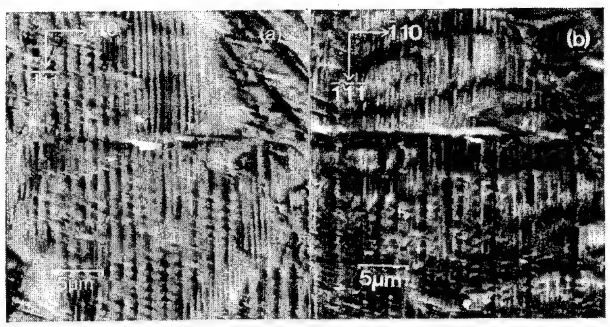

FIG. 6. MFM images from a similar area of a $(11\bar{2})$ surface ac demagnetized (a) along [111] and (b) along $[\bar{1}10]$.

erably under the influence of applied field, and applied external stress, and such observations are the subject of continuing study. The complex nature of the surface closure domain structure on these materials is demonstrated in Fig. 7 obtained from a $(11\bar{2})$ surface. The projections of the (100) and the (211) planes on to this surface are indicated on the figure. Such planes are low-energy Bloch wall planes[8] and geometrically suggest a possible configuration of the magnetic structure in this surface.

IV. CONCLUSION

The application of SPM techniques to the study of particular crystallographic surfaces of Terfenol-D crystals has yielded the first direct measurements of the deformation gradients associated with magnetostrictively driven lattice strains in neighboring deformation domains. A value of $\lambda_{111}=1.63\times10^{-3}$ has been obtained, with $\sigma\sim8\%$, from such measurements. The complex magnetic force gradient images from observations on both {110} and {112} surfaces are symptomatic of domain branching at surfaces and also illustrate exact compatibility of features across growth twin boundaries. Further work on the effect of magnetic field and applied stress to gain a better understanding of the relation between topography and domain structure is in progress.

We report on the possibilities of application of magneto-optical indicator film (MOIF) technique for visualization and direct experimental study in real time of the magnetization processes and nondestructive characterization of the quality of magnetic thin granular films and multilayers. The technique utilizes a transparent indicator film, a Bi-substituted iron garnet with in-plane anisotropy, placed on the top of a sample. Polarized light passes through the indicator film and is reflected back by an Al underlayer. Magnetic stray fields with a component perpendicular to the film plane are observed through the magneto-optic Faraday effect created in the garnet film. An investigation of the magnetic moment distribution in granular single films and multilayers was carried out using this method. Some examples of magnetic stray field images of domain walls of different types obtained by MOIF technique and magnetic force microscopy are described. The experimental data are compared with theoretical estimations. The detailed information is obtained on the spin rotation processes as well as on the domain wall nucleation and motion during the remagnetization of these materials. Peculiarities of the magnetization reversal of multilayers with different types of exchange interlayer coupling have been revealed and discussed.

High density recorded patterns observed by high-resolution Bitter scanning electron microscope method

O. Kitakami, T. Sakurai, and Y. Shimada
Research Institute for Scientific Measurements, Tohoku University, Sendai 980-77, Japan

We have developed a new and versatile method for observation of fine domain structures in ferromagnetic specimens. In this method, which we call here the high-resolution Bitter scanning electron microscope (HRBS) method, ferromagnetic fine particles as small as 20 nm are fabricated by sputtering, and are subsequently deposited on the surface of ferromagnetic samples to be investigated. The particles form very faithful domain patterns reflecting the leakage field distribution from the samples. We have applied this method to several magnetic and magneto-optic high density recording media, and have successfully observed the bit patterns at a recording density of 300 kFCI (bit length ~80 nm). Moreover, we have confirmed that the HRBS method is also effective in investigating the magnetized states within each recording bit. © *1996 American Institute of Physics.* [S0021-8979(96)55608-X]

I. INTRODUCTION

Recently, we have developed a versatile method for observation of fine domain structures in a ferromagnetic specimen.[1,2] In this method, ferromagnetic fine particles as small as 20 nm are fabricated by sputtering and are subsequently deposited on the surface of magnetic samples to be investigated, resulting in the evolution of the magnetic domain pattern. The method is referred to as the high-resolution Bitter–scanning electron microscope (HRBS) method. The HRBS has the following advantages over the other observation methods. First, this method is applicable to a variety of ferromagnetic specimens without any restrictions on their sample size and shape. Second, it has a high spatial resolution.[3] Third, it is possible to survey domain structures over a very wide area, as large as 100 mm,[2] enabling an easy search and a precise investigation of local points. Finally, high contrast domain images are available without any image processing. Owing to these merits, the HRBS is now widely applied to a variety of ferromagnetic specimens in order to investigate their domain structures.[3–8]

In the present paper, we will demonstrate the usefulness of the HRBS method through observations of magnetic and magneto-optic high density recording media.

II. EXPERIMENT

The schematic of our dc magnetron sputtering apparatus is shown in Fig. 1. Fine ferromagnetic particles with an average diameter of 20 nm are formed in room B by sputtering the target (in this case, Co or Fe), and they are subsequently transported into room A by a slight pressure difference between the two rooms. The particles are attracted toward the surface of the ferromagnetic sample in accordance with the distribution of the magnetic potential. The domain patterns decorated by the fine particles are observed by a scanning electron microscope (SEM). Samples for pattern observations are a Co-Cr alloy thin-film disk, an obliquely evaporated Co-O thin-film tape and a Tb-Fe-Co magneto-optic disk. In order to enhance the contrast of the domain patterns, an external field of about 100 Oe was applied to the samples along the direction of the recorded magnetization during the formation of the patterns.[1,9,10]

III. RESULTS AND DISCUSSION

According to the ferrohydrodynamic theory on Bitter pattern evolution by Hartmann and Mende,[11,12] the statistically averaged magnetic potential $\langle U \rangle$ of the ferromagnetic fine particles under the influence of a local field H can be expressed as

$$\langle U \rangle = -kT \ln(\sinh p/p), \tag{1}$$

where $p = \mu_0 mH/kT$, and m denotes the magnetic dipole moment of each fine particle, k the Boltzmann constant, μ_0 the permeability of vacuum, and T the temperature. Using this magnetic potential, the surface density ρ of the ferromagnetic particles on a ferromagnetic specimen is derived as[12]

$$\rho = \Lambda_0 \int \sinh p/p \, dy \quad (\Lambda_0\text{: constant}), \tag{2}$$

where y denotes the distance from the surface of the magnetic specimen. By calculating Eq. (2), we can predict the

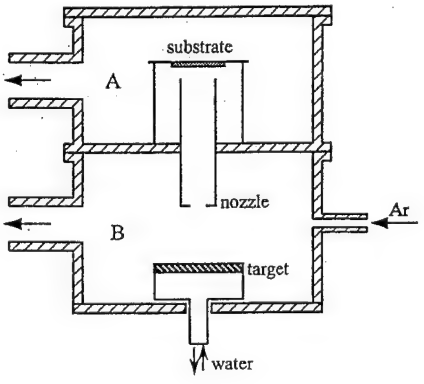

FIG. 1. Schematic draft of a dc magnetron sputtering system for formation of HRBS patterns.

 0021-8979/96/79(8)/6074/3/$10.00

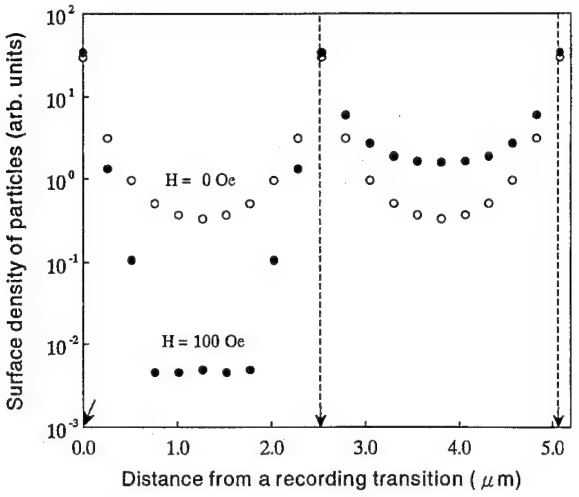

FIG. 2. Calculated surface density of ferromagnetic particles on a recorded thin-film disk at a density of 10 kFCI. Arrows in the figure indicate the positions of recording transitions.

density of ferromagnetic particles at the sample surface if its leakage field distribution can be determined. In the presence of an externally applied field, the magnetic field H used to evaluate p of Eqs. (1) and (2) is the magnitude of the vector sum of both the leakage and the externally applied fields. The detail calculation of the field H is described elsewhere.[10] Figure 2 shows the calculated density of ferromagnetic particles at the surface of a digitally recorded medium, where the thickness and the residual magnetization are assumed to be 25 nm and 350 G, respectively. It is noted that applying a weak external field along the recorded magnetization during the pattern evolution effectively enhances the contrast of the magnetic domain patterns. Such theoretical results are reproduced in the observed HRBS patterns, as shown in Fig. 3, where these patterns were obtained by depositing sputtered Co fine particles onto a longitudinal Co-Cr alloy thin film disk.

In our sputtering apparatus, it is possible to form a HRBS pattern over a sample area as wide as 100 mm^2. We have confirmed that very clear magnetic domain patterns can be successfully observed over the whole area by using a conventional SEM. Figure 4(a) shows the SEM micrograph of the HRBS pattern formed on a digitally recorded Co-Cr alloy disk. By merely increasing the magnification of the SEM, we can clearly observe the recording states of 150 kFCI [bit length ~170 nm) as shown in Fig. 4(b)]. In order to roughly estimate the spatial resolution of the HRBS, we

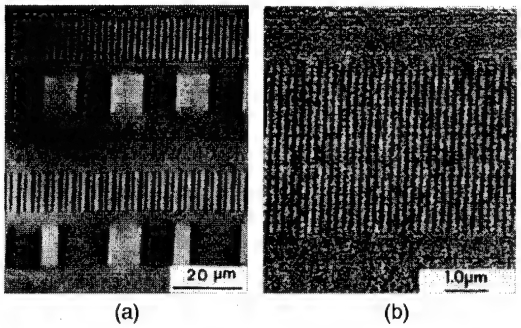

FIG. 4. (a) Several bit patterns recorded on a Co-Cr alloy thin-film disk, and (b) the recording track of 150 kFCI observed with high magnification.

have attempted to observe ultrahigh density recording states of an obliquely evaporated Co-O thin-film tape. Figure 5 is the HRBS pattern at a density of 300 kFCI (bit length ~80 nm). In spite of the extremely small output signals at this density, which are partly due to serious losses in the reproducing process, we can clearly see high density bit patterns, although the neighboring bits having parallel magnetizations are in some places linked to each other across an antiparallel recording bit. Recently, very similar bit patterns have been observed by the spin-SEM method for the same Co-O thin-film tape.[13] According to the above experiments, we believe that the spatial resolution of the HRBS is better than 80 nm. In order to determine the resolution more quantitatively, ideal recording media without any fluctuations of recording transitions are required.

The HRBS method is also effective in observing recording states of magneto-optic media. Figure 6 illustrates the dependence of the recorded bits of a Tb-Fe-Co disk on the input power of a laser source. The circular recording bits drastically shrink from 800 to 400 nm as the input power decreases from 7.5 to 6.8 mW. At present, very small recording bits as small as 200 nm can be clearly observed through a somewhat thick silicon-nitride and aluminum overlayers. By utilizing the HRBS method, intensive studies on the growth mechanisms of the magnetic domains are now in progress.[8]

We will show a typical example to demonstrate the usefulness of the HRBS method. Recently, Takano *et al.* have experimentally confirmed that the recording performance of a thin-film inductive head greatly depends on the electrical resistivity of magnetic materials.[7] According to their results, eddy currents are induced in the magnetic poles, which cause a phase lag of the recording field against the drive current

and deteriorate the recording performance of the magnetic head, especially at high frequencies. In order to investigate their recording states, we applied the HRBS method to Co-Cr alloy thin-film disks which are recorded by using two kinds of thin-film heads. The magnetic poles of head A consist of the polycrystalline films with low resistivity (ρ=16 $\mu\Omega$ cm), and the poles of head B are made of the highly resistive amorphous films (ρ=90$\mu\Omega$ cm). The observed HRBS patterns are shown in Fig. 7 as functions of recording

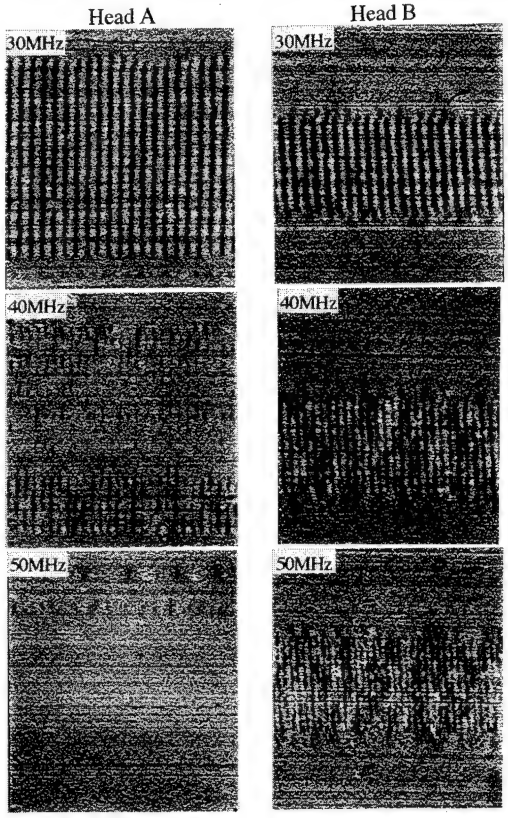

FIG. 7. HRBS patterns of a Co-Cr alloy thin-film disk recorded by two kinds of thin-film heads (heads A and B).

frequency. The relative velocity and the spacing between the head and the disk were maintained at 28 m/s and 100 nm, respectively. Head B exhibits good recording performance over the whole frequency range examined in this experiment. In contrast, head A cannot realize the uniform recording over the whole track width at 40 MHz, and finally no recorded patterns can be seen at 50 MHz. The fact that the fields at the middle of the track are attenuated indicates that the presence of the eddy currents considerably deteriorates the high-frequency performance of head A. Since the distribution of the eddy currents greatly depends on the dimensions of the magnetic poles as well as their electrical resistivity, very careful designing is required in constructing the thin-film heads for high frequency use.

As mentioned above, the HRBS method is one of the most effective measures for the investigation of fine domain structures in a variety of ferromagnetic specimens.

IV. SUMMARY

Our newly developed high-resolution Bitter SEM is a very versatile method for the observation of magnetic domain structures of various ferromagnetic specimens. Applications of this method to magnetic and magneto-optic high density recording media have revealed that its spatial resolution is better than 80 nm.

A new magnetic bar code system based on a magnetic anisotropy detection (abstract)

I. Sasada and N. Watanabe
Kyushu University 36, Fukuoka 812, Japan

Magnetic bar codes can be used in unclean environments, where widely used optical bar code systems cannot be applied. Readout system for magnetic bar codes can also be made much simpler than optical ones. A new magnetic bar code system is proposed, in which binary information is coded in the sign of tilted angles of magnetic strips from a given standard direction. This scheme is unique compared to the conventional optical bar code, where width or space of the parallel pattern carries information, or an already reported magnetic bar code,[1] where cross sectional shapes of pattern engraved in a ferromagnetic body carries information. Each of the magnetic strips brings about magnetic anisotropy due to its shape effect, hence angular dependent permeability in the proximity of the strip. The sign of the tilted angle of each magnetic strip is detected inductively through the angular dependent permeability by using a magnetic pickup head with a pair of cross-coupled figure-eight coils,[2] where the sign of mutual inductance between the primary and the secondary figure-eight coil has one to one relationship to the sign of the tilted angle. Because the detection of the tilted angle is independent of scanning speed, variation in the scanning speed of the readout head does not affect the performance. In our preliminary study, the proposed magnetic bar code system was examined using pickup head consisting of a pair of cross-coupled 10-turn figure-eight coils which was embedded in a rectangular ferrite rod with cross-shape groove on the top surface of 6.5×3 mm dimension. The head was made thinner in the scanning direction to allow dense alignment of the pattern. Two kinds of pattern were made: the one was by aligning short amorphous wires (5 mm in length and 120 μm in diameter) on the plastic film and the other by using a thin (10 μm in thickness) copper film with tilted slits backed by an amorphous ribbon. These samples of magnetic bar code patterns were scanned with lift-off of 1 mm under the operating condition of 120 kHz and 200 mA. Amplitudes of the positive and the negative peak of the output voltage well exceeded 10 mV. Density of the pattern in the preliminary study was 7 bits for the bar code length of 2.6 cm. We will discuss several factors to make density of the pattern higher. Because the pickup coils can be assembled with planar coils and because the magnetic bar code itself is thin, the total system of this bar code scheme can be realized in thin form. Giant magnetoresistance as a probe of interfacial electronic character (invited) (abstract)

S. S. P. Parkin[a)]
IBM Research Division, Almaden Research Center, 650 Harry Road, San Jose, California 95120-6099

The giant magnetoresistance (GMR) effect exhibited by magnetic multilayers and related structures is very sensitive to the nature of the interfaces between the magnetic and nonmagnetic layers. We have explored the dependence of GMR on the electronic character of these interfaces by inserting additional thin magnetic layers at the interfaces. Insertion of thin Co layers in Ni–Fe/Cu/Ni–Fe or thin Ni–Fe layers in Co/Cu/Cu exchange biased sandwiches leads to an increase or decrease, respectively, in the magnitude of the GMR effect; the variation is monotonic with thickness of the inserted layer. In contrast, insertion of thin layers of Fe at the Ni–Fe/Cu interfaces in Ni–Fe/Cu/Ni–Fe exchange biased sandwich structure results in a *nonmonotonic* variation of GMR with Fe layer thickness; for intermediate thicknesses in particular the GMR is substantially reduced. The magnetism and structure of the Fe layers is explored in related sputter-deposited single-crystalline Ni/Fe/Cu thin-film structures prepared using thin Fe/Pt seed layers grown at high temperatures on single crystalline polished wafers of MgO(100), MgO(110), and (0001)Al_2O_3. The magnetism of the Ni, Fe, and Cu layers is examined using x-ray magnetic circular dichroism (XMCD) and the structure of the Fe is analyzed using extended x-ray absorption fine structure (EXAFS) studies. These experiments show that the Fe moment varies nonmonotonically with thickness resulting from a structural phase transition from fcc to bcc Fe with increasing thickness. The Fe displays a very small magnetic moment for an intermediate range of Fe thickness for which the Fe structure is fcc. This range of thickness depends on the crystalline orientation of the Fe. It is within this same range of thickness that the GMR is suppressed in related exchange biased sandwich structures. Interestingly we find that such nonferromagnetic layers of fcc Fe can be used as spacer layers in magnetic multilayers of, for example, Ni/Fe. These multilayers display both antiferromagnetic interlayer coupling of the Ni layers and giant magnetoresistance, which each oscillate as a function of Fe thickness. [S0021-8979(96)43808-1]

Nanostructure fabrication via laser-focused atomic deposition (invited)

R. J. Celotta, R. Gupta, R. E. Scholten,[a] and J. J. McClelland
Electron Physics Group, National Institute of Standards and Technology, Gaithersburg, Maryland 20899

Nanostructured materials and devices will play an important role in a variety of future technologies, including magnetics. We describe a method for nanostructure fabrication based on the use of laser light to focus neutral atoms. The method uses neither a mask nor a resist, but relies on the direct deposition of atoms to form permanent structures. Since the atomic de Broglie wavelength is of picometer order, the size of structures produced is not significantly limited by diffraction, as in optical lithography. Lines as narrow as 38 nm full width at half maximum spaced by 213 nm have been produced and we have demonstrated the production of a two-dimensional array of dots. The highly parallel process of nanostructure formation and the intrinsic accuracy of the optical wavelength that determines structure spacing suggest a number of interesting applications, including calibration standards for various types of microscopy, lithography, and micromeasurement systems. Possible magnetic applications include the production of arrays of magnetic elements, laterally structured giant magnetoresistive devices, and the patterning of magnetic media.
[S0021-8979(96)22708-X]

I. INTRODUCTION

The fabrication and use of nanostructures, both as tools to further our understanding of physical principles and to provide novel functionality in devices, continues to expand unabated. Nanostructures are generally understood to possess at least one dimension on the nanometer scale, more typically below 100 nm. Frequently, the near atomic scale of the dimension gives rise to unique properties to be explored or exploited. While this definition includes the area of thin-film research, such work is usually not discussed as nanostructure science. However, multilayer structures of thin films are included within the definition. This general area of research has also been referred to as nanotechnology.

While far more work has been performed on the electronic characteristics of small structures, a growing body of research concerns the fabrication and properties of magnetic nanostructures. A great deal of current research is focused on giant magnetoresistive (GMR) devices generally involving multilayer structures.[1] One recent article reports the fabrication of a GMR device consisting of a series of GMR multilayer structures with all three dimensions in the nanometer range.[2] Another reports the use of a wedge-shaped nanostructure to systematically study exchange-coupled magnetic layers.[3] Others concentrate on fabricating arrays of isolated magnetic elements to study their interactions,[4–7] magnetic properties,[8,9] or magnetic quantum tunneling.[10] Applications include improved MFM tips[11] and high-density magnetic storage.[12]

The production of one-dimensional nanostructures is generally done with molecular beam epitaxy and/or sputter deposition. Structures with two and three dimensions in the nanometer range require a patterning technique, such as optical or electron-beam lithography. Optical lithography, while convenient because of its wide usage and ability to pattern large areas in parallel, is limited because of the diffraction of light to feature sizes of about 180 nm, i.e., just at the upper limit of the nanoscale regime. As a result, electron-beam lithography, which has an insignificant diffraction limit, has generally been the method of choice for fabricating higher-dimensional nanostructures. Features as small as 20 nm can be fabricated with relative ease, and in some special cases, features as small as 1–2 nm have been achieved.[13] Further progress has been made recently by replacing the electron beam with a scanning tunneling microscopy (STM) tip.[14] Despite its popularity and potential for high resolution, there are drawbacks associated with electron-beam lithography. Because patterns are formed by scanning a finely focused beam, structures are generated serially across a substrate. There is also an inherent trade-off between speed and resolution. Since electrons mutually repel each other, high resolution can only be achieved at the expense of beam current. Thus the beam must be scanned relatively slowly across the surface in order to fully expose the resist. Besides introducing problems like sample drift, proximity effects, and stitching errors, this limits the complexity of the pattern to be fabricated: a large array of very small features can require an exposure of many hours, a length of time that rapidly becomes impractical.

II. LASER FOCUSING OF ATOMS

Neutral atom focusing is a completely different approach to nanostructure fabrication. While still in its infancy, it already addresses several of the stumbling blocks of present methods. The diffraction limit is insignificant, as it is for electron beams, since the de Broglie wavelength of the atom is typically in the picometer range. Unlike electrons, however, the atoms are electrically neutral, so there is no space-charge repulsion limiting the flux in finely focused regions. Furthermore, the focusing scheme can be made massively parallel, allowing large areas to be patterned rapidly. In addition, the focusing schemes generally make use of highly stable optical wavelengths, so highly accurate patterns can be produced over relatively large areas without stitching errors. Still another advantage is that the process can be implemented in a direct-write manner, eliminating the need for a

physical mask and subsequent processing. Though, so far, no direct application to the fabrication of magnetic nanostructures has been carried out, it appears that many of these advantages could prove useful for such applications.

The focusing of neutral atoms is achieved by configuring electromagnetic fields in such a way as to exert forces on neutral atoms toward an axis. The study of the motion of atoms in electromagnetic fields is a major component of the new field of atom optics,[15] which treats the manipulation of atoms by devices that serve as lenses, mirrors, beamsplitters, and gratings in analogy with light optics. To date, most of the configurations used for focusing atoms have involved the use of laser fields in which the frequency of the laser is tuned very close to an atomic resonance. Some work has been done, however, on the focusing of atoms in a hexapole magnetic field.[16] Laser fields provide an especially good medium for generating the necessary fields for high-resolution focusing of atoms because gradients can be generated over optical-wavelength distances, and tuning near resonance can greatly enhance the interaction. In particular, making use of a laser standing wave allows for massively parallel focusing of atoms in an array of lenses that is spaced with interferometric precision across a substrate (see Fig. 1).

In the presence of a near-resonant laser field, two types of radiation forces are present, the spontaneous force and the dipole force. The spontaneous force is simply the light pressure, i.e., the transfer of momentum that results when an atom absorbs a photon from the direction of the light source and reradiates a photon in an arbitrary direction. After a number of such interactions a beam of neutral atoms will be deflected away from the light source. The dipole force can be thought of as resulting from the interaction between an oscillating electric dipole induced in the atom and any spatial gradient that might be present in the oscillating laser electric field. Over the past 15 years, methods have evolved to use these forces, separately or in combination, to cool and trap,[17] and also focus,[18] atom beams.

The first application of laser focusing of atoms to controlled deposition involved observing the "shadow" of a resonant laser beam traversing a beam of sodium atoms depositing onto a surface.[19] This was followed by observation of optical diffraction from a grating of sodium atoms generated by focusing the atoms with the dipole force generated in the nodes of a standing wave passing across the surface of a substrate.[20] These experiments demonstrated the essential principle of laser focused atomic deposition but, because the deposited atom was sodium, it was difficult to proceed with nanostructure fabrication, or carry out quantitative studies of the process. Sodium was chosen because it was easy to make an atomic beam and easy to tune a laser near the strong resonance at 589 nm. The first permanent laser-focused structures were fabricated using a chromium atomic beam, taking advantage of the atomic resonance at 425 nm.[21] This work has been followed recently by creation of structures in aluminum.[22] Because the use of a hard, fine-grained material such as chromium opens the possibility for precise fabrication and perhaps transfer of the patterns to other materials, and because of the relevance of chromium to magnetic materials, we discuss the results of the chromium research in some detail.

III. CHROMIUM EXPERIMENT

A schematic of the experimental arrangement[21] is shown in Fig. 2. In this experiment, Cr atoms effuse from a molecular beam epitaxy (MBE)-type evaporator, modified to produce a point source of atoms. They pass through a region where the beam is collimated optically, and then through a second, standing wave region where they are focused to form a pattern on a Si substrate. The optical standing wave, positioned immediately above the Si substrate, is formed by the reflection of a laser beam from a mirror in direct contact with the substrate. The laser wavelength used is 425.55 nm (in vacuum), which corresponds to the energy difference between the Cr $^7S_3$ ground state and the $^7P_4$ excited state, and the spacing between nodes of the resulting standing wave is just half that wavelength, or 212.78 nm. If the correct combination of laser beam size, intensity, wavelength, and position above the substrate is used, the standing wave acts as an array of cylindrical lenses to focus the atoms to form lines on the substrate.[21]

The dipole force is not strong, so the lenses described above are best thought of as weak immersion lenses. In order for their effect to be enough to bring the atoms into a fine focus, the incident atom beam must be highly collimated,

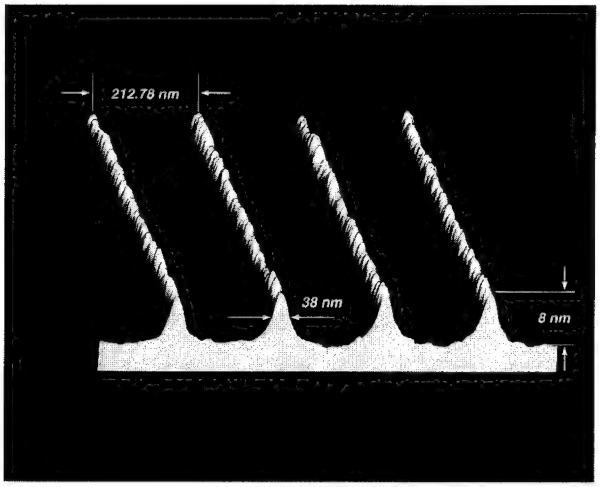

FIG. 3. Atomic force microscope image of Cr lines formed by laser-focused atomic deposition. The lines in this image have a height of 8±1 nm.

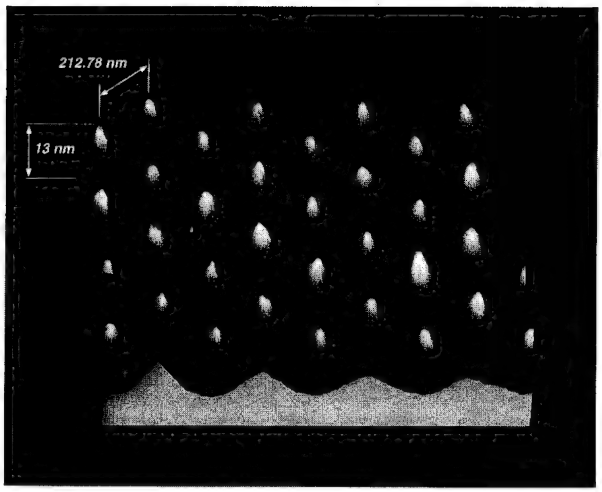

FIG. 4. Atomic force microscope image of a two-dimensional array formed by laser-focused atomic deposition of Cr.

possessing little transverse velocity. To achieve this, a collimation region is used, in which counterpropagating laser beams transverse to the atom beam are tuned to a frequency just below that of the resonant transition. In this process, photons are absorbed only if the transverse velocity of the atoms is large enough to Doppler shift the photon into resonance with the atom. In that case, the atoms will experience a momentum change that moves them closer to an ideally collimated beam. This collimation or laser cooling process, which is sometimes referred to as "optical molasses," has been studied in great depth in one, two, and three dimensions in relation to laser cooling and trapping of atoms.[23] Using a variant of the basic process, which makes use of polarization gradients in the laser beams,[24] an atom beam collimation of the order of one part in 7000 is achieved.

IV. CHROMIUM RESULTS

Using the apparatus schematically shown in Fig. 2, samples were fabricated with Cr lines covering an area of up to 1 mm×0.40 mm. Figure 3 shows an atomic force microscope (AFM) topograph of one of these samples. The lines are spaced by half the laser wavelength, 212.78 nm. The average height of the lines in Fig. 3 is 8±1 nm,[25] and the full width at half maximum (FWHM) is 38±1 nm, uncorrected for AFM tip shape (which could have an influence in this size range). The evaporation time, using a modest Cr oven, was 10 min. Although the AFM cannot distinguish between bare Si and Cr, we infer that there is a thickness of Cr in the valleys between the lines in this sample, based on measurements of the total atomic flux. We estimate this background to be 10±4 nm thick. A complete understanding of the background is still to be established, however significant contributions include 16% of other isotopes of Cr that do not interact with the laser, about 10% Cr atoms that decay into a metastable ^5D level and no longer interact with the laser, and a possible high-velocity tail in the laser-cooled transverse velocity distribution.

In addition to the one-dimensional array of lines shown in Fig. 3, a two-dimensional array has also been created.[26] Figure 4 shows an AFM topograph of a section of a two-dimensional array of Cr "dots" made by first optically collimating in two dimensions and then using two standing waves positioned at right angles to each other. These dots cover an area of approximately 100 μm×200 μm on the sample, have a FWHM of 80±10 nm, and have a height of 13±1 nm.

While the extension of the laser focusing process to two dimensions may seem straightforward, there are some subtleties that must be understood. When two standing waves that are temporally coherent (e.g., originating from the same laser) are superimposed upon each other at right angles, the resulting intensity pattern will, in general, depend on the relative temporal phase. However, for the special situation of orthogonal linear polarizations (one parallel to the substrate, the other perpendicular), this dependence is eliminated, allowing the laser focusing to be carried out without stabilizing the relative phase of the standing waves.

V. METASTABLE RARE GASES

Although the bulk of the work on laser focusing of atoms has been done with "direct-write" materials such as sodium, chromium, and aluminum, a new possibility has been suggested that makes use of metastable rare gases to exposure a lithographic resist.[27] The potential for this approach lies in the combination of lithography's ability to work with a wide range of materials with the atom optics advantages of high resolution, parallel fabrication, and low substrate damage. Metastable rare gases are both accessible to laser manipulation techniques, and they also have internal energy of up to 20 eV, sufficient to chemically alter a resist, yet not damage a substrate.

The ability of metastable atoms to act as a writing tool on a resist has been demonstrated using self-assembled monolayers (SAMs) of alkanethiolates on gold-coated silicon.[27] The SAM coating acts as a very thin resist, preventing etching of the gold when it is placed in an aqueous

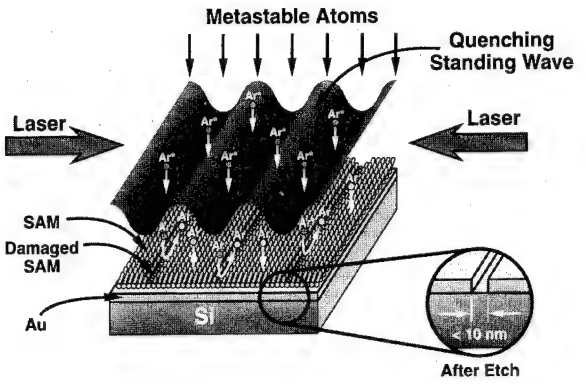

FIG. 5. Schematic of metastable rare gas lithography concept.

solution of ferricyanide. In regions where metastables have been allowed to strike the surface, the SAM is damaged, allowing the etch to penetrate.

So far, an upper bound of around 100 nm has been set for the resolution of this process by examining the edge roughness of a physical mask. The methods of laser manipulation have yet to be applied; however, work is ongoing, and several possibilities exist, using either 1.083 μm light on the He $(2^3S \rightarrow 2^3P)$ transition or 811 nm light on the Ar $(1s_5 \rightarrow 2p_9)$ transition. Metastable Ar opens a particularly interesting additional possibility in that it is possible to quench the metastable state using laser light at 764 or 801 nm. This allows the spatially selective removal of metastable atoms from the beam as an alternative to focusing (see Fig. 5), suggesting the possibility of significantly less background exposure. Preliminary estimates indicate that this quenching approach may result in features as small as 10 nm, though more work needs to be done to investigate this.

VI. FUTURE RESEARCH

We have only begun to investigate the application of atom optics to the manipulation of atoms as they impact a surface. There are a large number of possibilities that could lead to exciting new fabrication techniques. Given the current circumstances, a few areas for future improvement can be discussed, though many more may become apparent as the field develops.

Feature size is one area where improvement can be anticipated. Currently features as small as 38 nm FWHM have been created, but calculations of the focusing process, both semiclassical[28] and fully quantum,[29] predict that features as small as 10 nm should be attainable. This reduction in feature size will most probably arise from an improvement in the atomic source: reduction of the velocity spread, and still higher levels of collimation, appear to be the improvements that will help the most in this case.

The ability to create more complex patterns is also highly desirable if the process is to become useful for general nanostructure fabrication. To this end, arrays of complex patterns can be created by using the current two-dimensional process, perhaps with higher resolution, and simply scanning the substrate during deposition. In this way patterns can be "painted" within the unit cell of the standing wave, and these patterns will be repeated with very high accuracy across the substrate. Still more general patterns could be created by designing a more complicated optical field that puts the atoms exactly where they are required.

Another avenue for exploration is the possibility of extending the process to other atomic species. While nanostructures of other materials can be produced by using the metastable rare gas process discussed above or using Cr as a mask for reactive ion etching, it is also of interest to ask what other materials could be used directly. The essential characteristics are that the atomic species be relatively easily evaporated, and that there be a resonance transition accessible to an available laser wavelength. The resonance transition must have as its lower state one that has a significant population of atoms, either naturally or prepared (as in the case of metastable atoms). The full range of materials has not yet been explored, however it appears that many of the metallic species that might be of interest have resonant transitions in the ultraviolet, in the range from 200 to 300 nm. At present these wavelengths are difficult, though not impossible, to access with a laser. Nevertheless, laser technology is improving rapidly, and it is likely that in the future these atoms will become accessible.

The application of these new techniques to the fabrication of magnetic nanostructures remains in the realm of the future. However, the unique capabilities inherent in these new techniques offer several advantages when compared with other lithographic methods, and the length scale of their applicability is an interesting one from a magnetic perspective. We plan to explore the use of this method for magnetic nanostructure fabrication in the near future.

Using micron-level photolithography, we have prepared a set of patterned multilayer samples which have the form [Co/Cu/NiFeCo/Cu]×10 and which permit perpendicular current transport through the structure. Based on vibrating sample magnetometry, the multilayer stacks show a loss of ≈2 Å of magnetic material at each interface. The magnetoresistance was measured as a function of temperature, magnetic layer thickness, and element size and the $\Delta R/R$ values range up to 8% at 300 K and 18% at 10 K. The thickness dependent data are modeled using an extension of existing methods and can be fit using comparable resistivity, interface resistance, and spin asymmetry parameters. The magnetic fringe fields of the elements have an important effect on the observed R vs H curves. © *1996 American Institute of Physics.* [S0021-8979(96)22808-6]

I. INTRODUCTION

The strong interest in the giant magnetoresistance (GMR) effect is driven both by the opportunities for technological applications and by purely scientific curiosity about the physical basis of the observed effects. In the work reported here, we have attempted to make a contribution to both of these interests.[1] The perpendicular transport geometry[2] is particularly attractive for understanding the GMR effect because relatively simple theoretical models can be applied to the analysis.[3–5] However, unless one is willing to use superconducting leads and be confined to low-temperature measurements, there is the challenge of fabricating small device structures on the scale of a micron. The fabrication and characterization of these small structures is itself of technological interest for incorporating the GMR effect into electronic circuits with potential use as sensors or information storage. In this article, we report the procedures used in fabrication, the thermal and dimensional dependence of the observed effect and, finally, some physical understanding of the spin-polarized transport results based on the two current models for perpendicular transport through a magnetic multilayered structure containing two different ferromagnetic materials in alternating sequence.

II. SAMPLE FABRICATION AND MEASUREMENT TECHNIQUES

The samples used in this work were patterned from multilayers having the form (NiFeCo/Cu/Co/Cu)×10. This combination of materials was chosen to achieve simultaneously a sizable intrinsic GMR and distinctly different coercivities for the two types of magnetic layers, maximizing the GMR effect. We chose a NiFeCo permalloy (65% Ni, 15% Fe, 20% Co) and pure Co which have coercivities of 4 Oe and roughly 300 Oe, respectively.

Since we use normal metal (Cu) leads to permit measurements of the temperature dependence of the GMR, the cross sections of the individual elements must be reduced to micron dimensions to achieve adequate element resistances and signal strengths. This requires the use of photolithographic techniques, with careful attention to lead design. This approach was first demonstrated by Gijs *et al.*[6] for the multilayer system $[Fe/Cr]_N$. They found that accurate data could only be obtained using their lithographic pattern if postprocess laser trimming was used to exclude current from the voltage leads.[7,8]

Figure 1(a) is a scanning electron micrograph of a patterned microstructure used in the present study. The multilayer stack is in the center of the "X" and in this case is a 2.4 μm×2.4 μm square with a 1.2 μm diam contact area. To prevent current from entering the voltage leads it is essential for all leads approaching the stack to be as narrow as the lithography permits.

Using Si substrates coated with a 2000 Å layer of Si_3N_4, the multilayer films were grown by rf sputter deposition. The metal deposition begins with 50 Å NiFeCo for adhesion, then 2500 Å Cu which serves as the bottom Cu electrode in Fig. 1. Next comes the magnetic multilayer [t Å NiFeCo/(100-t)Å Cu/t Å Co/(100-t)Å Cu]×10 with t=10, 20, 40, 50, and 60 for the five wafers studied. Thus the number of ferromagnetic/nonferromagnetic interfaces and the total thickness of each multilayer is held constant throughout the series. Finally, the multilayer is capped with 750 Å of Cu. All metals were sputter deposited at 20 m Torr of Ar with the substrate 1.5 in. from the target.

The samples are then photolithographically processed. Details on this aspect of the sample preparation were presented earlier.[1] Here we only point out that rf sputtered Si_3N_4 is used as the insulation between the top and bottom leads and that the top leads consist of 1500 Å of Cu followed 1500 Å of $Al_{0.98}Cu_{0.02}$ (for wire bond adhesion). This last 3000 Å is wet etched to define the top electrical leads, $I+$ and $V+$ in Fig. 1. The minimum contact window diameter achieved was

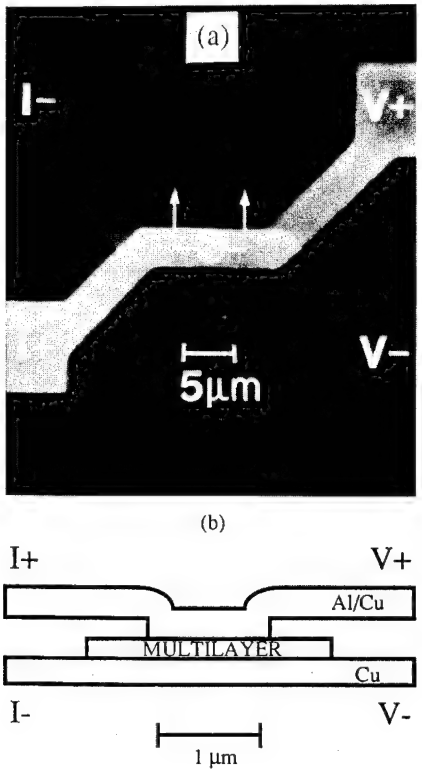

FIG. 1. Perpendicular current sample geometry: (a) Scanning electron micrograph of an element with a multilayer which is 2.4 μm×2.4 μm and 0.2 μm thick. The multilayer stack is located at the center of the "X" formed by the leads. (b) A vertical section through the element at the location marked by the arrows in (a). The layer of AlCu on top of the upper Cu lead facilitates wire bonding. The current contact is 1.2 μm across.

1.2 μm with a mask alignment tolerance of 0.5 μm. Other samples with contact window diameters up to 10 μm were produced simultaneously by the lithography.

The magnetic properties of the multilayers were measured at room temperature using vibrating-sample magnetometry (VSM) to determine the M vs H loops and absolute moments, and 35 GHz ferromagnetic resonance (FMR) to obtain additional anisotropy information. Transport measurements were carried out under computer control using a lock-in amplifier with the internal oscillator serving as the current source. The currents are in the mA range and do not generate fields large enough to effect the data. The magnetoresistance ratios ($MR=\Delta R/R$) found range between 5% and 8% at room temperature and up to 18% at liquid helium temperatures. In terms of magnetoresistance (MR) per magnetic layer, these values compare well with previous studies of perpendicular current magnetoresistance on both sputtered and molecular beam epilaxy (MBE) grown samples.[8]

III. EXPERIMENTAL RESULTS AND DISCUSSION

A. Magnetic properties

We will treat the magnetic properties of the samples prior to the magnetoresistance. The M vs H loops of 8 mm square pieces from the wafers containing 10 or 60 Å thick ferromagnetic (FM) layers are shown in Fig. 2. Note that for 10 Å thick layers there is a clear distinction between the

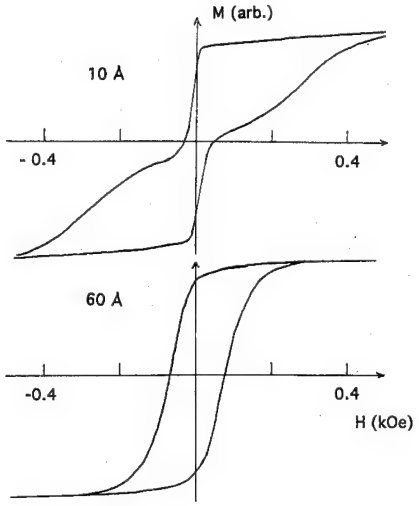

FIG. 2. Magnetization vs applied field loops of 8 mm square pieces taken from multilayer wafers containing ferromagnetic layers either 10 or 60 Å thick.

switching of the NiFeCo at about 5–10 Oe and that of the Co at about 300 Oe as expected. For 60 Å layers, however, no such distinction is apparent. Rather, the two types of FM layers appear to behave as a single or coupled system with an intermediate coercive field. We do not believe that the coupling is via the Cu interlayer because very similar behavior is seen even for 40 Å thick FM layers, in which case there is 60 Å Cu between them. We suggest that this apparent coupling is due to local stray fields associated with the interface roughness of the magnetic layers. Such stray fields would be proportional to the FM thickness which is consistent with increased coupling found for thicker magnetic layers. Note that for such large area samples the stray fields due to edge poles are not significant. This is in contrast to the situation for micron-sized samples, as we will see later.

The magnetic moment of the 8 mm square pieces is shown in Fig. 3 as a function of the total magnetic thickness $20t$ of the stack. The excellent linear fit shows that the magnetization in the interior of each FM layer is constant. Furthermore, the slope agrees quantitatively with that expected from the bulk magnetizations. However, the negative inter-

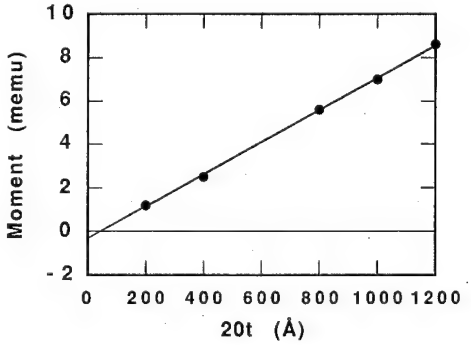

FIG. 3. Total magnetic moment of 8 mm square pieces taken from multilayer wafers as a function of the total magnetic layer thickness $20t$ of the multilayer stack. The solid line is a linear least-squares fit to the data. Note the negative intercept which implies a reduced moment in each layer.

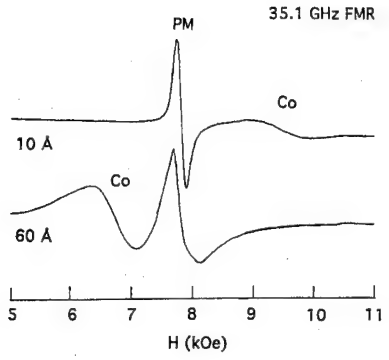

FIG. 4. Ferromagnetic resonance signals from multilayers containing magnetic layers either 10 or 60 Å thick. The signals due to the Co layers are labeled as Co and those due to the NiFeCo permalloy as PM.

cept indicates a net loss of magnetic moment. When the 50 Å seed layer is taken into account, one finds that there is an average loss of about 2 Å of ferromagnetic material at each interface. This is most likely due to the formation of a nonmagnetic interfacial alloy.

The FMR signals from multilayers containing 10 and 60 Å FM layers are shown in Fig. 4. Typical sample areas are about 15 mm^2 for these measurements. Note that, while in both cases the NiFeCo and the Co FMR signals are distinct, there is a major change in the resonance field for the Co layer as the magnetic thickness is increased. For in-plane FMR measurements, the principal relevant parameter which influences the resonance field is the sum of $4\pi M$ and the perpendicular anisotropy $2K_\perp/M$. The value of this sum for Co is given for the complete set of layer thicknesses in Table I. Since the data of Fig. 3 indicate that the magnetization of the interior of each magnetic layer has essentially the bulk value, the variation with FM thickness arises entirely from the perpendicular anisotropy. The deduced values of $2K_\perp/M$ are also given in Table I and indicate an out-of-plane anisotropy which increases strongly as the thickness decreases. This is consistent with well-known results for thin films of Co.

B. Magnetoresistive properties

We define ΔR as the difference between the maximum and minimum sample resistances $R_{\max}$ and $R_{\min}$ as the magnetic field is swept from positive to negative saturation. The value $R_{\min}$ occurs at saturation and corresponds to the parallel moment resistance R_p. Ideally, $R_{\max}$ corresponds to antiparallel resistance R_{ap}, although the true antiparallel case seldom seems to be achieved fully in our samples. The temperature dependence of ΔR and R_p are shown in Fig. 5 for a sample having 60 Å magnetic thickness and the minimum contact area studied. The saturated R_p has a very linear dependence on T over an extended temperature range while ΔR appears to vary as $R_0(1-aT^2)$. A similar T^2 dependence of the quantity $[(R_{ap}-R_p)R_{ap}]^{0.5}$ was found for the Fe/Cr system and ascribed to magnon scattering.[8]

TABLE I. Values of $4\pi M+2K_\perp/M$ and $2K_\perp/M$ deduced from 35.1 GHz ferromagnetic resonance data on multilayer samples with the magnetic layer thicknesses shown. A negative value favors M out of plane.

t (Å)	10	20	40	50	60
$4\pi M+2K_\perp/M$ (kOe)	4.3	7.1	12.8	13.4	14.4
$2K_\perp/M$ (kOe)	−14.0	−11.1	−5.4	−4.9	−3.8

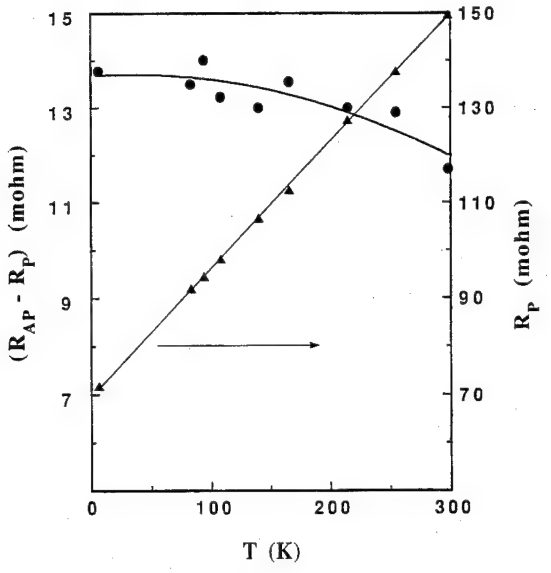

FIG. 5. The temperature dependence of the resistances R_p and $\Delta R=(R_{ap}-R_p)$ for a 1.2 μm diam multilayer stack. The ΔR data are fit to the form $R_0(1-aT^2)$ while the R_p data vary linearly with temperature.

The GMR ratio $\Delta R/R_p$ (not shown) decreases nearly linearly as T increases. The only previous CPP temperature-dependent GMR data are for Fe/Cr and Co/Cu.[6–8] Neither of these systems show the linear T dependence found for our NiFeCo/Cu/Co/Cu multilayers, although the fractional change in $\Delta R/R_p$ between liquid helium and room temperature found here, between 2.1 and 3.9 for different stacks, is roughly the same magnitude as for uncoupled multilayers in that earlier work. It is clear that the temperature dependence of R_p dominates the GMR behavior in our samples.

The magnetic field dependence of the sample resistance is shown in Fig. 6 for a set of 2.4 μm×2.4 μm square multilayer stack samples for different thicknesses of the magnetic layers. The half-maximum width of these curves shows an approximately linear increase with increasing thickness, with a significant shape asymmetry for 20 and 10 Å thickness. The R/R_p maximum for the thicker layers occurs at ≈100 Oe, and their curves are symmetric about this value. In the absence of any coupling between the magnetic layers, one would expect that at zero applied field H all of the magnetic layers would have their moments parallel, left in remanance in a negative direction after lowering the negative H_{ap} from saturation. Thus R/R_p should remain equal to 1, the saturation value. This condition only begins to be approximated for the thinnest of our magnetic layers when the sample edge fringe fields are a minimum. Since the separation via Cu layers is large enough to preclude exchange coupling, the magnetoresistance-deduced anti-alignment which sets in as the applied field magnitude decreases is due predominantly to fringe-field interlayer coupling.

One can obtain a first-order estimate of these fields by assuming a uniform pole distribution on the edges of the

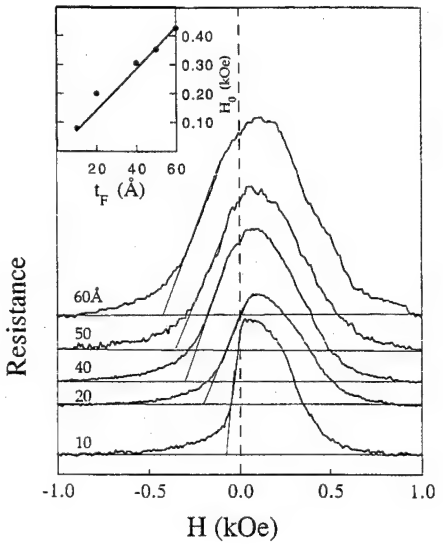

FIG. 6. The magnetic field dependence of the sample resistance for 2.4 μm×2.4 μm multilayer stacks. (The magnetic field was swept from negative to positive values.) The ferromagnetic layer thicknesses are indicated on the various traces which are offset vertically. The linear extrapolations of the leading edge of these traces are shown and define the onset fields H_{on}. *Inset*: H_{on} plotted as a function of t_F. The solid line is calculated from Eq. (2) using bulk ferromagnetic parameters.

magnetic element perpendicular to the magnetization vector. In the two-dimensional approximation, where the magnetic element dimension in the plane perpendicular to the magnetization direction is infinite, the dimension in the plane along the magnetization (x direction) is ℓ and the thickness of the magnetic layers (measured in the y direction) is t, one obtains for the magnetic field x-component at (x,y) due to the poles at $\pm\ell/2$:

$$H_x(x,y)=-4tM\left[\frac{\ell-2x}{4y^2+(\ell-2x)^2}+\frac{\ell+2x}{4y^2+(\ell+2x)^2}\right] \quad (\text{for } t\ll\ell), \tag{1}$$

where (0,0) is at the center of the magnetic film midway between the ends and also its top and bottom surfaces. If the distance y to the neighboring magnetic layer is much less than ℓ, then one obtains[9]

$$H_x(x,y)=-8M\left(\frac{t}{\ell}\right)\left[\frac{1}{1-4x^2/\ell^2}\right]. \tag{2}$$

In this limit, which corresponds closely to our samples, there is no dependence upon separation, and for $|x|\ll\ell/2$ (i.e., away from the ends), H_x should vary linearly with layer thickness and inversely with the element size. This is exactly what is observed from the inset in Fig. 6, which plots the observed magnetoresistance onset field H_{on} (due to the initial reversal of the permalloy layers) versus magnetic film thickness and compares the data to calculations based on Eq. (2). The agreement is quite good. Quantitatively, the calculated field at a permalloy layer from all 20 magnetic layers (2.4 μm square, 60 Å thick) is 430 Oe. For the 10 Å layer sample, this field is only 70 Oe and one can begin to see a situation in which an isolated permalloy element would switch (≈10 Oe). The long saturation tail on the 10 Å curve is largely due to the coercive field of the Co layer. These approximate calculations have been verified by two-dimensional finite-element analysis. Both calculations, of course, overestimate the actual field and three-dimensional finite-element analysis will be required for more precise field values.

IV. EFFECT OF TWO TYPES OF MAGNETIC LAYERS ON THE MAGNETORESISTANCE

One of the principal advantages of measuring perpendicular GMR is the ability to separate the contributions from spin dependent bulk and interface scattering. In this geometry, if the spin diffusion length is much longer than the layer thicknesses, then the currents carried by up and down spin electrons are independent and do not mix. Therefore, the resistance encountered by an up or down spin electron at each layer is simply added in series to determine the total resistance for that spin. The two expressions are then combined as parallel resistors to obtain the total resistance of the multilayer. This technique was initially proposed by Lee *et al.*[3,4] and later justified by Valet and Fert.[5] Given this approach, the expression for the GMR in our samples, which contain two distinct types of magnetic layers, is derived as follows.

Within a ferromagnetic layer F (Co or alloy), the resistivity encountered by an electron whose spin is parallel (antiparallel) to the magnetic moment is $\rho_{\uparrow(\downarrow)}=2\rho_F/(1+(-)\beta_F)$. Here ρ_F is the ordinary resistivity and β_F is the bulk scattering asymmetry parameter to be extracted from the data. For Cu interlayers $\rho_\uparrow=\rho_\downarrow=2\rho_{Cu}$ and the corresponding resistance for any layer is just $R=\rho_{\uparrow(\downarrow)}t/A$ where t is its thickness and A the area of the contact window of the multilayer. Similarly, the resistance at each F/Cu interface is $R=2R_{F/Cu}/(1+(-)\gamma_{F/Cu})$ with $\gamma_{F/Cu}$ being the interface scattering asymmetry parameter. One then obtains the rather complex but symmetric expression

$$A(R_{ap}-R_p)=4NX_1X_2/Z, \tag{3a}$$

$$X_1=\rho^*_{Co}t_{Co}\beta_{Co}+2AR^*_{Co/Cu}\gamma_{Co/Cu}, \tag{3b}$$

$$X_2=\rho^*_{al}t_{al}\beta_{al}+2AR^*_{al/Cu}\gamma_{al/Cu}, \tag{3c}$$

$$Z=\rho^*_{Co}t_{Co}+2AR^*_{Co/Cu}+\rho^*_{al}t_{al}+2AR^*_{al/Cu}+2\rho_{Cu}t_{Cu}+AR_{con}/N. \tag{3d}$$

Here al stands for the NiFeCo alloy, N is the number of repeats of the basic four layer unit, R_{con} is the contact resistance between the leads and the stack, and we use the standard abbreviations $\rho^*_F=\rho_F/(1-\beta^2_F)$ and $R^*_{F/Cu}=R_{F/Cu}/(1-\gamma^2_{F/Cu})$.

In the present case, the fortuitous cancellation, which occurred in the earlier derivation[3] of the quantity $[(R_{ap}-R_p)R_{ap}]^{0.5}$ for stacks containing only one type of magnetic layer and which allows the bulk and interface spin scattering to be separated easily, does not occur for GMR stacks containing two types of magnetic layers. Nevertheless, it is still possible to compare Eq. (3) with the experimental

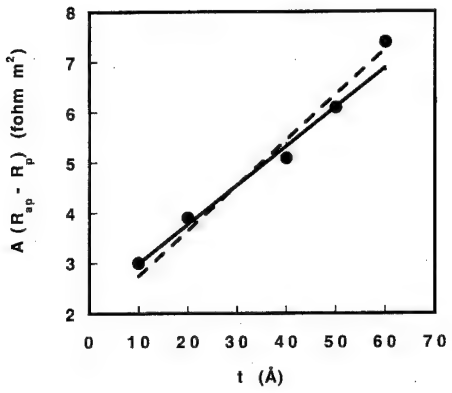

FIG. 7. Thickness dependence of $A(R_{ap}-R_p)$ at 4.2 K for a range of magnetic layer thicknesses t_F. Data are from circular shaped multilayers with 2 μm diam contact windows. The solid and dashed lines are calculated from Eq. (3) using the spin dependent conductivity parameters for Co given in the text plus the following parameters associated with the NiFeCo alloy (al) layers: $\beta_{al}=0.46$, $\gamma_{al/Cu}=0.30$, $AR_{Con}=0.05$ $f\Omega$ m^2 (solid line) and $\beta_{al}=0.46$, $\gamma_{al/Cu}=0.17$, $AR_{Con}=0.00$ $f\Omega$ m^2 (dashed line).

results. In making this comparison we use the literature values of the Michigan State group:[10] $\rho_{Co}=6.5$ $\mu\Omega$ cm, $\rho_{Cu}=0.7$ $\mu\Omega$ cm, $\beta_{Co}=0.50$, $\gamma_{Co/Cu}=0.76$, $AR_{Co/Cu}=0.21$ $f\Omega$ m^2 and our independently measured value of $\rho_{al}=12.9$ $\mu\Omega$ cm. Fits to the $A\Delta R$ data are shown in Fig. 7 using the parameters given in the figure caption and assuming $AR_{al/Cu}=AR_{Co/Cu}$ since the interface resistance in the literature does not vary much from system to system.[10]

The principal conclusion we come to from the data and fits shown in Fig. 7 is that spin dependent bulk scattering is important in the case of the NiFeCo permalloy used in the present samples and is the main cause of the clear thickness dependence observed for $A(R_{ap}-R_p)$. Because our mask set did not allow reliable measurements of the contact resistance between the device leads and the magnetic stacks, we cannot determine $\gamma_{al/Cu}$ accurately but, by determining what combinations of fitting parameters yield reasonable fits, we can conclude that it is no greater than 0.35 (see Fig. 7 caption.) Hence, it appears that the spin dependent scattering at the NiFeCo/Cu interfaces is significantly smaller than is the case for Co/Cu interfaces.

V. LATERAL SIZE-DEPENDENT EFFECTS

There are two factors dependent on the lateral size of the samples which need brief discussion, viz., current nonuniformity and stray magnetic fields. Because the lateral width of the sample contact windows is always at least several times the thickness of the Cu current leads and the lead thickness is several times the magnetic stack thickness, one cannot avoid some nonuniform distribution of current in the device element. As a result, we have emphasized data only from the samples having the smallest lateral dimensions, typically, 1.2 or 2 μm. Furthermore, since the temperature dependence of the multilayer stack resistance is much less than that of the Cu leads, the nonuniformity is temperature dependent. Although they lie outside the scope of the present paper, further experimental information on the impact of this nonuniformity can be found in Ref. 1.

Finally, the lateral dimensions of the magnetic stack part of the sample structures affects the stray magnetic fields generated by the edge poles of the stack as is apparent from Eq. (2). Our measurements of the magnetic field dependence of the magnetoresistance of structures with 60 Å thick magnetic layers show that the width at half-maximum of the $R(H)$ vs H traces (similar to those in Fig. 6) decreases with increasing magnetic stack diameter in reasonable agreement with the expectations of Eq. (2). This again emphasizes the necessity of finding a means of controlling the stray fields of the elements before submicron samples can be prepared with reasonable switching fields.

VI. CONCLUSIONS

In this study of perpendicular transport in lithographically defined devices several important issues have become clear. First, it is possible with standard procedures to fabricate device structures with lateral dimensions of about 1 μm. Above these dimensions, when using conventional materials (e.g., Cu) for leads, obtaining uniformly distributed currents is a challenge. At these dimensions, however, the magnetic fringing fields from dipoles at the film edges become significant and act to depolarize the magnetic structure. This can lead to an antialigned state at zero field even for nonmagnetic spacer layers more than sufficient to eliminate any exchange coupling. The temperature dependence of the GMR in our samples arises largely from the temperature dependence of the resistance itself, with only small changes in the magnetoresistance. We find some loss of moment in the magnetic layers which we attribute to about 2 Å of alloying at each magnetic interface. Finally, analyzing our data within the framework of the two-current model, we find our results are consistent with the published data on the interface and bulk scattering obtained by others[10] for systems containing two different ferromagnetic layers.

Note added in proof: The authors have learned that a version of the magnetoresistance model involving two parallel chains of resistors, one for each spin, was published prior to the work of Refs. 3 and 4 by S. Zhang and P. M. Levy [J. Appl. Phys. **69**, 4786 (1991)].

Multilayered Co/Cu wires with a diameter of 80 nm and a length of 6 μm were produced by electrodeposition in nanoporous polycarbonate membranes. Their magnetoresistance has been measured in a geometry where the current was perpendicular to the layer plane. The anisotropic part of the magnetoresistance was limited to 1.5%. The study, for layer thicknesses ranging from 3 to 100 nm interpreted in terms of the Valet and Fert model, gave estimates of the spin dependent bulk and interface resistivities and their change with temperature. The large Co bulk resistivity value, caused by a large amount of Cu impurities, limited the magnetoresistance in our samples to 20% at room temperature and 30% at 20 K. The Cu spin flip mean free path was found to be temperature independent and determined by scattering at Co impurities in the Cu layer. It was measured for two sets of samples with different amounts of Co impurities. © *1996 American Institute of Physics.* [S0021-8979(96)22908-2]

I. INTRODUCTION

The study of the large negative magnetoresistance (MR) in magnetic multilayers in a geometry where the current is perpendicular to the interfaces (CPP-MR) is an experimental challenge, which has been overcome by ultrasensitive voltage measurements at low temperatures[1] or by making pillar structures by lithography.[2] The possibility of making multilayered wires by electrodeposition with a diameter smaller than 100 nm and a length of a few microns opened the possibility of measuring the CPP-MR as a function of temperature on samples with resistance values reaching hundreds of ohms.[3] In contrast to the geometry where the current is parallel to the layer plane, the CPP-MR is expected to be larger[4] and the data can be explained by adding the resistances of the layers and the interfaces in a two-current model.[4,5] This model was improved by Valet and Fert[6] by introducing the concept of spin diffusion lengths (SDL). This quantity is a measure of the length scale over which the spin accumulation at the interfaces relaxes in the ferromagnetic and neutral layers. The experimental results of the Michigan State University (MSU) group on sputtered samples showed that the spin dependent resistivities of the bulk and the interface of the ferromagnetic layers both contributed to the CPP-MR and that the SDL of the neutral layer could be modified by the introduction of impurities.[5,7] We used a similar approach of getting spin dependent scattering parameters although with totally different samples. We made a series of samples with equal Cu and Co thicknesses (constant bulk resistivity) and measured the CPP-MR at low and ambient temperature. We used the two-current model to deduce the spin asymmetry parameters. We also took advantage of the versatility of the electrodeposition technique: we varied the deposition conditions of the Cu to change the amount of Co impurities in the Cu layers. The change of the CPP-MR values revealed that the interface spin asymmetry was also modified. The Co impurities played the role of spin-flip scattering centers, from which the Cu SDL, expressed in a free electron model, corresponded to our observations.

II. SAMPLE PREPARATION

The technique of electrodeposition of the Co/Cu multilayers in nanoporous membranes has been previously described.[8] In a single bath electrodeposition technique, we apply a large potential difference (with respect to a Ag/AgCl reference electrode) V_{Co} to deposit a majority of Co and a smaller potential difference V_{Cu} to deposit Cu. The concentration of Cu ions in the electrolyte is minimized to limit the amount of Cu co-deposited with the Co. The energy dispersive x-ray spectroscopy (EDS) analysis made by electron microscopy (Hitachi HF200 with Norian Voyager EDS system) revealed that the Co had $15\pm3\%$ of Cu impurity content. The Cu being more noble than Co, the use of a small potential V_{Cu} should ensure pure Cu layers. In fact, there is some Co co-deposited with Cu. Careful EDS measurements performed on Cu wires deposited at -0.300 V (set 1) and -0.600 V (set 2) showed that some fraction p of Co impurities was present

$$p(-0.3V)=0.50\pm0.15\%, \quad p(-0.6V)=1.0\pm0.3\%.$$

The uncertainties correspond to the variation of the amount of impurities between wires of the same batch. For both sets, we used the same electrodeposition conditions for the Co layers, deposited at 1.000 V. As the voltage transition is less sharp in set 2 than in set 1, it could be expected that the quality of the Co/Cu interface was different in both sets.

The total number of layers in a wire filling a membrane of thickness 6 μm$\pm$0.6 μm could be estimated by counting

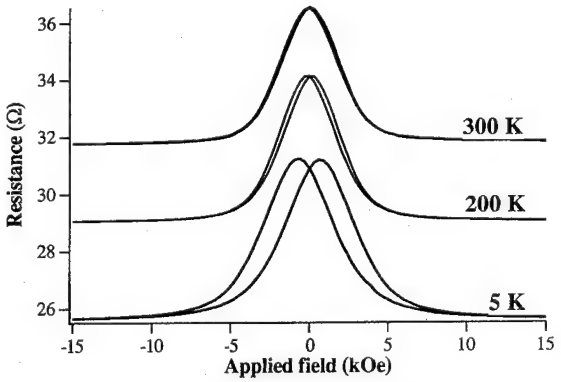

FIG. 1. CPP-MR of Co/Cu wires with Co and Cu thicknesses of 6($\pm$2) nm. The applied field was parallel to the membrane plane.

 0021-8979/96/79(8)/6090/5/$10.00

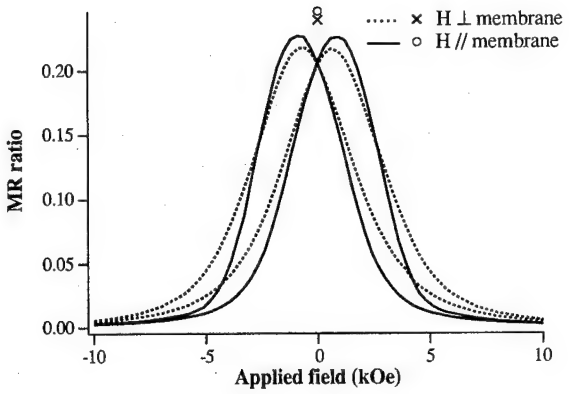

FIG. 2. CPP-MR at 5 K for two orientations of the field with respect to the membrane. The sample was the same as in Fig. 1. The ratio is defined as $\Delta R/R(\infty)$.

the number of voltage cycles until the current would increase when the membrane was filled and a crust would begin to form. An alternative measure of the number of layers and their thickness came from saturation magnetization measurements combined with the relative amount of Co determined by EDS. We estimated the precision in the control of the growth of the layers to be limited to variations of about 2 nm along the wires or between wires of the same membrane. Taking advantage of the roughness of the membrane (100–200 nm), we stopped the deposition at the beginning of the current increase, allowing a small fraction of the wires to reach the surface. We could thus glue gold wires with silver epoxy on a large surface of the sample (a few mm^2), keeping a small number of wires connected. We measured samples with resistance values from 1 to 400 Ω, with a current density of typically 10^7 A/m^2. Contacts were formed at the surface of the membranes, to an unknown number of wires connected in parallel. The difficulty of not getting a direct measurement of resistivities was overcome by doing a statistical study of a large number of samples and also by making use of Matthiessen's rule to deduce resistivities from the temperature dependence of the resistances.[8] Furthermore, the data analysis was based on CPP-MR ratios ($\Delta R/R$), since they are independent of the number of wires connected.

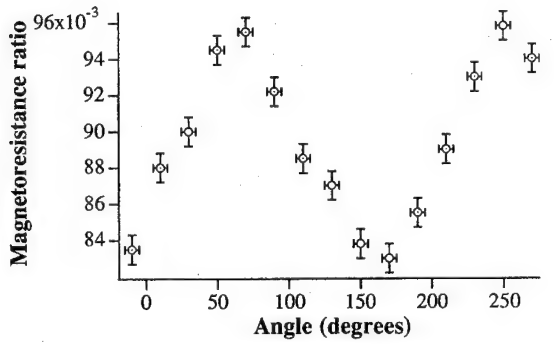

FIG. 3. CPP-MR ratio as a function of the angle between applied field and plane of the membrane, performed at ambient temperature.

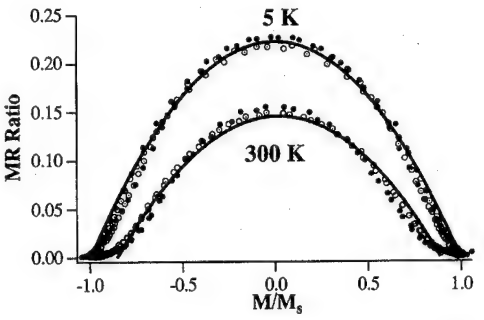

FIG. 4. CPP-MR ratio as a function of the relative magnetization. Applied field parallel to the membrane (filled symbols) and perpendicular to the membrane (open symbols). The curves are the fits to a parabola.

III. RESULTS

The measurements of CPP-MR were performed as a function of temperature with the applied field parallel or perpendicular to the layers (see Figs. 1 and 2). A larger resistance value was observed when an alternating and decreasing field was applied. The resistance value observed in this "demagnetized" state approached the value observed for virgin samples. The MR curves with field in two directions (see Fig. 2) differ for two reasons. First, the saturation field is anisotropic. Second, there is an anisotropic magnetoresistance (AMR) superposed on the CPP-MR. The AMR was

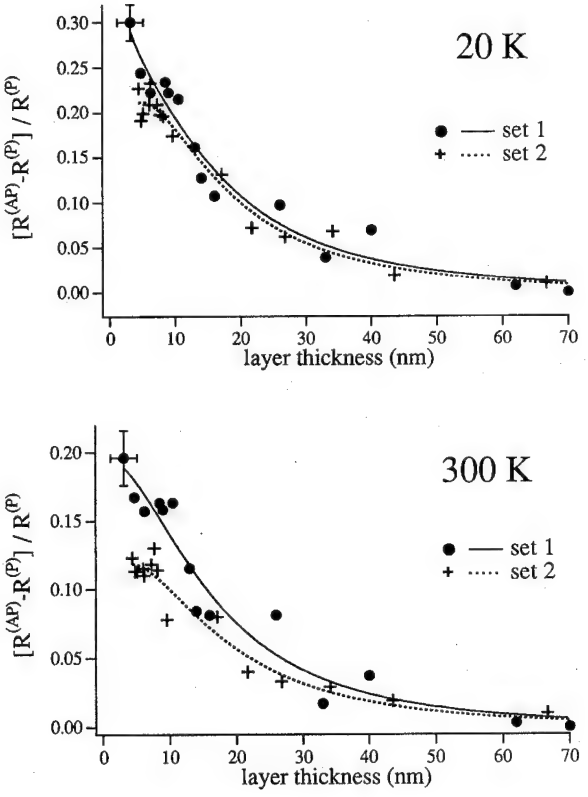

FIG. 5. CPP-MR ratio as a function of equal Cu and Co layer thicknesses. The measurements were performed at two temperatures, for two sets of samples produced under different electrodeposition conditions. The lines correspond to the fit using Eqs. (2)–(4) and the results given in Table I.

deduced from the angular dependence of the CPP-MR (see Fig. 3). This AMR contribution was at most 1.5% and decreased with increasing thickness to 0.5% at a layer thickness of 100 nm. Uniform nanowires produced by deposition at V_{Co} presented an AMR of 1% to 1.5%. In Fig. 3 the angular dependence of the AMR reached a maximum at an angle of 15° between the field and the normal to the membrane. This is consistent with the distribution of wire orientations in the membranes.[9]

The temperature dependence of the field at the maximum MR was that of the coercive field, which changed by one order of magnitude between room temperature and 5 K. The MR measurements, which can be carried out on a very small number of wires, can be seen as a means of measuring coercive fields free of averaging over a large angular distribution of the wire orientations in the membranes.

The relation between CPP-MR and the magnetization is shown in Fig. 4. If the magnetic layers are uncorrelated, the MR can be simply expressed as[10]

$$\frac{\Delta\rho}{\rho(\infty)} \propto \left(\frac{M}{M_s}\right)^2. \tag{1}$$

This relation described well the low-temperature data and only small discrepancies were found at room temperature near the saturation magnetization.

The CPP-MR ratios were measured for two sets of samples produced under different electrodeposition conditions. Samples with equal Cu and Co thicknesses were measured at room and low temperatures (see Fig. 5). The MR increased with increasing density of interfaces, until a limit of layer thickness of approximately 3 nm below which the MR effect vanishes,[8] indicating unreliable layering on this length scale, in agreement with the precision of 2 nm mentioned above.

IV. DISCUSSION

In the Valet and Fert article,[6] the expression for the resistance per unit area $R^{(P)}$ (all ferromagnetic layers parallel) and $R^{(AP)}$ (magnetic layers antiparallel) of M bilayers is given by

$$R^{(P,AP)} = M(r_0 + 2r_{SI}^{(P,AP)}) \tag{2}$$

with

$$r_0 = (1-\beta^2)\rho_F^* t_F + \rho_N^* t_N + 2(1-\gamma^2) r_b^*, \tag{3}$$

where t_N and t_F are the thicknesses of the nonferromagnetic and ferromagnetic layers. The spin dependent resistivities $r_{SI}^{(P,AP)}$ are given by

$$r_{SI}^{(P,AP)} = \frac{\dfrac{(\beta-\gamma)^2}{\rho_N^* l_{sf}^{(N)}} f^{(P,AP)}\left[\dfrac{t_N}{2l_{sf}^{(N)}}\right] + \dfrac{\gamma^2}{\rho_F^* l_{sf}^{(F)}} \coth\left[\dfrac{t_F}{2l_{sf}^{(F)}}\right] + \dfrac{\beta^2}{r_b^*}}{\dfrac{1}{\rho_N^* l_{sf}^{(N)}} f^{(P,AP)}\left[\dfrac{t_N}{2l_{sf}^{(N)}}\right] \dfrac{1}{\rho_F^* l_{sf}^{(F)}} \coth\left[\dfrac{t_F}{2l_{sf}^{(F)}}\right] + \dfrac{1}{r_b^*}\left\{\dfrac{1}{\rho_N^* l_{sf}^{(N)}} f^{(P,AP)}\left[\dfrac{t_N}{2l_{sf}^{(N)}}\right] + \dfrac{1}{\rho_F^* l_{sf}^{(F)}} \coth\left[\dfrac{t_F}{2l_{sf}^{(F)}}\right]\right\}}, \tag{4}$$

where $f^{(P)}[x] = \tanh(x)$ and $f^{(AP)}[x] = \coth(x)$. The coefficient β is a measure of the spin asymmetry of the Co resistivity, which is $2\rho_F^*(1-\beta)$ for the majority spin charge carriers $2\rho_F^*(1+\beta)$ for the minority spins. The Co layers have a bulk resistivity $\rho_F = \rho_F^*(1-\beta^2)$. The Cu (neutral) layers have a bulk resistivity given by ρ_N^*. The coefficient γ represents the asymmetry of the spin dependent interface resistance, with a resistance per unit area of $2r_b^*(1-\gamma)$ in the majority case and $2r_b^*(1+\gamma)$ in the minority case. The expressions 2–4 are valid under the assumption of a negligible spin mixing and the electronic mean free paths much smaller than the corresponding spin diffusion lengths.

The CPP-MR dependence on layer thickness (see Fig. 5) was analyzed using Eqs. (2)–(4). We could deduce the asymmetry parameters and the spin diffusion length of the Cu layers (see Table I), using set values of the bulk resistivities ρ_N^*, ρ_F^* and the interface resistance r_b^*. The choice for these values was discussed in Ref. 8. A reasonable range of values was used in Table I.

The predictions of the Valet and Fert model showed that the Co SDL had little influence on the CPP-MR.[11] In our fitting procedure, the Co SDL was fixed at a large value. Any choice of the Co SDL larger than 10 nm would give us similar parameters. In order to bring out the effects of the spin diffusion length of the Co, a set of samples with an increasing Co thickness was produced (see Fig. 6). The Cu layer thickness was fixed at 10 nm. Parameters deduced from the fittings of the more complete sets of data of Fig. 5, with $l_{sf}^{(F)}$ values of 3, 10, and 100 nm, were used to draw the lines shown on Fig. 6. We observed that the CPP-MR was strongly decreased when the layer thicknesses were too different. We consider that our synthesis becomes defective for these types of samples.[8]

The main difference between the two sets of samples is the value of the interface asymmetry parameter γ. In the samples from the set 2, the lower spin dependent interface resistance is reflected in the lower CPP-MR ratios observed at small thicknesses. The difference in the deposition conditions between the two sets of samples, with a deposition potential gap changed by a factor of 2, appears to be reflected in the spin asymmetry of the interfaces.

The spin asymmetry coefficients γ and β depend slightly on the original choice of the resistivities. To the contrary, the value of the SDL strongly depends of this choice. We overcame the uncertainty in the resistivity of the Cu layers by

TABLE I. Parameters of the two-channel model. The range of the choice for the resistivity values is given. The uncertainties are those deduced from the fittings, including the indicated variation of parameters ρ_N^*, ρ_F^*, and r_b^*.

considering the spin flip mean free path. Figure 7 is a plot of the SDL deduced from the fits to the data of Fig. 5, as a function of the choice made for the resistivity ρ_N^*. The data at 20 and 300 K of each set of samples are superposed and the SDL of set 2 are systematically smaller than that of set 1. In Fig. 5, no evidence of a contrast between the two sets of samples at large thicknesses (in particular at 20 K) can be seen. However, Fig. 7 took advantage of the statistics from Fig. 5 to exhibit a systematic difference.

A simple physical model can account for the apparent correlation between the resistivity and the SDL of the copper layers. In the free electron model, we can express the SDL as a function of the resistivity as[8]

$$l_{sf}^{(N)} = \sqrt{\frac{m v_F}{6ne^2}}\ \sqrt{\frac{\lambda_{sf}^{(N)}}{\rho_N^*}} = C\sqrt{\frac{\lambda_{sf}^{(N)}}{\rho_N^*}}, \tag{5}$$

where $C = 1.048\times10^{-8}\ \sqrt{\Omega}\ m$ for Cu. Given the dependence of the SDL on ρ_N^* from Eq. (5), the fitted spin-flip mean free paths $\lambda_{sf}^{(N)}$ are

$$\lambda_{sf}^{(N)} = 450\ \text{nm (set 1)} \quad \text{and} \quad \lambda_{sf}^{(N)} = 300\ \text{nm (set 2)}.$$

The spin-flip mean free path can be expressed in terms of the spin flip cross section by

$$\lambda_{sf}^{(N)} = \frac{1}{N\sigma}, \tag{6}$$

where N is the number of impurity per unit volume. The spin-flip cross section σ of Co in Cu is known from electron spin resonance (ESR) experiments to be of about 5×10^{-21} m^2.[12] Using the impurity contents measured by EDS, Eq. (6) yields

$$\lambda_{sf}^{(N)}(-0.3\ \text{V}) = 470\ \text{nm (set 1)},$$

$$\lambda_{sf}^{(N)}(-0.6\ \text{V}) = 235\ \text{nm (set 2)}.$$

These values are in remarkable agreement with those deduced from Fig. 7. The Cu spin-flip mean free path, due to impurities, is temperature independent. As a consequence, the temperature dependence of the Cu SDL is caused by the variation of the Cu resistivity with temperature. The asymmetry parameters are found to decrease with increasing temperature.

V. CONCLUSIONS

The magnetoresistance, in a geometry where the current was perpendicular to the layer plane, was measured in samples of resistance values ranging from 1 to 400 Ω, at temperatures of 5–300 K. The two-current model was used to fit the thickness dependence of the CPP-MR of samples with equal Cu and Co layer thicknesses. At low temperatures, we found the Co spin asymmetry parameter to be about the same as found by others for sputtered samples,[5] even though the samples were produced by totally different methods. The spin asymmetry of the interfacial resistance is found to be slightly smaller than for the vacuum deposited samples. Our samples, with a typical area of 10^{-13} m^2, gave no evidence that the spin accumulation could be hindered by domains in the ferromagnetic layers,[13] a configuration which

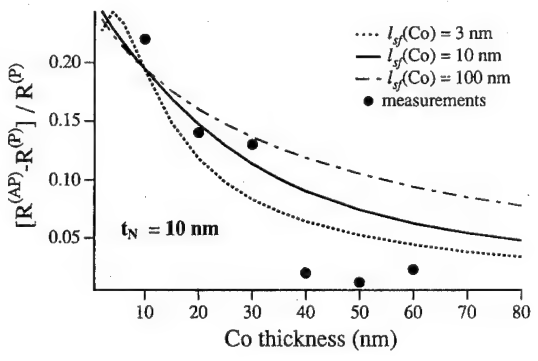

FIG. 6. CPP-MR ratios for samples with a fixed Cu thickness of 10 nm as a function of the Co layer thickness. The drawn lines correspond to different choices in the Co spin diffusion lengths in the fitting of the data of Fig. 5.

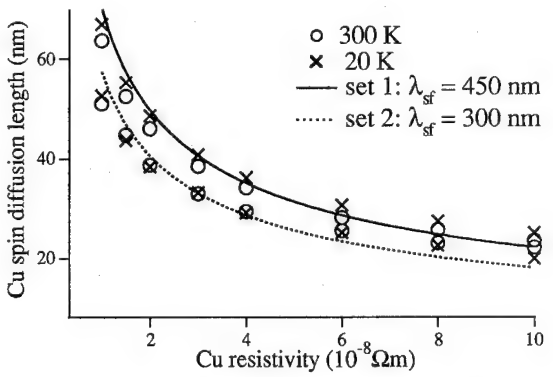

FIG. 7. Cu spin diffusion length found from fitting of the data of Fig. 5 as a function of the choice for the Cu resistivity.

could occur in the vacuum deposited samples of area of 10^{-6} m^2. The spin diffusion length in the Cu layers was found to be due to Co impurities. The corresponding spin-flip mean free path was found temperature independent and its value corresponded to the one deduced from ESR experiments.

This picture is confirmed by the study of two sets of samples, produced by changing the electrodeposition conditions of the Cu layers. The amount of Co impurities was varied and the corresponding change of the spin-flip mean free path was observed. Furthermore, the interface was changed and its spin dependent resistance modified.

The single bath electrodeposition technique limited the quality of the samples by adding a large amount of impurities of Cu in the Co layers. The resulting large Co resistivity limited the magnetoresistance to 30% at low temperatures.

We have designed a low-temperature femtosecond-resolved near-field scanning optical microscope to study spatiotemporal excitonic spin behavior in magnetic semiconductor heterostructures. Local disorder introduced by focused-ion-beam implantation reduces the otherwise large Zeeman splittings in modest magnetic fields, creating a planar spin-dependent energy landscape for diffusing carriers. Near-field polarization-resolved static and femtosecond measurements map out excitonic spin behavior with ~125 nm spatial resolution, revealing spin-dependent diffusion. We demonstrate the applicability of two distinct time-resolved techniques in the near field, and discuss limitations on the measurement of polarized luminescence from semiconductors in the near field. © *1996 American Institute of Physics.* [S0021-8979(96)23008-7]

I. INTRODUCTION

A detailed understanding of spin scattering in mesoscopic electronic systems remains, for the most part, an open issue in condensed matter physics.[1] To directly investigate the dynamic behavior of electronic spin, one needs to develop both a host material in which the fundamental spin interactions are well understood, and techniques for probing spin scattering on the relevant time and length scales.

Extensive research in recent years has identified II–VI magnetic semiconductor quantum structures as flexible systems in which to study electronic spin interactions in a well-characterized environment.[2] In such systems, the strong exchange coupling between electronic states and paramagnetically aligned magnetic ions results in large effective Landé g factors at low temperatures (g_{eff}~400 at $T=4$ K). Quantum well (QW) confinement enhances by several orders of magnitude the coupling of excitonic states to visible light, enabling a wide array of optical techniques to be used. The Zeeman splittings in recently grown structures can be made much larger than inhomogeneous linewidths,[3] providing model field-tunable two-level systems ideal for magneto-optical studies of spin-dependent phenomena.

Conventional time-resolved optical spectroscopies have successfully probed dynamical spin-dependent phenomena in this class of structures, yielding important information about exciton spin scattering and magnetic relaxation.[3,4] However, to examine directly the role of interfaces, alloy fluctuations, disorder, local magnetic environments, impurities, and defects on excitonic spin *transport*—factors which involve *spatial degrees of freedom*—one requires a technique capable of resolving the relevant physical length scales, from exciton diffusion lengths (~1 μm) to magnetic correlation lengths (>50 nm in antiferromagnetically ordered MnSe),[5] to the exciton Bohr radius (~4 nm for ZnSe/ZnCdSe).[6] Conventional optical techniques, being diffraction limited, cannot provide sufficient resolution on the length scales of interest. Near-field scanning optical microscopy (NSOM) circumvents the diffraction limit[7] and, combined with femtosecond-resolved spectroscopies, provides a unique capability of interrogating spatiotemporal exitonic spin dynamics in magnetic semiconductors.

Here we present static and time-resolved luminescence studies of excitonic spin behavior in magnetic semiconductor QWs using a low-temperature polarization-resolved NSOM. A series of patterned defects, introduced by Ga^+ focused-ion-beam implantation, reduces both the QW luminescence intensity and the local g factor, creating a magnetic-field-driven spin-dependent energy landscape for diffusing excitons. Carrier spin distributions are inferred from the near-field images of the dc luminescence intensity and polarization. Exciton diffusion is found to have a minimal effect on the local magnetic interactions which contribute to Zeeman split states. The incorporation of time resolution, using a luminescence intensity correlation technique, provides additional evidence for spin-dependent exciton diffusion. Time-resolved absorption, another powerful tool, yields direct information about the spatiotemporal evolution of photoexcited excitons. Fundamental limitations on the measurement of polarized luminescence from semiconductors in the near field are demonstrated and discussed.

II. DIGITAL MAGNETIC HETEROSTRUCTURES

A new class of magnetic semiconductors—Digital Magnetic Heterostructures (DMH)[3]—serve as the host systems that are studied in these experiments. These structures consist of single 12 nm $ZnSe/Zn_{0.80}Cd_{0.20}Se$ MBE-grown quantum wells containing systematic planar distributions of magnetic ions (Mn^{++}). Far-field magneto-optical studies show large Zeeman splittings in modest magnetic fields (effective Landé g factor ~430 at 4.2 K), and relatively narrow inhomogeneous linewidths (6 meV).[3] The structures are grown on GaAs(001) substrates with an MBE-deposited 700 nm buffer layer of ZnSe to relieve lattice mismatch strain, and a 100 nm cap layer. Measurements performed in transmission require removal of the GaAs substrate without disturbing the QW or buffer layer. Presently, no stop etch is known for ZnSe; however, preferential etch rates of GaAs vs ZnSe (20:1 selectivity)[8] can be utilized. The GaAs substrate is

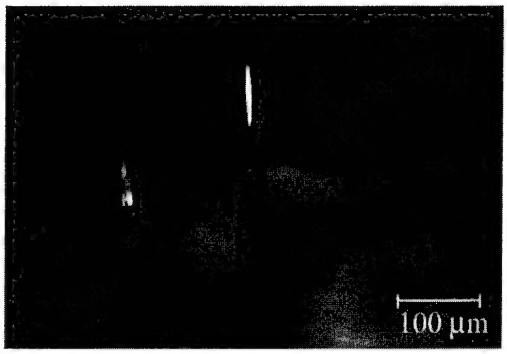

FIG. 1. Micrograph of an NSOM tip between single mode (left) and multimode (right) fibers, used to implement shear-force feedback in a compact microscope design.

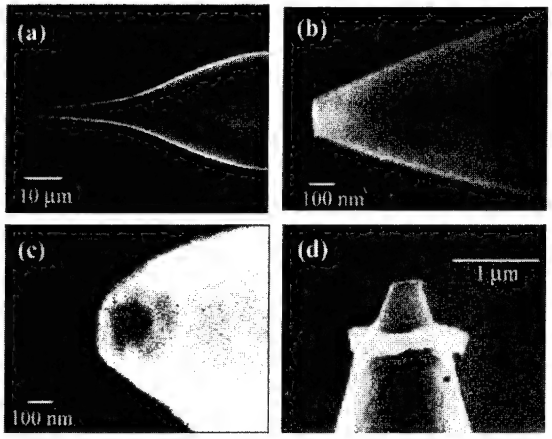

FIG. 2. Scanning electron micrographs of NSOM tips. (a), (b) Pulled fiber tip. (c) Ag-coated NSOM probe viewed at a 45° angle with the dark circle showing the transmitting core. (d) Destroyed coating after coupling 5 mW of HeCd laser light (442 nm) into the fiber.

thinned by polishing to 50–100 μm to achieve a surface roughness <0.2 μm, with care taken to keep the thickness uniform. Wet spray etching[8] removes the remaining GaAs on a lithographically patterned circle, leaving smooth (50 nm surface roughness) ZnSe buffer. The processed sample consists of a 300 μm diam circular film of QW sandwiched between 700 nm buffer and 100 nm ZnSe cap layers, mechanically supported by the surrounding unetched structure. Samples are mounted on a thin (0.2 mm) fused silica slide with the cap layer exposed.

To study the effect of local disorder on exciton spin dynamics, a 140 keV focused (100 nm diam spot size) beam of Ga^+ ions is used to implant specific patterns on the processed structure in the plane perpendicular to the growth direction. The small implantation dosage used (10^4 μm^{-2}) introduces lattice defects without destroying the QW. The pattern consists of a series of 100, 200, 400, and 800 nm-wide parallel stripes, each separated by 2 μm.

III. LOW-TEMPERATURE NEAR-FIELD SCANNING OPTICAL MICROSCOPY

We have developed a femtosecond low-temperature NSOM, designed to fit in the 30 mm bore of continuous He gas flow optical cryostat, and to operate at temperatures $T=4-300$ K. Measurements are performed in zero and $B=0.2$ T magnetic field in the Faraday configuration, the latter achieved by mounting samples on a permanent annular magnet attached to the microscope sample stage. The stage is kinematically supported and positioned with respect to the near-field probe by three mechanical feedthroughs, allowing coarse (~10 μm) adjustment of the lateral position as well as fine (~1 μm) approach toward the near-field probe. Piezoelectric transducers enable the tip to scan the sample surface over a 5 μm×20 μm area at $T=5$ K.

Shear-force feedback is employed to measure and control the tip-sample separation.[9] In this technique, the near-field fiber is laterally excited—dithered—a small amount (5–10 nm) at a mechanical resonance, and the damping of that resonance is monitored as the tip approaches the sample surface. To employ shear-force feedback in a compact design of the microscope, the dither amplitude of the near-field fiber is monitored by two side fibers (see Fig. 1). The tip is placed in the small gap between an illuminating single-mode fiber and a collecting multimode fiber, and its position is adjusted so as to partially obstruct the transmitted light. Oscillations of the near-field fiber result in modulations of the detected intensity. The tip-sample separation is determined from an "approach curve," obtained by moving the tip a known amount towards the sample while measuring the lock-in detection signal at the dither frequency. The lock-in signal is fed back to the piezo transducer to keep a constant tip-sample separation.

Near-field probes are manufactured by pulling single-mode optical fibers locally heated by a focused CO_2 laser.[10] By varying the laser power and other pull parameters, different near-field probe shapes and tip sizes are obtained [Figs. 2(a) and 2(b)]. Pulled tips are evaporation coated with ~100 nm of a high reflectivity metal to confine the light where the tip diameter d becomes comparable to the wavelength λ. Silver was found to be a good choice for coating due to its high reflectivity and good adhesion to the fiber surface. As a result, probes are obtained with subwavelength apertures [Fig. 2(c)], through which light is collected and sent up the fiber. An important characteristic of the tip is the throughput $T=I_{tr}/I_{in}$ where I_{tr} the transmitted intensity through the tip aperture, and I_{in} is the intensity of light coupled into the fiber from the other end. Both the tip shape and aperture diameter affect T. The tip shape is optimized to obtain the highest possible throughput for a chosen aperture size ($T\sim10^{-5}$ for a $d=100$ nm aperture). Aperture sizes are chosen to balance spatial resolution against photon shot noise and, depending on the type of measurement, are varied between 100–180 nm. High intensity light, coupled through the fiber, can destroy the metallic coating due to the enormous power density at the tip aperture [Fig. 2(d)], thus limiting the maximum incident power to ~5 mW for 100 nm tips. Prolonged exposure to air oxidizes the silver, forming pinholes, so tips are stored in vacuum until use. Samples are excited by focusing a laser beam on one side of the sample, and collecting luminescence with the near-field probe on the opposite side. In this configuration, the sample is uniformly illuminated with-

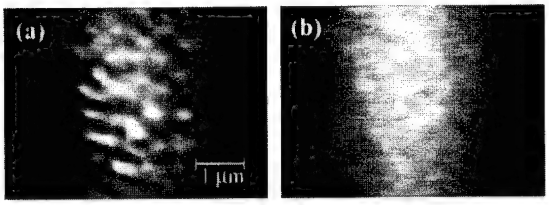

FIG. 3. (a) NSOM image of a tightly focused HeCd laser, transmitted through the etched sample. (b) The NSOM image of the luminescence intensity from the same region at $T=5$ K.

out shadowing from the tip,[11] allowing a variety of optical techniques to be employed.

Despite the care taken to ensure a smooth and flat buffer layer, the laser intensity profile remains highly irregular after passing through the etched nonimplanted sample. Small nonuniformities in the etched buffer layer thickness, exacerbated by the high index of refraction near the absorption edge of ZnSe, produce an interference pattern with sharp features, resolved in the near field [Fig. 3(a)]. Luminescence from the same region, seen in Fig. 3(b), is in comparison more uniform, indicating that photoexcited excitons diffuse on micron length scales within their lifetime.

The processed structures are extremely fragile, consisting only of the buffer, QW and cap layers, with a combined thickness totaling less than 1 μm. In near-field measurements, the probe is brought close (25–50 nm) to the sample surface using shear-force feedback. It is likely that contact is made when feedback is employed, as prolonged scanning over the same position adversely affects the structure. Figures 4(a)–4(d) show topography and luminescence images from a patterned sample before and after a 24-h line scan. During the scan, the probe is positioned at one point on the line, with the feedback on, while near-field measurements are performed. Despite the lack of apparent topographical changes, a quench in luminescence is observed not only on the scanned line, but also in the surrounding regions along the vertical crystallographic axis, indicating strain-induced destruction of the QW. To prevent damage to the sample, two scan modes are used: raster scan and lift-up scan. In the raster-scan mode, the probe is continuously scanned across the sample, feedback on, while acquiring near-field data. These scans are short (~1 h) and are used mainly for dc

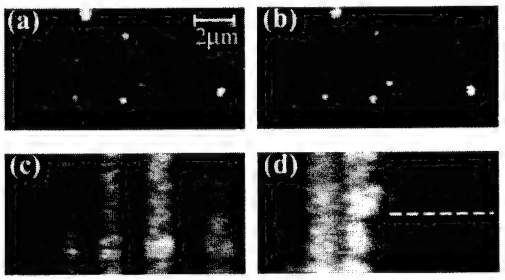

FIG. 4. (a), (b) Shear-force topographic image of a structure before (a) and after (b) a 24-h line scan. (c), (d) Concurrent luminescence intensity images before (c) and after (d) the same scan. The dashed line indicates the scanned path of the NSOM tip. Luminescence quenching occurs in regions above and below the scanned line.

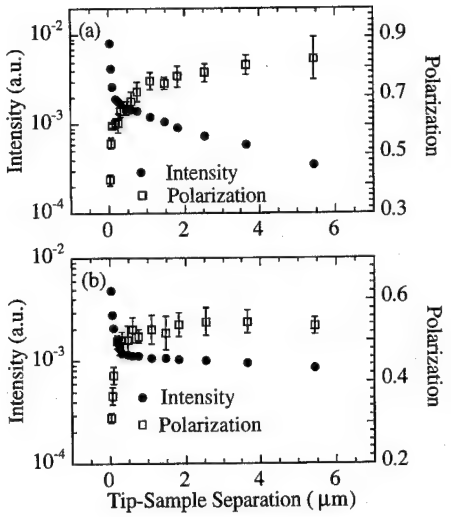

FIG. 5. The dc photoluminescence intensity and polarization of the nonpatterned DMH sample at $T=5$ K in $B=0.2$ T as a function of the sample-probe separation for a tightly focused (5 μm) (a) and defocused (100 μm) (b) laser spot.

luminescence measurements. In the lift-up scan mode, the probe position is fixed and the tip lifted ~50 nm from the surface, feedback off, while near-field measurements are taken. Feedback is used only for the short time required to move the tip to a new position; thus, even for long scans, the risk of sample damage is minimized.

A. Near-field polarization

Polarization analysis in the near-field is complicated by two factors. First, strain-induced birefringence in the single-mode optical fiber "scrambles" the incident polarization. To obtain meaningful results, the polarization must first be "unscrambled" using a variable waveplate and polarizer. The correct parameters are determined in one of two ways. In the first method, circularly polarized luminescence from the magnetic heterostructure is collected in an applied magnetic field. The waveplate angle and retardance are scanned to find a maximum and minimum, corresponding to the two spin states. Alternatively, circularly polarized light from a laser, tuned to the wavelength of interest, is focused onto the near-field tip to find the appropriate waveplate settings. Both methods give identical and consistent values for polarization analysis.

Second, it has been found that polarization from semiconductors, measured under otherwise identical conditions, is significantly reduced in the near field compared to the far field.[12] To investigate the origin of this effect, we have explored the dependence of the sample-probe separation on the measured polarization. A nonpatterned sample in $B=0.2$ T at $T=5$ K, with 80% polarization measured in the far field, is photoexcited by a linearly polarized HeCd laser focused to 5 μm. Polarized luminescence is collected by the near-field probe, positioned in the laser spot center a distance d over the sample. As the probe approaches the surface, the detected luminescence intensity increases and the polarization decreases [Fig. 5(a)]. The sharp knee in the luminescence in-

tensity curve clearly delineates the near- and far-field regimes.

To explain the loss of polarization in the far-field ($d>\lambda$) regime, we note that the polarization of luminescence from semiconductors depends on the angle θ between the point of observation and the field direction as $P(\theta)=P(0)\cos\theta$,[13] where $P(0)$ is the polarization measured along the field direction. Luminescence collected over a solid angle Ω will therefore have an appropriately reduced polarization. An ideal near-field probe collects light from all directions, but its effective numerical aperture is determined by the luminescence spot size and sample-probe separation. As the probe is brought closer to the sample, its effective numerical aperture increases, and the polarization decreases. This contribution to the loss of polarization is seen clearly by comparing Fig. 5(a) with Fig. 5(b), where the same measurements are performed with the laser focused to 100 μm. In this case, the effective numerical aperture of the probe changes negligibly with distance, and the polarization therefore remains essentially constant over distances $d>\lambda$. This explanation accounts well for the data taken in the far-field regime, but does not explain the near-field data, where the polarization decrease is most dramatic. An intriguing explanation for the loss of polarization in the near field is that the evanescent fields do not propagate angular momentum and hence cannot couple to circularly polarized light in the far field. Regardless of the explanation, the loss of circular polarization in the near field appears to be a general feature associated with NSOM measurements on semiconductors.

B. Static spin behavior

Static excitonic spin-dependent behavior in the presence of disorder is studied on patterned DMH structures through polarization-resolved dc photoluminescence measurements, performed at $T=5$ K and $B=0.2$ T in the Faraday configuration. Structures are excited with linearly polarized light from a HeCd laser ($E_{ex}=2.807$ eV) with ~ 1 kW/cm^2 power density. Near-field images are obtained by collecting luminescence at a fixed detection energy in the raster-scan mode. The luminescence intensity [Fig. 6(a)] exhibits maxima in the center of undamaged regions, monotonically decreasing toward the implanted regions. The reduction of luminescence intensity in the implanted regions is attributed to an increase of nonradiative channels created by the focused ion beam. The lack of a sharp interface between intrinsic and implanted areas on the structure, as compared to the sharpness of the polarization image, indicates diffusion of photoexcited excitons. The contrasting interface sharpness of the polarization images [Fig. 6(b)] supports this interpretation, the polarization remaining constant over intrinsic regions and dropping sharply to zero only in the implanted areas. This result suggests that lattice damage, along with increasing the number of nonradiative channels, also destroys the rotational symmetry of the lattice, reducing magnetic interactions responsible for Zeeman splitting. Moreover, the constant polarization over the intrinsic regions implies that exciton diffusion does not result in increased spin scattering.

A more quantitative analysis is obtained by performing a line scan across several interfaces in the lift-up mode.

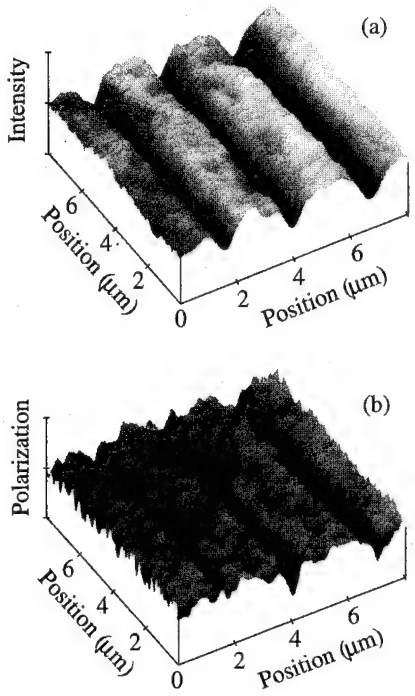

FIG. 6. The dc luminescence (a) and polarization (b) images on a patterned DMH sample at $T=5$ K and $B=0.2$ T.

Polarization-resolved luminescence spectra are collected at points along the line under otherwise identical conditions at $T=9$ K and $B=0.2$ T. The luminescence intensity, polarization, energy of the luminescence peak, and Zeeman splitting profile [Figs. 7(a)–7(d)] are extracted from the collected data. The slow variations in the luminescence intensity and the sharper features of the polarization profiles resemble the 2D images. The luminescence peak energy profile for both spin states [Fig. 7(c)] shows modulations defined by implantation, as well as small (<1 meV) scan-to-scan reproducible fluctuations. Surprisingly, the spatially resolved Zeeman energy splitting shows much smaller fluctuations, but is modulated by implantation much like the polarization. The potential and Zeeman energy variations are attributed mainly to alloy fluctuations.

C. Femtosecond-resolved NSOM

Femtosecond time resolution is added to the near-field measurements using a luminescence intensity autocorrelation (LIA) technique.[14] By detecting nonlinear photoluminescence corresponding to a certain spin state, the exciton time correlation function $c(\tau)=\langle n(t)n(t+\tau)\rangle$ for that state can be obtained. Measurements are performed using the frequency-doubled output of Ti:Sapphire laser producing 130 fs pulses, tuned 100 meV above the exciton ground state energy. The linearly polarized laser output is split into two equal intensity pulses, separated by a time τ through a variable delay line. A good spatial overlap of the two beams on the sample is imperative: the beams are coaligned after going through delay optics and their spatial overlap is verified both by examination of the far-field interference pattern and by direct imaging of each beam using the near-field microscope. Optical choppers modulate the two beams at different fre-

quencies, and phase-sensitive detection at sum frequency yields the LIA signal, whose time decay provides a measure of the exciton lifetime.

Figures 8(a) and 8(b) show the LIA signal as function of position and time delay. Measurements are performed on a patterned DMH sample at $T=9$ K in $B=0.2$ T in the lift-up scan mode. Data is taken by collecting time-varied signal for both polarizations on a line perpendicular to the patterned stripes. For both spin states the initial exciton distribution is

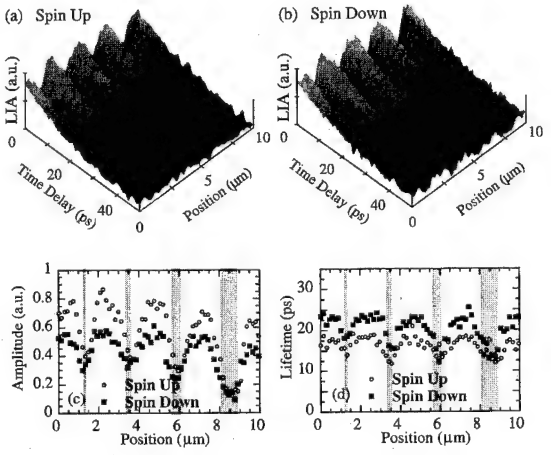

FIG. 8. Time-resolved exciton spin dynamics obtained by LIA measurements in a line scan across four interfaces ($B=0.2$ T, $T=9$ K). (a) Spin up. (b) Spin down. (c), (d) Amplitude and lifetime vs position, extracted by a single exponential fit from the above data. Shaded areas indicate regions of ion implantation.

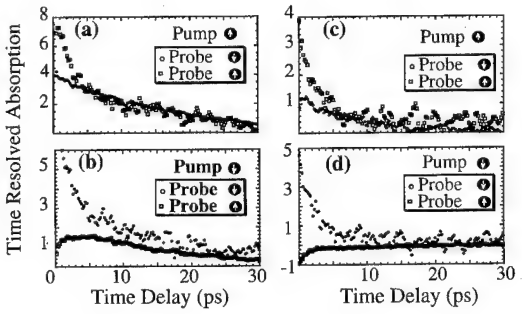

FIG. 9. Time-resolved absorption for both spin up and spin down excitonic states in intrinsic (a), (b) and implanted (c), (d) regions, with the pump pulse initially photopopulating spin up (a), (c) and spin down (b), (d) excitonic states at $T=5$ K and $B=0.2$ T.

spatially modulated, having been suppressed in the implanted areas. The time evolutions for the two spin states, however, are quite different: the spin-up lifetime is significantly shorter than the spin-down lifetime. A more qualitative comparison is made by applying a single exponential fit $A\exp(-t/\tau)$ to the curves at each spatial location. The lifetime of the spin down state [Fig. 8(c)] is decreased almost a factor of 2 in the implanted areas, whereas variations in lifetime of the spin-up state are small. This result indicates preferred diffusion of spin-up excitons from intrinsic into implanted regions.

Similar measurements are performed on a patterned nonmagnetic sample. Exciton lifetimes are several times longer than in the magnetic samples, a fact consistent with far-field measurements performed on unpatterned samples. The $\tau=0$ exciton distribution defined by implantation is smeared out at later times by diffusion. Exciton lifetimes are reduced in the implanted areas, and are smaller for wider implanted stripes.

Another technique employed—time-resolved absorption—provides even more direct information about the time-dependent exciton population. A circularly polarized femtosecond pump pulse resonantly photopopulates an exciton spin state, while a much weaker (-20 dB) time-delayed probe measures absorption changes. By choosing the helicity of the probe pulse and the time delay τ, the population of either excitonic spin state can be determined as a function of τ. Both beams are modulated using optical choppers at different frequencies, and lock-in detection occurs at the sum frequency. In far-field measurements the pump beam is blocked at the detection end, allowing only pump-induced changes in the probe beam to be detected. In the near-field this separation is not possible, and photon shot noise from the pump limits the sensitivity attainable using this technique.

Figures 9(a)–9(d) show time-resolved measurements in the intrinsic and implanted regions shown on a patterned sample at $B=0.2$ T and $T=5$ K. The reduced lifetime for both spin states is consistent with LIA measurements. It is also worth noting that when spin-down excitons are optically injected, the number of spin-up carriers increases in the implanted region, but drops down in the intrinsic region, indicating preferential diffusion of spin-up carriers into implanted regions from the nearby intrinsic regions, also in

agreement with LIA measurements. Nonuniformities in both the pump and probe pulse profiles (see Fig. 3), however, make interpretation of spatially resolved images difficult. Smoother etched surfaces may in the future allow this technique to fulfill its promise of providing direct spatiotemporal information on excitonic spin behavior in these systems.

IV. CONCLUSION

We have demonstrated the unique capability of femtosecond near-field microscopy to optically study spatiotemporal excitonic spin behavior in magnetic semiconductors. The patterned defects introduced by the ion implantation result in locally suppressed magnetic interaction, and create the observed spin-dependent energy landscape for the photoexcited carriers. Time-resolved measurements employing the luminescence intensity autocorrelation technique show that, in the presence of such nonuniform potentials, exciton diffusion acquires a spin component. Both static and time-resolved near-field measurements suggest that exciton diffusion does not affect their interaction with the magnetic matrix and concurrent spin scattering. Time-resolved measurements reveal spin-dependent excitonic lifetimes consistent with the carrier diffusion in nonuniform energy potential.

Nanolithographically defined magnetic structures and quantum magnetic disk (invited)

Stephen Y. Chou, Peter R. Krauss, and Linshu Kong
NanoStructure Laboratory, Department of Electrical Engineering, University of Minnesota, Minneapolis, Minnesota 55455

Isolated and interactive arrays of magnetic nanostructures as small as 15 nm are fabricated using nanolithography and related technologies, and are characterized using magnetic force microscopy. It has been demonstrated that manipulating the size, aspect ratio, and spacing of these nanostructures can lead to unique control of their magnetic properties. A quantum magnetic disk based on discrete single-domain nanomagnetic structures with storage density of 65 Gbits/in.^{2} is demonstrated along with a low-cost method for mass producing such disks. Other impacts that nanofabrication can bring to the development of future magnetic storage are discussed. © *1996 American Institute of Physics.* [S0021-8979(96)41908-8]

I. INTRODUCTION

In the epic of information and multimedia, there are increasing demands for magnetic storage devices with higher density, faster speed, lower power consumption, smaller size, and lower weight than the current state-of-the-art devices. Presently, most magnetic storage devices are based on the properties of magnetic thin films. Therefore, enormous research efforts have been devoted to the study and control of the key factors that affect magnetic thin film properties.[1–4] These factors include the size and shape anisotropy of the grains in the film, the grain magnetization orientation, the spacing and coupling between the grains, and material compositions.

The advent of nanofabrication technology opens up new avenues to manipulate magnetic materials, thereby leading to unique opportunities in developing innovative ultrahigh density magnetic storage, engineering new magnetic materials and devices, and obtaining better understanding of micromagnetics. Nanofabrication can make magnetic structures with dimensions comparable to or smaller than some fundamental length scales in magnetics, such as domain wall size and exchange interaction length, thus making the behavior different from that of a thin film. Nanofabrication can create arrays of interactive magnetic nanoparticles with precisely controlled interparticle spacing. Nanofabrication can arrange the orientation and position of the nanoparticles at one's will. With such unique manipulation ability offered by nanotechnology, many revolutionary device concepts are no longer regarded as "wild dreams," but become reality.

This article reviews research on nanomagnetic structures fabricated using electron-beam lithography and other fabrication technologies carried out at the NanoStructure Laboratory at the University of Minnesota. Particularly, this article will discuss (1) fabrication and characterization of isolated and interactive single-domain magnetic nanostructures such as bars, pillars, and rings, and (2) properties and low-cost fabrication of a 65 Gbits/in.^{2} quantum magnetic disk—a new paradigm for ultrahigh density magnetic recording media with a recording density two orders of magnitude greater than current state-of-the-art disks. The work done elsewhere on lithographically defined magnetic structures can be found in Refs. 5–8.

II. FABRICATION OF MAGNETIC STRUCTURES USING NANOLITHOGRAPHY

A typical fabrication process is illustrated in Fig. 1. In the fabrication, a resist film, polymethylmethacrylate (PMMA), is first spun onto a substrate, typically silicon. A high resolution electron beam lithography system is used to expose patterns in the PMMA.[9] The exposed PMMA is developed in a cellosolve and methanol solution to form a resist template on the substrate. Ferromagnetic materials can be patterned using either a lift-off or electroplating process. In a lift-off process, a ferromagnetic metal film is first deposited onto the entire sample. The sample is then immersed in acetone that dissolves the PMMA template and lifts off the metal on the PMMA surface, but not the metal on the substrate. In an electroplating process, a thin metal plating base is placed between the PMMA and the substrate, and the PMMA template is removed after plating. Besides use for lift-off and plating, the PMMA template also can be used to etch nanostructures into the substrate that will be used later to create magnetic nanostructures.

Figures 2–4 show scanning electron microscope (SEM) images of three magnetic nanostructures fabricated using nanolithography and a lift-off process.[10,11] The nanostructures are a high aspect ratio, isolated Ni bar 15 nm wide and 1 μm long, an interactive Ni bar array of 20 nm wide and 200 nm long bars, and Ni rings with a 90 nm mean diameter

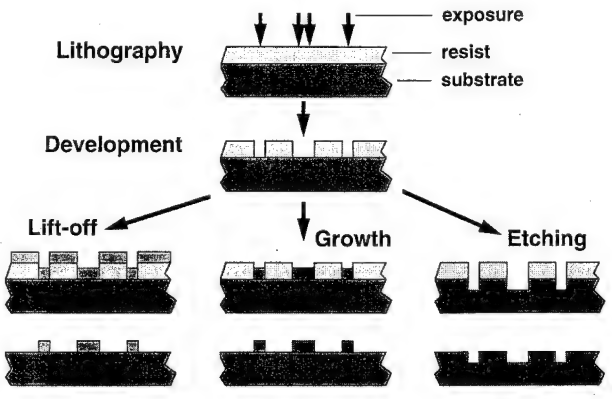

FIG. 1. Schematic of a typical process for fabricating nanomagnetic structures using nanolithography and related technologies.

and 25 nm ring width. The Ni structures have a thickness of 35 nm and were fabricated on a Si substrate. Figure 5 shows a SEM image of a Ni pillar array with 100 nm spacing, 75 nm average diameter, 700 nm height, and therefore 9.3 aspect ratio fabricated using nanolithography and electroplating.[12]

III. PROPERTIES OF NANOMAGNETIC STRUCTURES

The first striking property of nanolithographically defined magnetic structures is that without an applied magnetic field, each structure can magnetize itself, making the magnetic moments of all polycrystalline grains in the structure align to the same direction. The single-domain formation is due to the fact that the magnetostatic energy in these magnetic nanostructures is lower than the domain wall energy.

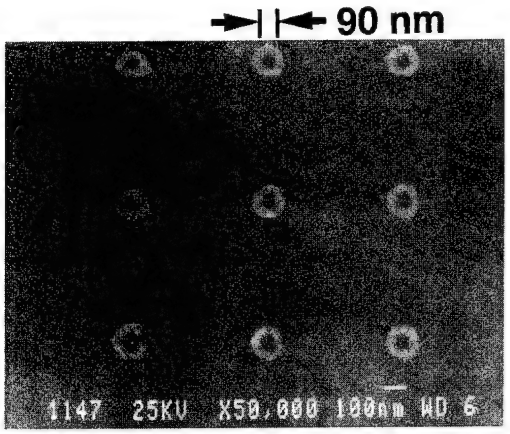

FIG. 4. SEM image of Ni rings of a 90 nm mean diameter, 25 nm ring width, and 35 nm thickness on Si.

Furthermore, the shape anisotropy of the structures forces the magnetization to be aligned along the long axis of the bars and pillars. This single-domain formation and alignment make the magnetic moment quantized with only two stable states, equal in magnitude but opposite in direction. Figure 6 shows that when examined using magnetic force microscopy, each nickel bar, which is 100 nm wide, 35 nm thick, and 1 μm long, has two opposite magnetic poles at the ends of the bar and no poles in between—a clear picture of a single magnetic domain element.

The second property is that the magnetic field needed to switch the magnetization of a single-domain element from one direction to the opposite direction can be controlled by changing the geometry of the structure, such as bar's width, length, and thickness. Figure 7 shows that the switching field of nickel and cobalt bars with a 1 μm length and 35 nm thickness increases as the width of the bar decreases. The peak switching fields are 740 Oe for Ni and 3000 Oe for Co, respectively, which are over 30 times larger than the switching field of the as-deposited films.[11,13]

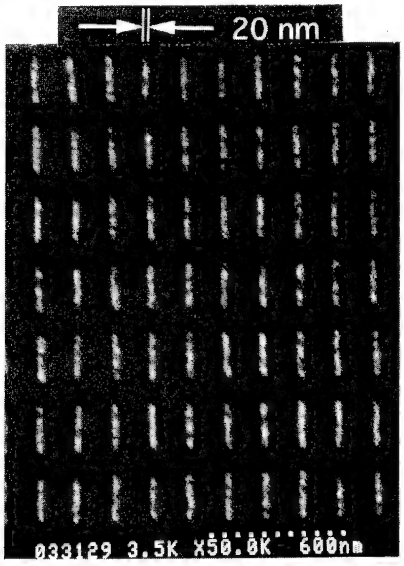

FIG. 3. SEM image of an interactive Ni bar array. Each bar is 20 nm wide, 200 nm long, and 35 nm thick.

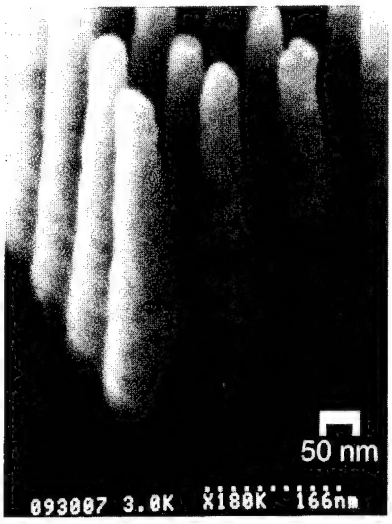

FIG. 5. SEM image of Ni pillar array of a 100 nm spacing, 75 nm average diameter, 700 nm height, and therefore 9.3 aspect ratio.

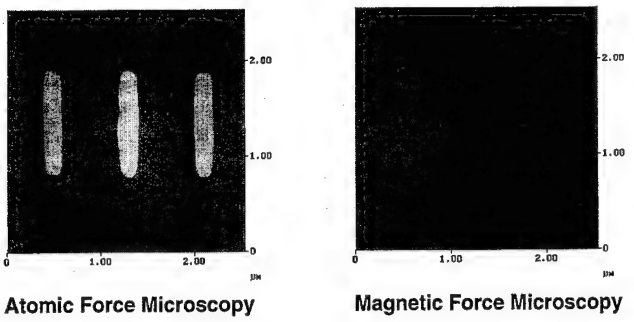

FIG. 6. The atomic force microscopy (a) and magnetic force microscopy (b) of three single-domain nickel bars that are 100 nm wide, 1 μm long, and 35 nm thick.

The switching field of the single-domain bars can be further controlled by varying the bar length as shown in Fig. 8. It was found that the length dependence is nonmonotonic.[13] The switching field increases with the bar length initially, but then decreases after reaching a peak. For isolated nickel and cobalt bars with a thickness of 35 nm and a width of 100 nm, the peak switching field and corresponding bar length are, respectively, 640 Oe and 1 μm for Ni, and 1250 Oe and 2 μm for Co. Moreover, it was observed that the decrease of the switching field with the increase of the bar width is much faster in Ni bars than in Co bars. These results suggest that quasi-coherent switching occurs in short bars and incoherent switching occurs in long bars, and that the exchange coupling is much stronger in Co bars than that in Ni bars.

The effects of the magnetostatic field of a single-domain bar on the crystalline anisotropy and the switching field of its neighbors were studied using nanolithography technology.[14] In this study, pairs of single-domain cobalt bars that were 35 nm thick, 50 nm wide, 1 μm long and with a spacing from 50 to 1000 nm, were fabricated using electron-beam lithography and a lift-off process. Magnetic force microscopy was used to study the switching behavior of one bar in the presence of another bar and the intrinsic switching field of one bar after the other bar was physically removed. Figure 9 shows the measured switching field for the three cases: (a) only one of the twin bars is switched, $H_{\uparrow\downarrow}$; (b) both bars are switched, $H_{\uparrow\uparrow}$; (c) one bar switched after the other bar was

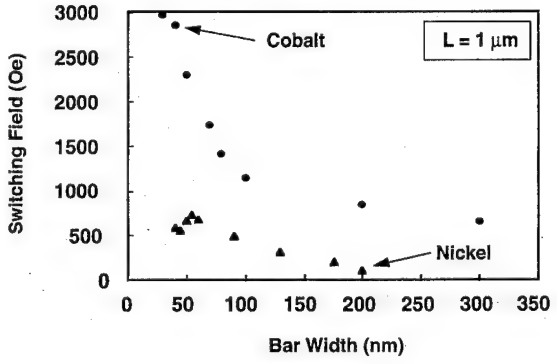

FIG. 7. Switching field of isolated Ni and Co bars vs bar width. The bars are 1 μm long and 35 nm thick. The actual bar width was measured using SEM.

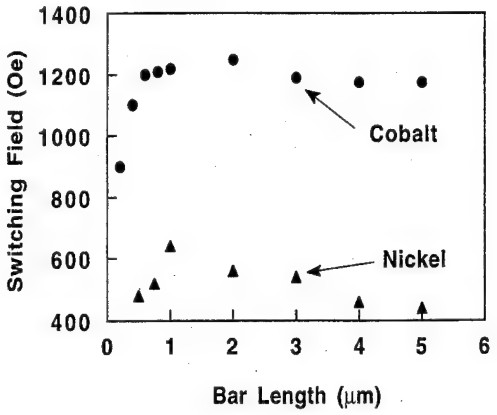

FIG. 8. Switching field of isolated Ni and Co bars vs bar length. The bars are 100 nm wide and 35 nm thick.

physically removed by a nanotechnique, $H_{\uparrow}$. One of the key findings is that even after the neighboring bar was physically removed, the intrinsic switching field of one bar still strongly depends on the original spacing between the bars. Also, the smaller the bar spacing was, the larger the intrinsic switching field. This is attributed to the spontaneous formation of a single-domain region during the Co deposition, whose magnetostatic field enhances the crystalline anisotropy of its neighbors. These results suggest that during the deposition of magnetic media, substrate roughness and large in-plane shape anisotropy of magnetic grains will strongly affect the magnetic properties of neighboring grains and therefore the uniformity of the disk.

Finally, ferromagnetic rings were studied using MFM. It was found that for the rings with a diameter 500 nm or less, no magnetic poles can be observed, indicating the rings are a single domain.

IV. QUANTUM MAGNETIC DISK

As data storage densities reach 500 MBits/in.^{2} in commercial magnetic hard disks and 3 Gbits/in.^{2} in the most advanced laboratory disks, it becomes apparent that one of

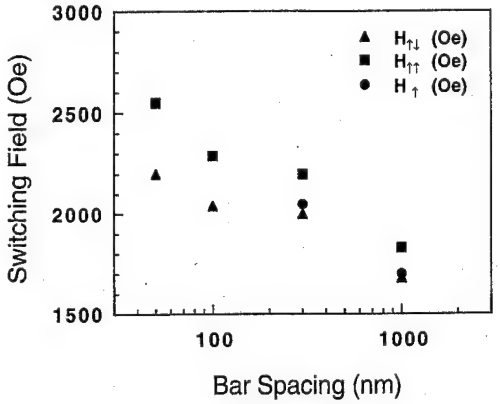

FIG. 9. Switching field of twin single-domain Co bars vs the bar spacing $H_{\uparrow\downarrow}$, only one of twin bars is switched; $H_{\uparrow\uparrow}$, both bars are switched; $H_{\uparrow}$, switching field after one of the twin bars was removed.

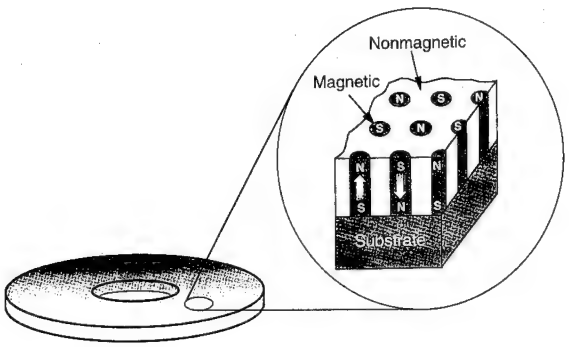

FIG. 10. Schematic of a quantum magnetic disk which consists of prepatterned single-domain magnetic structures embedded in a nonmagnetic disk. Only the vertical magnetization is shown, but the disk can be made with longitudinal magnetization.

the key factors that limit the storage density is the nature of magnetic thin films that are used as the recording media. Many of the limitations can be readily removed if each bit is stored in a discrete magnetic element that is separated from its neighbors by a nonmagnetic material. More advantages can be obtained if each element is made of a single magnetic domain. These ideas are the basis for a new magnetic recording paradigm, the quantum magnetic disk.

A quantum magnetic disk (QMD) completely abandons the continuous magnetic thin film as the recording media used in the conventional disk. Instead, the QMD uses prefabricated discrete single-domain magnetic elements uniformly embedded in a nonmagnetic disk, as shown in Fig. 10.[11] Each element has a uniform and well-defined shape, a prespecified location, and most importantly, a quantified magnetization that has only two states, identical in magnitude but opposite in direction. Each element can store a bit of binary information. The other striking property is that the magnetic field needed for switching the magnetization direction of the elements can be controlled by engineering the elements' geometry.

Before discussing the unique advantages of QMDs in writing, reading, and tracking, let us look at the fabrication process and properties of one QMD embodiment that consists of single-domain nickel (magnetic) nanopillars uniformly embedded in a SiO_2 (nonmagnetic) disk.[15,16] In fabrication, electron-beam lithography was used to define the QMD bit's size and location, and reactive ion etching was used to drill holes in the SiO_2 layer carried on a Si substrate. Nickel electroplating was used to selectively deposit nickel into the holes and chemical mechanical polishing was used to planarize the surface.

The properties of the QMD have been investigated using scanning electron microscopy (SEM), tapping mode atomic force microscopy (TMAFM), and magnetic force microscopy (MFM).[16] A SEM micrograph of a 3 bit by 3 bit section of the QMD in a top view is shown in Fig. 11(a). The micrograph shows that the nickel pillars of the QMD have a 50 nm diameter and a 100 nm period. The pillars are 200 nm tall and thus have an aspect ratio of 4.

TMAFM and MFM images taken simultaneously on the same area of the QMD are shown in Figs. 11(b) and 11(c), respectively. The TMAFM image of a 3 bit by 3 bit section of the QMD shows that the topology of the nickel pillars is indistinguishable from that of the SiO_2. The surface is very smooth with a roughness of 0.5 nm root-mean-squared. The corresponding MFM image, on the other hand, clearly shows that each bit has a quantized magnetization orientation and the magnetic image of each pillar of the 9 bit section can be resolved. Five bits have the south pole (bright) on the top surface and the other four bits have the north pole (dark) on the top. The QMD was demagnetized before imaging, therefore the nearest neighbor bits have opposite magnetic directions. This magnetization configuration is the lowest energy state for the QMD. Our study also showed that the nickel pillar can be switched using a MFM tip with a large magnetic moment. The storage density of the QMD is 65 Gbits/in.^{2}, which is over two orders of magnitude higher than that of state-of-the-art commercial magnetic disks.

The advantages of quantum magnetic disks over the conventional disks are apparent. First, the writing process in the quantum disk is simplified and becomes quantized, resulting in much lower noise and lower error rate and allowing much higher density. Instead of precisely defining the magnetic moment, area, and location of each bit as in a conventional magnetic disk, the writing process in a QMD simply requires flipping the magnetization direction of a discrete single-domain bit. Micromagnetics simulation has shown that even if a writing field is smaller than the size of the bit, the writing field will flip the magnetization direction of the entire bit, leading to a perfect writing.[17] Furthermore, simulation has shown that if the overlap between the writing field and a bit is insignificant, the writing field would only temporarily perturb the magnetic moment distribution of the bit. When the writing field is removed from the bit, the magnetic moment of the bit returns to its original state. In other words, the writing process in a QMD is quantized: a write head either writes perfectly the entire bit, or it does not write the bit at all. The quantized writing process in the QMD will allow the use of a smaller and therefore faster write head. It will avoid errors due to the misplacement and the fringing field of the wire head, and hence is suitable for ultrahigh density storage.

The second advantage of the QMD is near zero transition noise. The transition region between two bits is replaced by a nonmagnetic material and the grains in a QMD bit are tightly coupled and behave like a single large grain. As a result, the noise from the fluctuation of grain magnetization orientation should be greatly reduced, if not completely eliminated. In QMDs, the boundaries between the bits are defined by lithography and etching. They can be very smooth, giving quiet reading signals.

The third advantage of the QMD is reduced cross talk between bits. The cross talk in conventional disks comes from the interbit exchange interaction and magnetostatic interactions. In QMDs, by replacing the ferromagnetic material that is between the bits with a nonmagnetic material, the exchange interaction between the bits gets cut off completely and the interbit magnetostatic interaction is greatly reduced.

The fourth advantage is a solution to the tracking problem. In conventional magnetic disks, the bits do not always have physically recognizable boundaries between them.

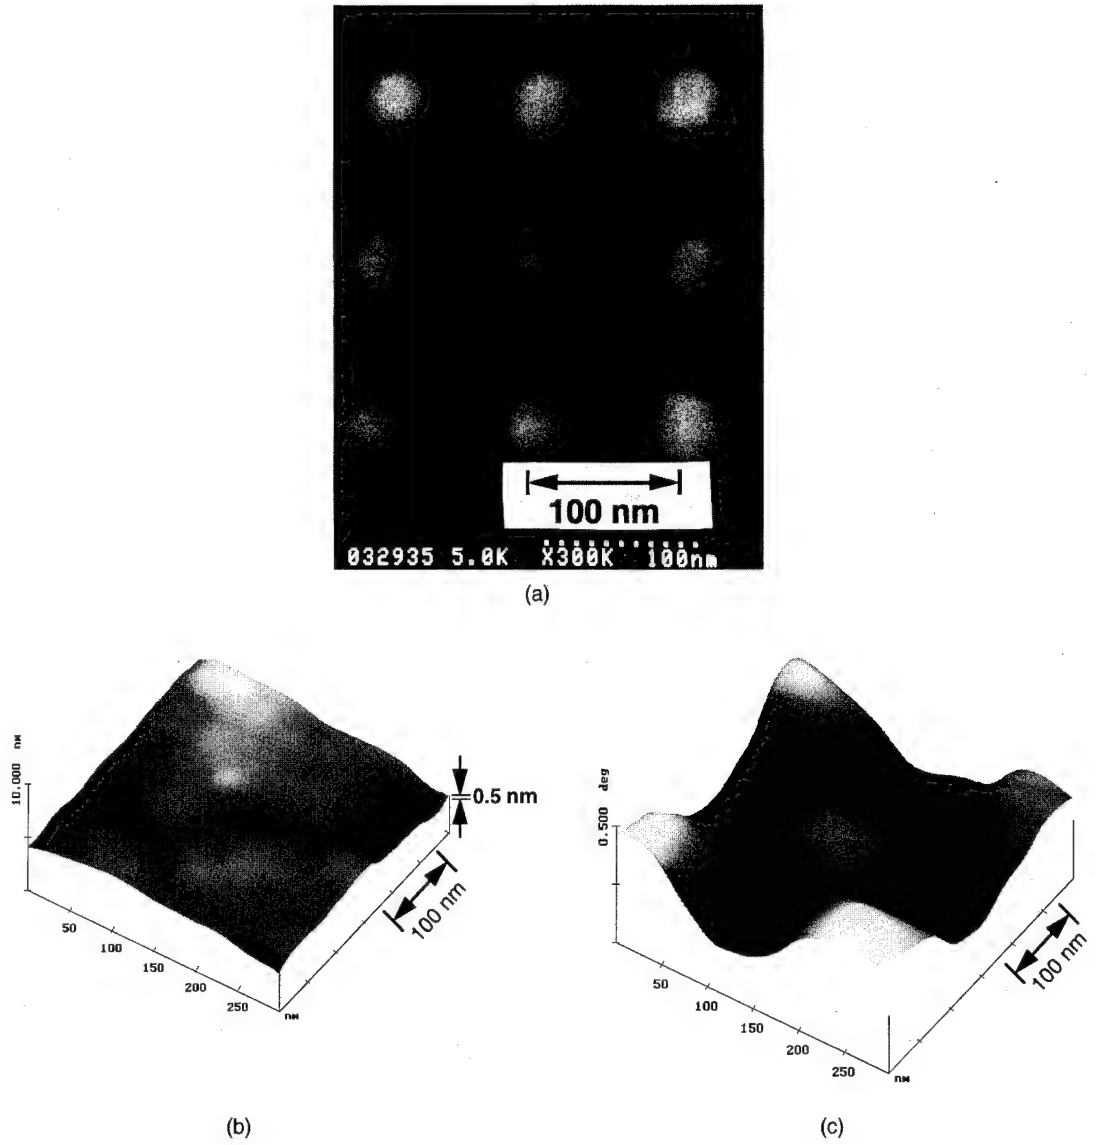

FIG. 11. (a) SEM image, (b) TMAFM image, and (c) MFM image of 3 by 3 bits of a QMD with 65 Gbits/in.^{2} density. Each bit consists of a nickel pillar uniformly embedded in 200 nm SiO_2 with a 50 nm diameter (aspect ratio of 4) and a 100 nm period. The TMAFM image shows a very smooth surface with a roughness of 0.5 nm rms. The MFM image shows an alternating pattern of magnetization directions from each bit.

Tracking depends on the writing of the tracking marks and the ability to rotate the disk the exact amount so that the desired data aligns with the head that writes or reads it. In other words, the tracking is "blind." Furthermore, over 14% of total disk area is used to write the tracking marks in current commercial disks. The area for tracking marks is expected to take up significantly more disk area in future high density disks where more precise tracking is required. In the QMDs, each bit is isolated from one another by nonmagnetic material. Therefore, there is always a variation of magnetic field between the bits (regardless of their magnetization directions) that provides the signal for actual tracking of each bit. Namely, in a QMD drive, each bit can be physically seen before writing or reading.

Clearly, to make the QMDs a competitive technology, low-cost mass production methods must be developed. One of the very promising technologies that we have developed is the nanoimprint lithography which replaces *e*-beam nanolithography.[18] In nanoimprint lithography, a mold is first made with the nanoscale features. Then it is pressed into a resist to create a thickness contrast pattern. After removing the mold, the pattern will be transferred into the entire resist by RIE. A SEM micrograph of 25 nm diam metal dots fabricated by nanoimprint lithography and lift-off is shown in Fig. 12.

From the above discussion, it is clear that the QMD differs from the discrete track disk[19,20] and the discrete segment disk.[21,22]

Finally, we would like to point out that although development of QMDs is still in its infancy, great interest has been generated. Our research shows that with the state-of-the-art nanofabrication technology, the density of QMDs can reach a

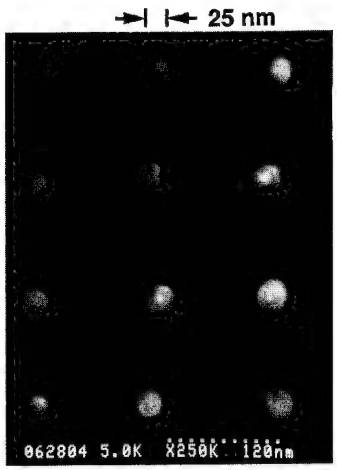

FIG. 12. SEM image of 25 nm diameter metal dots fabricated by nanoimprint lithography and lift-off.

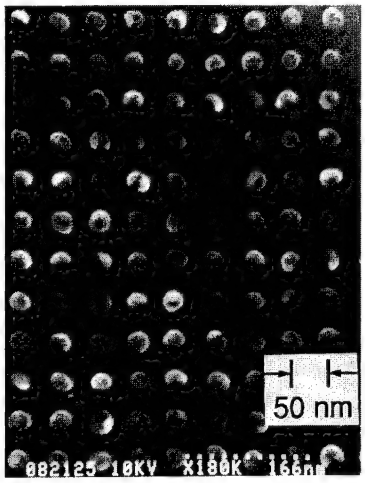

FIG. 13. SEM image of a metal dot array with a density of 0.25 Tbits/in.^{2}

0.25 Tbits/in.^{2} (Fig. 13) and yet each bit is thermally stable. Besides the QMD media, the future development of the QMDs involves the development of the ultrahigh resolution, high-speed read and write heads as well as new drive systems. The heads will very likely utilize the advanced technologies of nanofabrication and scanning force probes. They will be in the form of large parallel arrays. The disk drive may deviate from the classic circular geometry; instead it may be a linear drive based on state-of-the-art micromechanical elements. Because of the ultrahigh density offered in the QMDs, the total disk area for a 30 Gbit disk can be well less than the size of a penny.

V. CONCLUSION

Using nanolithography based fabrication technology, magnetic structures can be engineered to have magnetic properties that cannot be achieved by conventional methods. Undoubtedly, the nanofabrication approach opens up new opportunities for engineering novel magnetic materials, understanding the fundamentals of magnetics, exploring limits of magnetic storage, and developing ultrahigh density magnetic storage and innovative magnetic devices such as read and write heads for hard disks, magnetotransport devices, and magneto-optical devices.

ACKNOWLEDGMENTS

It gives us great pleasure to thank many past and current members of NanoStructure Lab at the University of Minnesota who have contributed significantly to the magnetic nanostructures and quantum magnetic disk projects; in particular, Mark Wei for his study of single-domain elements, Usman Suriono for micromagnetics simulation, Preston Renstrom for his assistance in developing the nanoimprinting technology, and Dr. Paul Fischer and Robert Guibord for their technical assistance in fabrication. We are also grateful to Professor J. G. Zhu for stimulating discussion. This work was partially supported by Office of Naval Research, Advanced Research Program Agency, and a Packard Fellowship. The magnetic force microscope is supported by Army Research Office through a DURIP.

Chiral quantum spin solitons

Hans-Benjamin Braun and Daniel Loss
Department of Physics, Simon Fraser University, Burnaby, British Columbia V5A 1S6, Canada

The concept of chirality is introduced in the quantum dynamics of spin solitons. For half-integer spin chains we find as universal properties that the Brillouin zone is halved and that two subsequent band minima have opposite chirality. This effect occurs in quasi-one-dimensional (1D) magnets in the semiclassical limit, in anisotropic spin-1/2 chains and for holes propagating in a two-dimensional (2D) antiferromagnetic background. © *1996 American Institute of Physics.* [S0021-8979(96)76608-9]

I. INTRODUCTION

Spin solitons leave a wake of reversed spins as they propagate. Such excitations occur in a wide range of systems: Extended domain walls in ferromagnets (FM) or antiferromagnets (AF) whose center tunnels between adjacent lattice sites provide an example of a macroscopic quantum phenomenon (MQP).[1] Solitons rather than spin waves form elementary excitations in AF[2,3] and FM spin-1/2 chains. A prominent example of spin solitons are holes moving through a two-dimensional (2D) antiferromagnetic background in the context of high-T_c superconductors. Such holes flip each spin they pass in order to maintain the local Néel order. In all these cases, solitons tunnel between lattice sites and thus form Bloch bands.[4]

So far, quantum solitons have been considered as compact objects without internal degree of freedom. It is the purpose of this contribution to demonstrate that spin solitons indeed carry an internal degree, the chirality, and that tunneling between chirality states has striking consequences in half-integer spin systems: The Brillouin zone is halved and two subsequent band minima have opposite chirality. This effect is shown to occur in all of above systems and gives rise to a hole dispersion which is in remarkable agreement with recent ARPES (angular resolved photoemission spectroscopy) data on $Sr_2CuO_2Cl_2$ studied in the context of high-T_c superconductivity.[5]

II. QUANTUM DYNAMICS OF BLOCH WALLS

We describe the spin configuration in a quasi-1D ferromagnetic sample by the unit vector field $\mathbf{n}(x,\tau)$. The energy for N_0 coupled spin chains of length L is then given by

$$H=N_0\int_{-L/2}^{L/2}dx\ \{J(\partial_x\mathbf{n})^2-K_y n_y^2+K_z n_z^2\}, \tag{1}$$

with the field conveniently parametrized as $\mathbf{n}=(\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta)$. The first term in Eq. (1) represents the exchange interaction with coupling J, while the next terms are anisotropies of easy-axis and hard-axis type with strength $K_y, K_z>0$. The hard-axis anisotropy renders the xy plane an easy-plane for the spin configuration. We consider the imaginary time action ($\hbar=1$), $\mathcal{S}_E=\mathcal{S}_B+\int_0^\beta d\tau\, H$, with β the inverse temperature. $\mathcal{S}_B$ is the sum of the Berry phases of all individual spins:

$$\mathcal{S}_B=i\frac{sN_0}{a}\int_{-L/2}^{L/2}dx\int_0^\beta d\tau\ \dot{\phi}(1-\cos\theta). \tag{2}$$

The total derivative $\dot{\phi}$ in Eq. (2) is essential.[6] While it does not affect the classical equations of motion, it ensures, e.g., the correct semiclassical quantization of half-integer spins.

As discussed in Ref. 4, the model (1), (2) can also be explicitly derived from a Heisenberg model with on-site anisotropies in the large-s limit. However, it is equally useful to regard it as an effective model which supports solitons and keeps track of the quantum spin phases of the reversed spins as the soliton propagates.

The model (1), (2) exhibits soliton (or Bloch wall) solutions which satisfy $\delta\mathcal{S}_E=0$ and interpolate between the two easy-axis anisotropy minima such that the spins always stay in the easy plane. As a consequence of the symmetries of the energy H, there are four degenerate solitons:

$$\phi_s(x)=-QC\frac{\pi}{2}+2\arctan\ e^{\,Cx/\delta},\quad \theta_s=\pi/2, \tag{3}$$

with $Q,C=\pm1$, and $\delta=\sqrt{J/K_y}$ the soliton width. The "chirality" $C=1/\pi\int dx(\mathbf{n}_s\times\partial_x\mathbf{n}_s)_z=1/\pi\int dx\partial_x\phi_s$ reflects the fact that the transition between the anisotropy minima can be accomplished by a right- or left-handed spin rotation in the easy plane as one proceeds along the x axis.

For the moment, we neglect tunneling between different chirality states of the soliton. As discussed in detail in Ref. 4, the effective action for the position X of a moving soliton $\phi_s(x-X)$ then reads as follows

$$\mathcal{S}=\int_0^\beta d\tau\left\{-i\alpha C\dot{X}+\frac{M}{2}\dot{X}^2+V(X)\right\}, \tag{4}$$

where $\alpha=\pi sN_0/a$ and $M=N_0s^2/K_za^2\delta$ is the Döring mass. The first term is a chirality dependent gauge potential and results from insertion of $\phi_s(x-X(\tau)), \theta_s=\pi/2$ into the Berry phase term (2). The second term is the soliton kinetic energy and $V(X)=2V_0\sin^2(\pi X/d)$ is a periodic potential which arises from the crystal lattice or from a superlattice structure. The period d is assumed to be an integer multiple of the lattice constant a.

The effective action (4) simply describes a massive particle in a periodic potential. The gauge potential is the only part that reminds of the spin origin of the particle. The action (4) is equivalent to the Hamiltonian $\mathscr{H}=(1/2)M\,(p-\alpha\sigma_3)^2+V(X)$, where $p=-i\partial/\partial X$ is the soliton momentum, and the Pauli matrix σ_3 characterizes the chirality pseudospin. The eigenstates are products $|k,C\rangle=|k\rangle|C\rangle$ of chirality states, $\sigma_3|C\rangle=C|C\rangle$, and Bloch states $|k\rangle$ satisfying $\mathscr{H}|k,C\rangle=E(k,C)|k,C\rangle$, where the band index has been suppressed since we are only interested in the lowest band.

We are now in a position to calculate the dispersion of a spin soliton. Consider first the nearly free limit $V_0\to 0$. The spectrum of $\mathscr{H}$ then consists of the pair of parabolas $E(k,C)=(1/2M)\,(k-\alpha C)^2$ with chiralities $C=\pm 1$, periodically extended by the reciprocal lattice vector $K=2\pi/d$. For s_0 half-odd integer, we have $\alpha=(\pi/2d) \mod K$ and thus the parabolas are separated by π/d. We thus arrive at the striking result that *the Brillouin zone (BZ) is halved and two consecutive parabolas have opposite chirality.* For s_0 integer, the parabolas are separated by $2\alpha=K$, and the BZ is not halved.

The same result is also obtained in the tight-binding limit: An instanton calculation[4] yields for half-integer s_0 the dispersion

$$E(k)=-(\Delta/2)|\sin(kd)|. \tag{5}$$

The bandwidth is given by $\Delta=8\omega\sqrt{\mathscr{S}_0/2\pi}e^{-\mathscr{S}_0}$, where $\mathscr{S}_0=(4d/\pi)\sqrt{MV_0}$ the tunneling action and $\omega=(2\pi/d)\sqrt{V_0/M}$ the instanton frequency. Most important, the parts where $\sin(kd)$ is positive (negative) belong to positive (negative) chirality and thus BZ halving and chirality correlation occurs as in the nearly free limit. For integer s_0, the band has the simple tight-binding form $E(k)=-(\Delta)/2\cos(kd)$ and is degenerate with respect to the chiralities $Q=\pm 1$.

III. CHIRALITY TUNNELING

We now investigate how the dispersion (5) is altered due to tunneling between the two degenerate chirality states. To this end we return to the action $\mathscr{S}_E$ and choose angles adopted to describe chirality tunneling, $\mathbf{n}=(\sin\theta\sin\phi,\cos\theta,\sin\theta\cos\phi)$, i.e., the polar angle is now measured from the (easy) y axis. The soliton (3) then reads $\theta_Q=2\arctan e^{Qx/\delta}$ and the two chirality states $\phi_C=CQ\pi/2$ are separated by the barrier of the hard-axis anisotropy. Chirality tunneling thus consists of transitions between $\phi=\pm\pi/2$. Inserting $\phi(\tau)$ into $\mathscr{S}_E$ and integrating out the fluctuations around the (static) soliton we arrive at the effective action for the chirality dynamics

$$\mathscr{S}_{\rm eff}=\int_0^\beta d\tau\left\{\frac{\mu}{2}\dot{\phi}^2+\kappa\cos^2\phi+\eta\cos\phi+\eta^2/2\kappa\right\}. \tag{6}$$

The fluctuations around the soliton give rise to an effective "mass" $\mu=N_0(s^2\delta/a^2K_y)\,c_0$ ($c_0>0$ is a numerical constant of order one). The second term is the energy barrier due to the hard-axis anisotropy $\kappa=2N_0K_z\delta$. This barrier between the two chirality states is lowered by an external field B_z along the hard axis which is described by the third term with $\eta=\pi g\mu_B sN_0B_z\delta/a$. The chirality then tunnels between potential minima defined by $\cos\phi_{\rm min}=-B_z/B_a\equiv\nu-1$ with the anisotropy field $B_a=4aK_z/\pi g\mu_B s$. A standard instanton calculation gives for the tunnel splitting $\epsilon=4\gamma\omega_c\sqrt{\mathscr{S}_c/2\pi}e^{-\mathscr{S}_c}$, where $\gamma>0$ is a constant of order one, and $\mathscr{S}_c=2\pi s N_0(\delta/a)\sqrt{c_0K_z/K_y}\nu^{3/2}$, $\omega_c=(8a/\pi)\sqrt{K_yK_z/c_0}\nu^{1/2}$. Since typically ϵ can be made quite large (by tuning B_z or small N_0) this tunneling scenario is a promising candidate for MQP behavior.

In the presence of chirality tunneling, the effective Hamiltonian becomes $\mathscr{H}_\epsilon=1/2M\,(p-\alpha\sigma_3)^2+V(X)+(\epsilon/2)\,\sigma_1$, where $\sigma_1|C\rangle=|-C\rangle$. In the tight-binding limit we have

$$\mathscr{H}_\epsilon=-\frac{\Delta}{4}\sum_{m,l,C}e^{i\alpha Cld}\,|m+l,C\rangle\langle m,C|+\frac{\epsilon}{2}\sigma_1, \tag{7}$$

with $l=\pm 1$, and where $|m,C\rangle$ describes a soliton of chirality C at lattice site m. $\mathscr{H}_\epsilon$ is immediately diagonalized and for s_0 half-integer we have $E_\epsilon(k)=-(\Delta/2)\{\sin^2 kd+(\epsilon/\Delta)^2\}^{1/2}$, and thus the cusps in Eq. (5) are removed. In our case of interest, $\epsilon\lesssim\Delta$, the explicit form of the eigenfunctions reveals that two adjacent minima belong to opposite chirality. This correlation could be detected as follows. First one measures the chirality in a given ground state, e.g., by optical dichroism techniques or spin polarized neutrons. Then the soliton is adiabatically moved by an external field[7] (applied along the easy axis) until it reaches an adjacent band minimum, and then the chirality is measured again. For half-integer spin solitons the two chiralities are opposite, whereas for integer spins there is no correlation.[8]

Finally, we note that the same chirality effects exist for solitons in AF. In this case the effective action contains the same gauge potential as in Eq. (4) since the total derivative $\dot{\phi}$ in Eq. (2) is *not* affected by the staggering induced by local Néel order (the action contains the term $i(SN/a)/dxd\tau\dot{\phi}$ in addition to the Pontryagin index). The above formulas remain essentially unaltered except that the effective masses are changed into $M=N_0(s^2/J\delta)$ and $\mu=N_0(s^2\delta/J)\,c_0$, with corresponding changes in the tunneling actions. Note that tunneling is more favorable in AF than in FM since typically $J\gg a^2K_{y,z}$.

IV. SPIN PARITY TUNING AND EXTERNAL FIELDS

We now discuss some consequences of an applied external field $\mathbf{B}$ which is described by adding a term $N_0\mathbf{h}\cdot\int dx\ \mathbf{n}$ with $\mathbf{h}=g\,(\mu_B s/a)\,\mathbf{B}$ to the energy H. For large hard axis anisotropy $K_z\gg K_y$ and a field h_z along the hard axis, the soliton solutions are still given by ϕ_s as in Eq. (3) but with $\cos\theta=-h_z/K_z$. We then obtain the effective action (4) but with a field dependent gauge potential $\tilde{\alpha}=\alpha(1+h_z/K_z)$. Since the dispersion of the lowest band corresponds in the limit $\epsilon/\Delta\to 0$ to the lower envelope of the two curves $\cos(kd\pm\tilde{\alpha}d)$, an increasing external field h_z changes the dispersion periodically between integer and half-integer behavior with the period $\Delta h_z=(K_z/sN_0)\,d/a$.

If $h_z(t)$ depends on time, then the kinetic part of $\mathscr{H}$ is $(1/2M)\,(p-\tilde{\alpha}(t)\sigma_3)^2$ and thus $d\tilde{\alpha}/dt$ plays the role of a *force* driving the Bloch wall in positive/negative direction for

positive/negative chirality. Note that this force has its origin in the classical part of the Berry phase $\dot{\phi}\cos\theta$. As shown in Ref. 4 such forces are also induced by a field h_y along the easy axis and lead to Bloch oscillations of the magnetization. Finally, a field h_x gives rise to a bias energy $4\pi N_0 \delta h_x$ between the two potential wells of opposite chirality, or conversely, this field can be used to offset unwanted level detuning between the two chirality states.

V. SPIN-1/2 CHAINS

In this case the soliton width approaches one lattice constant and it is no longer possible to assign a chirality to a *static* soliton. However, quite surprisingly, we shall see that for both, FM and AF chains, the chirality is generated dynamically. We consider an Ising Hamiltonian with small additional anisotropies, $\mathscr{H}_I = -\Sigma_i [J_z S_i^z S_{i+1}^z + J_y S_i^y S_{i+1}^y + J_x S_i^x S_{i+1}^x]$, where $\mathbf{S}_i$ is a spin-1/2 operator at lattice site i and $|J_z| \geqslant |J_y|, |J_x|$. These inequalities ensure that bands with a different number of solitons are well separated.

Let us first consider the FM case with $J_y > J_x$, and all J's positive. A soliton is characterized by its position and charge $Q = \pm 1$, e.g., $|m, Q=1\rangle = |.\uparrow\uparrow\uparrow\downarrow\downarrow\downarrow.\rangle$ with the last up spin at the mth lattice site. The existence of one soliton is enforced by twisted boundary conditions, i.e., $S_{N+1}^{y,z} = -S_1^{y,z}$, $S_{N+1}^x = S_1^x$. Under the action of $\mathscr{H}_I$, the soliton $|m,Q\rangle$ hops by two lattice constants, $|m \pm 2, Q\rangle$ plus higher energy states with more than one soliton. In the spirit of Villain's approach[2] to the AF, we restrict ourselves to the subspace of one soliton. The energy eigenstates are given by $|k, C_x\rangle = (1/\sqrt{2N}) \Sigma_m e^{ikmd} [|m,1\rangle + e^{ikNd} |m, -1$ with the dispersion $E(k) = \frac{1}{2}(J_y - J_x)\cos(2kd)$, where $k = (\pi/Nd)\, n$, and $n = -N+1, .., N$. Thus, again, the BZ is halved. To investigate the chirality correlation, we consider $\mathbf{C} = \Sigma_i \mathbf{S}_i \times \mathbf{S}_{i+1}$, which displays the chiral character of a magnetic excitation. Clearly, the expectation value of $\mathbf{C}$ vanishes in a static soliton, $\langle m, Q | \mathbf{C} | m, Q \rangle = 0$. However, we easily verify that in the one-soliton subspace, the energy eigenstates are simultaneous eigenfunctions of C_x, $C_x |k, C_x\rangle = \sin(kd) |k, C_x\rangle$, and the x component of the total spin, $\Sigma_i S_i^x |k, C_x\rangle = \cos(kd) |k, C_x\rangle$, while $C_z |k, C_x\rangle = 0$. Thus they remain good eigenfunctions in the presence of a uniform external field B_x, where they have a dispersion $E_B(k) = E(k) + g\mu_B B_x \cos(kd)$. Similarly, a complete basis can be found in which C_y and $\mathscr{H}_I$ are simultaneously diagonal. Thus, again we find that subsequent band minima have opposite chirality. We note that a field along the z axis can give rise to Bloch oscillations,[7] analogous to the semiclassical limit discussed above.

In the AF case we study the Hamiltonian $\mathscr{H}_I$ with all $J's$ negative and $J_x = J_y = J_t$. (Note the absence of an "easy-plane" anisotropy in this case.) An odd number of lattice sites on a ring then enforces a soliton, e.g., $|m, Q=1\rangle = |.\uparrow\downarrow\uparrow\uparrow\downarrow\uparrow.\rangle$, where m denotes the first spin constituting the soliton. Proceeding as before, we obtain $E(k) = J_t \cos(2kd)$, and again, states differing by π/d have opposite chirality C_x. While this AF dispersion is theoretically[2] and experimentally[3] well-known, the existence of the chirality and its correlation does not seem to have been noticed before.

In passing we note that for FM spin-1 chains with on-site anisotropies of easy- and hard-axis type we can construct soliton eigenstates in a similar way as above. We then find the dispersion $E(k) = -(K_h/2)\cos kd$ where K_h is the hand-axis anisotropy constant. This is in agreement with the semiclassical approach in Secs. II and III.

We thus have convinced ourselves that the effective Hamiltonian (7) indeed captures (for $\epsilon \lesssim \Delta$) the essential physics also in spin-1/2 chains.

V. HOLES IN 2D ANTIFERROMAGNET

We now discuss propagating holes in a 2D AF background of spin-1/2. While restoring the spin background, such holes consecutively flip spins as they propagate and thus act as spin solitons in 2D. As they hop, solitons of opposite chirality acquire relative Berry phases of $e^{\pm is\pi} = \pm i$. With this physical picture in mind, we propose a model Hamiltonian for the hole propagation which is a direct generalization of the 1D case, Eq. (7): $\mathscr{H}_h = -(\Delta/4) \Sigma_{\mathbf{m},\mathbf{l},\mathbf{C}}\ e^{i(\pi/2)\,\mathbf{C}\cdot\mathbf{l}}\ |\mathbf{m}+\mathbf{l}, \mathbf{C}\rangle\langle \mathbf{m}, \mathbf{C}| + (\epsilon/2)\,\sigma_1^{(x)} + (\epsilon/2)\,\sigma_1^{(y)}$, where $d=1$, and $|\mathbf{m}, \mathbf{C}\rangle$ describes a hole-soliton at site $\mathbf{m}$ with $\mathbf{l}$ connecting nearest neighbors. $\mathbf{C} = (C_x, C_y)$, $C_i = \pm 1$, characterizes its chirality state along the x and y directions. $\sigma_1^{(i)} |C_i\rangle = |-C_i\rangle$ describes chirality tunneling. While Δ, ϵ are, in principle, still free parameters with $\epsilon/\Delta \lesssim 1$, our 1D discussion suggests that Δ is of the order of the exchange coupling. Next, $\mathscr{H}_h$ is easily diagonalized with the lowest band being simply additive, $E_h = E_\epsilon(k_x) + E_\epsilon(k_y)$, where $E_\epsilon(k)$ as given above. Independent of the values of $\Delta > \epsilon > 0$, this dispersion has three distinct properties in remarkable agreement with recent ARPES data on $Sr_2CuO_2Cl_2$.[5] It exhibits "hole pockets" at $\mathbf{k}_{\pm,\pm} = (\pm(\pi/2), \pm(\pi/2))$, separated by saddle points at $(\pm(\pi/2), 0), (0, \pm(\pi/2))$. And third, in marked contrast[5] to the t–J model, $E_h(k_x, k_y = \pi - k_x) = E_h(k_x, k_x)$, and thus the dispersion reaches the *full* bandwidth between $(\pi, 0)$ and $(0, \pi)$. Finally, we see from the exact eigenfunctions that, again, states in different hole pockets are correlated by their chiralities.

We investigate the reversal of magnetization and the coherence of tunneling when an external magnetic field is rotated instantaneously in systems of a few (N) spin 1/2 particles described by an anisotropic Heisenberg Hamiltonian at $T=0$. The temporal evolution is calculated by a numerically exact solution of the time-dependent Schrödinger equation, and the mean value in time of each spin component is computed as a function of the magnetic field. The correlation function and the spectrum are analyzed in terms of the macroscopic quantum coherence. Our calculations demonstrate that this model for small ($N<11$) magnetic particles exhibit collective tunneling of the magnetization only for some specific resonant values of the applied magnetic field, at variance with the Stoner–Wohlfarth model. © *1996 American Institute of Physics.* [S0021-8979(96)76708-5]

The ability to miniaturize magnetic materials and study the magnetic properties of a single isolated particle has revealed classical and quantum phenomena[1–3] that questions the present understanding of the fundamentals of magnetism. The phenomenon of macroscopic quantum tunneling (MQT)[4,5] has received a lot of attention and consists of the tunneling of a macroscopic variable through the barrier between two minima of the effective potential of a macroscopic system. For small single-domain ferromagnetic clusters,[1,6–8] these minima correspond to the two states of opposite magnetization. When there is a repeated coherent tunneling back and forth between the two wells we have a case of macroscopic quantum coherence (MQC). The Stone–Wohlfarth (SW) model,[9] due to its success in the explanation of many classical magnetic phenomena, provided the idea that the dynamics of small magnetic particles in the single-domain regime would keep its simplicity. However, the SW model has been found inadequate for explaining some details in experimental systems.[3] The quantum mechanical effects have been studied theoretically by the quantization within a path integral formalism of the classical micromagnetic theory of magnetic dynamics.[6–8] Chudnovsky and Gunther[6] showed that in addition to superconducting devices, single-domain magnetic particles represent a rich field for MQT study. In the semiclassical approximation, a uniform and coherent rotation of all spins is imposed, that is, spins are considered to behave dynamically as a single quantum spin. This is known as single spin model (SSM). In experiments with superconductivity quantum interference device microsusceptometers,[10] a well-defined resonance in the frequency-dependent magnetic susceptibility $\chi''(\omega)$ has been found and it is tempting to be associated with a MQC phenomenon although there is some controversy on this interpretation.[11] On the other hand, the process of magnetization reversal in single particles[12,13] is also being studied nowadays with much interest. Recent experimental[13] and theoretical[14] works have studied the mechanism of the nonuniform reversal of the magnetization in this kind of particles.

In the present work we have assumed that there is no dissipation, $T=0$ and we have considered applied magnetic fields for which the energy barrier is present, giving rise to the appearance of tunneling phenomena in the reversal of magnetization. The results we have found calculating the exact quantum evolution of the spins show a qualitatively different landscape to what has been explained above: There is essentially a sharp resonance corresponding to coherent quantum tunneling of the magnetization but only for a particular magnetic field, whereas for lower and larger fields this phenomenon does not appear. Notice that in general, the quantum evolution of the spins is noncoherent. This resonant coherent quantum tunneling occurs at fields much lower than the values corresponding to the vanishing of the barrier in the Stoner–Wohlfarth mode.[9] The former model is at variance with the exact calculations presented in this paper.

We need to introduce the two-time correlation function of the magnetization,[4] which compares the z component of S at one time with its value at a time later: $\langle S^z(t')S^z(t'+t)\rangle$. In the present work, it has been calculated the symmetrized correlation function $C(t)$ defined as $C(t)=1/2\langle\Psi(0)|S^z(0)\times S^z(t)+S^z(t)S^z(0)|\Psi(0)\rangle$. With negligible dissipation present, coherent tunneling back and forth between the two states (magnetization up and down) leads to a sinusoidal oscillation of $C(t)$ at a frequency twice the off-diagonal matrix element. For two measurements of the magnetization separated by the time interval t, one should have $\langle S(t')S(t'+t)\rangle=S_0^2\cos(2\Gamma t)$. As the fluctuation–dissipation theorem shows that the frequency-dependent magnetic susceptibility $\chi''(\omega)$ is essentially the Fourier transform of the correlation function, the former equation predicts a resonance at $\omega_R=2\Gamma$ for $\chi''(\omega)$.

 0021-8979/96/79(8)/6110/3/$10.00

We have represented a system containing N spin 1/2 particles in presence of an applied magnetic field $\mathbf{H}$ through its Heisenberg Hamiltonian:

$$H=-J_x\sum_{\langle ij\rangle}\sigma_i^x\sigma_j^x-J_y\sum_{\langle ij\rangle}\sigma_i^y\sigma_j^y-J_z\sum_{\langle ij\rangle}\sigma_i^z\sigma_j^z-H_x \times\sum_i\sigma_i^x-H_z\sum_i\sigma_i^z, \tag{1}$$

where $\sigma_i^\alpha(\alpha=x,y,z)$ are the Pauli-spin matrices at site i related to the spin operators by $\mathbf{S}=\hbar\boldsymbol{\sigma}/2$, the sum $\langle ij\rangle$ is over nearest-neighbor pairs, J_x,J_y,J_z are the exchange constants, and H_x,H_z are the components of the external magnetic field. We have limited ourselves to systems with uniaxial anisotropy Δ along the z direction $[J_x=J_y<J_z=J$, $\Delta=(J_z-J_x)/J]$, containing N particles $(2<N<11)$ with different geometrical forms and to instantaneous rotations of the magnetic field of several angles. The range of the parameters is $0.01J\leqslant\Delta\leqslant 0.1J$ for the anisotropy and $0\leqslant H\leqslant 0.2J$ for the magnetic field. The temporal evolution of the system is calculated by a numerically exact solution of the time-dependent Schrödinger equation (TDSE).[15] This requires the computation of all eigenvalues and eigenvectors of the Hamiltonian. For larger systems $(N>8)$ we use Suzuki's fourth-order fractal product formula[15–17] to solve TDSE.

In our particular model, at $t=0$ there is a field applied along the z direction, $\mathbf{H}_1=(0,0,H_{z1})$ with $H_{z1}<0$. Then the ground state of the ferromagnet has all spins down and we prepare the system in this state. At $t>0$, the magnetic field is rotated instantaneously about the y axis so that $\mathbf{H}_2=(H_{x2},0,H_{z2})$ with $H_{x2},H_{z2}>0$ forms an angle θ_f with the z axis (notice that nothing happens in the exact propagation for $\theta_f=0°$). We have studied the dependence of $\bar{S}_i^z$, mean value in time of $\langle S_i^z(t)\rangle$ for each different spin i, on the size of the second magnetic field $\mathbf{H}_2$:

$$\bar{S}_i^z=\lim_{\tau\to\infty}\left[\tau^{-1}\int_0^\tau dt\langle S_i^z(t)\rangle\right]. \tag{2}$$

The correlation function $C(t)$ for the second Hamiltonian is also analyzed, as well as the eigenvalues, eigenstates and system energy for each magnetic field considered. Depending on the value of the magnetic field the barrier between the two directions of the magnetization can exist or not, and this way we can speak about two regions: (a) tunneling region when there is a barrier between the two wells and (b) non-tunneling region when that activation barrier has vanished.

Let us concentrate on the results for uniaxial anisotropy $\Delta=0.1(J_x=J_y=0.9J_z)$ and a magnetic field forming an angle $\theta_f=45°$ with the z direction, $\mathbf{H}_2=(H_{x2},0,H_{z2})$ with $H_{x2}=H_{z2}$. The result obtained is the following: clusters with $N\geqslant 5$, and with different geometrical forms (chain, ring, and others) present a pronounced resonance in the curve of $\bar{S}_i^z$ in terms of $H_{x2}=H_{z2}$ for a specific magnetic field H_r that clearly falls in the tunneling region (a). In Fig. 1(a) we show this result for an open linear chain of seven spins. We have found that these resonances correspond to pure sinusoidal oscillations in the correlation function $C(t)$ as it must occur when there is MQC. However, for points around these resonances $C(t)$ does not present this sinusoidal shape at all. In

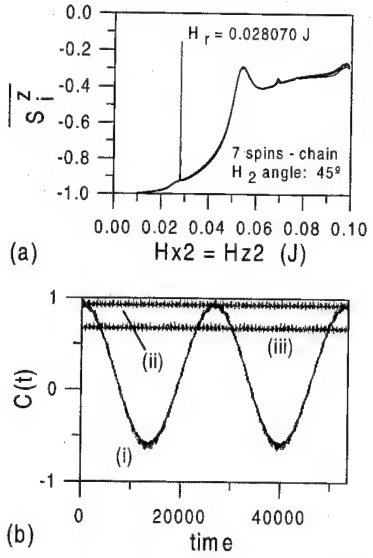

FIG. 1. (a) $\bar{S}_i^z$ for each different spin i as a function of the size of the second magnetic field for a linear chain of seven spins, with $\Delta=0.1$ and $\theta_f=45°$, and (b) symmetrized correlation function for the resonant field $H_r=0.028\,070J$ (i) and two fields around it: (ii) $H=0.0276J$ and (iii) $H=0.0285J$-(iii) curve has been shifted 0.25 in the y axis in order to clarify the picture.

Fig. 1(b) we present $C(t)$ at the resonant field [Fig. 1(b)-(i)] and at two fields around it [Fig. 1(b)-(ii), (iii)] for the same linear cluster. Clusters with $N<5$ do not show this behavior and the reason can be explained in terms of the spectrum and the curve of H_r vs N. Clusters with eight and more spins present more than one peak although only one is really sharp.

In order to understand why a particular magnetic field provokes the resonant MQC we have studied the system spectrum calculating its eigenstates energies for each magnetic field applied. For a complete discussion of the spectrum analysis see Ref. 18. This point of view has also been considered for the study of a SSM.[19] To give a slight idea, the specific field that produces the resonance makes practically equal the energies of the second and third eigenstates of the system, which correspond essentially to all spins in one direction and in the opposite, respectively, and which are the only relevant eigenstates in the system state at that field. The system energy for that field is slightly above these two levels of energy. This fact permits a resonant tunneling of the magnetization for a determined field in each case. It must be said that the levels do not cross, there is a small splitting ΔE between their energies that is related to the tunnel frequency and in consequence to the oscillating period T of the correlation function $C(t)$ by $T=2\pi\hbar\Delta E^{-1}$. The values of T and ΔE fit very well to this formula.

Other anisotropy values and other directions have been studied and we have also found sharp resonances corresponding to sinusoidal correlation functions.[17] This way it can be said that the resonance found is a general feature of the system considered; it appears for several sizes with any geometrical configuration, different values of the anisotropy and for all the directions of the magnetic field $\mathbf{H}_2$ studied.

In Fig. 2 we show the dependence of the resonant fields H_r and the field H_b that makes the barrier disappear in the

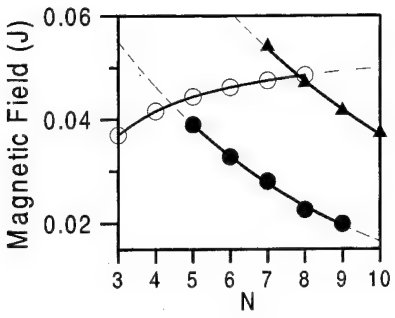

FIG. 2. Dependence of the resonant field H_r (solid circles) and the field needed to vanish the activation barrier H_b (open circles) on the number of spins for a fixed geometrical configuration. The solid triangular symbols correspond to the second peak in the $\tilde{S}_i^z$ curve for clusters with more than seven spins.

single spin model (SSM) on the number of spins ($N<11$) for the same geometrical configuration (chain). As we can see in Fig. 2 $H_r<H_b$ for systems with $N\geq 5$. However H_r and H_b have an opposite dependence on the number of spins: while H_b increases with the number of spins since the barrier height is proportional to N,H_r decreases with it. The difference between H_r and H_b increases with N and in consequence the resonance is situated further from the region where the barrier vanishes and the semiclassical approaches are applied.[6] The tendency shown by the two curves can explain why clusters with $N<5$ do not present such resonance, as well as the fact that the second and third eigenstates energies do not get close but keep a considerable gap between them. An interesting point is that when N increases and so the separation between H_r and H_b becomes larger, new peaks or resonances appear. We have observed this behavior in clusters with more than seven spins. The field corresponding to the second peak in eight spins cluster is below H_b whereas in seven spins cluster the second peak field is above H_b (see Fig. 2). The sharpness of the peaks is related to the separation between the levels involved. When the repulsion between the levels involved becomes larger the peak gets less important. As N increases and new resonances appear in the tunneling region, those corresponding to very low fields become smaller.

In conclusion, we have studied the reversal of magnetization and the coherence of tunneling when an external magnetic field is rotated instantaneously in systems for a few spin 1/2 particles described by an anisotropic Heisenberg Hamiltonian at $T=0$. Our calculations demonstrate that the model studied for systems with $4<N<11$, for any geometrical configuration and for different anisotropy values exhibits collective tunneling of the magnetization only for some specific resonant values of the magnetic field, at variance with the Stoner–Wohlfarth model that predicts coherent rotation at all fields.

Frequency mixing phenomena in a bistable system

A. N. Grigorenko, P. I. Nikitin, and G. V. Roschepkin
General Physics Institute of Russian Academy of Sciences 38 Vavilov Str., Moscow, 117942 Russia

A response of a bistable system subject to several periodic and random forcing is discussed. It is shown that spectrum components of the response on mixed frequencies demonstrate a noise-induced enhancement typical for stochastic resonance. The quenching of the spectrum harmonics due to an application of a constant force that destroys symmetry of the potential is calculated. The theory is checked on a simple bistable magnetic system: a local part of a domain wall in a thin ferrit–garnet film. © *1996 American Institute of Physics.* [S0021-8979(96)76808-1]

I. INTRODUCTION

A response of bistable systems subject to periodic and random forcing attracted a lot of interest.[1–7] It was found that a signal, which is a spectrum component of the system response on the frequency of the periodic force, can be enhanced by an application of an additional noise source. As a result, the signal-to-noise ratio R for a bistable system has a peak at some noise strength. This phenomenon is called stochastic resonance (SR). The "quality," Q, of SR can be characterized by the ratio of the maximum $R_{\max}$ over the minimum $R_{\min}$ of a SR curve:

$$Q=R_{\max}/R_{\min}, \tag{1}$$

where the SR curve is the dependence of the signal-to-noise ratio (SNR) upon the noise strength D. The "canonical" dependence of R upon D is given by[2,3]

$$R=\frac{C}{D^2}\exp\left(-\frac{\Delta U}{D}\right), \tag{2}$$

where C is a constant and ΔU is the barrier height. One may expect from (1) and (2) that the resonance quality can be arbitrary large. However, this is not true. Equation (2) accounts for transitions between minima and disregards system motion inside the well. Taking this motion into account,[2] we find

$$Q\cong\omega_0/\omega, \tag{3}$$

where ω is the modulation frequency and ω_0 is the frequency of system vibrations inside the well. Thus, the higher the frequency of the periodic force, the smaller the resonance peak is observed. If the driving frequency is close to the vibration frequency, we see no enhancement of SNR at all.

There is also an experimental problem of conventional SR: an inevitable influence of the driving circuit upon the signal registration circuit.

Both problems can be solved by measurement of spectrum components of the response of a bistable system subject to two different periodic forcing. System motion inside one well is linear for small force amplitudes and does not contribute to spectrum harmonics (signals) on mixed frequencies. So, we can expect to achieve higher values of the resonance quality even for a large driving frequency. In addition, signals shall be measured on frequencies different from those of periodic forcing. This excludes the circuitry problem.

In this paper we show that the spectrum harmonics of the response of a bistable system subject to several periodic forcing in the presence of noise exhibit stochastic resonance behavior. We also discuss the case of an asymmetric bistable potential and check the theory on an isolated magnetic domain wall.

Closing this section, we note that the quality of SR can be characterized by the ratio of signals at the maximum and at the minimum of the noise dependence of the signal: $Q'=S_{\max}/S_{\min}$. This ratio is proportional to $(\omega_0/\omega)^2$ and presents the same feature as Q.

II. THEORY

A. Model

Let us consider system motion in a symmetric bistable potential $U_0(x)$ exposed to an action of a driving force, $F(t)=f_1\cos(\omega_1 t)+f_2\cos(\omega_2 t)$, a constant force, h, and a random force. We use the simple approach to the problem, in which a continuous bistable system is replaced by a discrete system governed by a rate equation.[2] Let $n_+(t)$ be the probability to find the system near the right minimum of the potential and $n_-(t)$ be the probability to find the system near the left minimum. We can write

$$n_+(t)=1-n_-(t)=\int_{x_0}^{+\infty}p(x,t)dx, \tag{4}$$

where x_0 is the position of the maximum of the potential and $p(x,t)$ is the probability distribution of the continuous system. The corresponding rate equation is

$$\frac{dn_+}{dt}=-\frac{dn_-}{dt}=W_-(t)n_--W_+(t)n_+, \tag{5}$$

where $W_\pm(t)$ is the transition rate out of the $\pm$ state. The probability density of the discrete system can be found as

$$P(x,t)=n_+\delta(x-x_+)+n_-\delta(x-x_-), \tag{6}$$

where $x_\pm$ is chosen to minimize errors in the calculation of moments.

We consider the case where the noise strength D is not high, so that important integrals, e.g., (4), are concentrated near the minima of the potential. This restriction is given by

$$D\ll a^2\left(\frac{\partial^2 U}{\partial x^2}\right)\Bigg|_{x=x_\pm}. \tag{7}$$

where $2a$ is the distance between minima of the symmetric potential.

 0021-8979/96/79(8)/6113/3/$10.00

In the absence of modulation we have stationary populations

$$n_{\pm 0}=\frac{\exp(\pm ha/D)}{2ch(ha/D)} \tag{8}$$

and $x_{\pm}=\langle x\rangle \pm 2n_{\mp 0}a, \langle x\rangle = a\cdot th(ha/D)$. It is worth noting that $x_+ - x_- = 2(n_{+0}+n_{-0})a = 2a$ even in the presence of the constant force h.

We need an expression for transition rates in order to solve time-dependent problem (4). Under the same restriction (7) the rates can be written as[8]

$$W_{\pm}=\frac{\sqrt{U''(x_{\pm})U''(x_0)}}{2\pi}\exp\left[-\frac{U(x_0)-U(x_{\pm})}{D}\right], \tag{9}$$

where $U(x_0)$ is the maximum value of the potential. It is easy to find for the symmetric potential

$$U(x_0)-U(x_{\pm})=\Delta U \pm ha+(h^2/2)([U''(x_0)]^{-1} + [(U''(x_{\pm})]^{-1}), \tag{10}$$

where ΔU is the barrier in the absence of external forces. We also assume that forces are small ($ha, Fa \ll \Delta U$) and slow ($\omega_1, \omega_2 \ll \omega_0$). Then, the third term in (10) can be neglected and adiabatic approximation can be used, which gives

$$W_{\pm}(t)=\nu \exp\left(-\frac{\Delta U \pm ha \pm F(t)a}{D}\right),$$

$$W_{\pm 0}=\nu \exp\left(-\frac{\Delta U \pm ha}{D}\right). \tag{11}$$

Introducing (11) into (5) and developing all values in series with a small parameter $\epsilon = Fa/D$: $n_+ = n_{+0}+n_{+1}+n_{+2}+\cdots, W_{\pm}=W_{\pm 0}+W_{\pm 1}+W_{\pm 2}+\cdots$, we find

$$\frac{dn_{+0}}{dt}=0=W_{-0}-[W_{+0}+W_{-0}]n_{+0}, \tag{12a}$$

$$\frac{dn_{+1}}{dt}=\frac{W_{-1}W_{+0}-W_{+1}W_{-0}}{W_{+0}+W_{-0}}-[W_{+0}+W_{-0}]n_{+1}, \tag{12b}$$

$$\frac{dn_{+2}}{dt}=-[W_{+1}+W_{-1}]n_{+1}-[W_{+0}+W_{-0}]n_{+2}\cdots . \tag{12c}$$

Equation (12a) gives stationary populations (8), (12b) describes SR in case of nondegenerate minima, (12c) and the following equations describe frequency mixing phemonema. The calculation is straightforward and we present only the results.

B. A constant force and periodic driving

First, we consider the asymmetric case $h \neq 0$ with only one periodic component $f_1 = f$, $f_2 = 0$. Solving (12b) gives the spectral density $S_1(\omega)$,

$$S(\omega)=\left(4n_{+0}n_{-0}-\frac{2A^2}{B^2+\omega_1^2}\right)\frac{4a^2B}{B^2+\omega^2}+\frac{4\pi a^2A^2}{B^2+\omega_1^2}\delta(\omega_1-\omega) \tag{13}$$

where the coefficients are $A=[2W_{+0}W_{-0}/(W_{+0}+W_{-0})](fa/D)$, $B=W_{+0}+W_{-0}=2\nu_{Kr}ch(ha/D)$, $\nu_{Kr}=\nu_0\exp(-\Delta U/D)$ is the Kramers frequency, and $\nu_0=\omega_0/(2\pi)$. Equation (13) contains all information about SR. It gives the signal

$$S_1=\frac{4\pi f^2a^4}{D^2}\frac{\nu_{Kr}^2}{[4\nu_{Kr}^2ch^2(ha/D)+\omega_1^2]ch^2(ha/D)}, \tag{14}$$

noise

$$N=\frac{8a^2\nu_{Kr}\Delta f}{[4\nu_{Kr}^2ch^2(ha/D)+\omega_1^2]ch(ha/D)}, \tag{15}$$

and the signal-to-noise ratio

$$R=\frac{\pi f^2a^2}{D^2}\cdot\frac{\nu_{Kr}}{2ch(ha/D)\Delta f}=\frac{R_0}{ch(ha/D)}, \tag{16}$$

where R_0 is SNR in the absence of the constant force h. If $W_{+0}+W_{-0}\gg\omega_1$, then we have $S_1\cong S_0/ch^4(ha/D)$, where S_0 is the signal for the conventional SR.

We draw an important conclusion from Eqs. (14)–(16): SNR and the signal are very sensitive to the symmetry of the bistable potential. Another useful conclusion is connected to the scale of changes of SNR and the signal with h. It is clear from Eqs. (14)–(16) that the scale is simply D/a. This information can be used to evaluate small constant forces or/and to find parameters of an unknown bistable potential.

C. A constant force and two periodic drivings

Let us return to the main case where forces h, f_1, f_2 are not equal to zero. In order to investigate frequency mixing we should solve linear equations (12.2), (12.3),... subsequently. An analytical solution is possible. However, it is very complicated. For this reason we present the analytical solution for the case $W_{+0}+W_{-0}\gg\omega_1, \omega_2$. Being much simpler, this case contains all essential features of the phenomenon. Then, the signal on the mixed frequencies is

$$S_2(\omega_1\pm\omega_2)=\frac{\pi a^4f_1^2f_2^2}{D^4}\frac{\nu_0^2\exp(-2\Delta U/D)th^2(ha/D)}{4ch^2(ha/D)} \tag{17}$$

and noise is given by (14). Third-order approximation yields

$$S_3(\omega_1\pm 2\omega_2)=\frac{2\pi a^6f_1^2f_2^4}{3D^6}\frac{\nu_0^2\exp(-2\Delta U/D)}{[4\nu_{Kr}^2ch^2(ha/D)+\omega^2]ch^2(ha/D)}. \tag{18}$$

We see that the signals are proportional to $S_n\sim(fa/D)^n\nu_{Kr}^2$, where n is the order of approximation. Consequently, the spectrum harmonics demonstrate typical stochastic resonance behavior. The interesting feature of (17) and (18) is the general property of S_n as a function of h. One can see that $S_{2n}, n=1,2,...$ has the minimum at $h=0$, while $S_{2n-1}, n=1,2,...$ has maximum at $h=0$, see also Ref. 4. Moreover, the spectrum components S_{2n} of the response are zero when h is zero. The maximum of second harmonics (17) is reached at $h=D/a$ where the potential is asymmetric.

Again, the scale of signal changes with h is D/a. This information can be used for noise evaluation.

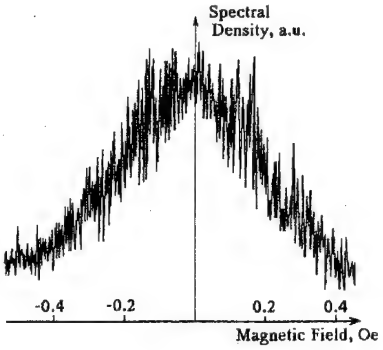

FIG. 1. The signal $S_1(\omega)$ as a function of the constant magnetic field. The sample is ferrit–garnet film with magnetization 50 G, thickness 30 μm, the anisotropy field 1300 Oe. The frequency is 1 kHz, the length of the studied domain wall part is 5 μm.

III. EXPERIMENT

The theory has been checked on an isolated domain wall of a thin ferrit–garnet film. Experimental installations, samples, and adjustment procedures are described in Ref. 9. A position of a local part (5 μm) of a domain wall pinned between two neighboring microdefects has been measured by means of magnetooptics. The domain wall was subjected to several periodic drivings in the presence of constant and noiselike magnetic fields. The spectrum components of the response were measured by a spectroanalyzer as a function of the noise strength and the constant magnetic field. Figure 1 displays a harmonic of odd order as a function of the magnitude of the constant field. The same dependence for a harmonic of even order is shown in Fig. 2. We note that the function of Fig. 1 has the maximum at zero field, while that of Fig. 2 has the minimum at zero field in agreement with the theory. Figure 3 demonstrates third-order harmonics as a function of h for two different noise strengths. Again, we see qualitative agreement with the theory: the bigger the noise strength, the larger the scale of signal changes. Experiments also confirmed the stochastic resonance dependence of harmonics upon the noise strength.

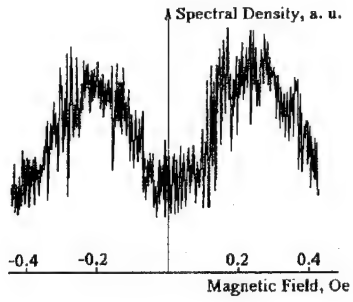

FIG. 2. The signal $S_2(\omega_2-\omega_1)$ as a function of the constant magnetic field. The frequencies are: $\omega_1=3$ kHz, $\omega_2=4$ kHz. The sample is the same as in Fig. 1.

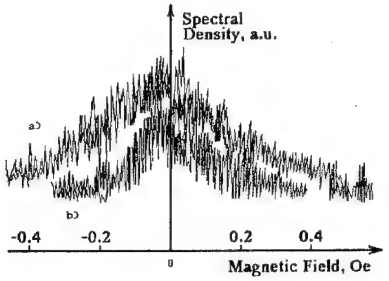

FIG. 3. The signal $S_3(3\omega)$ as a function of the constant magnetic field for two different noise strength. The frequency is 1 kHz, (a) the dimensionless noise strength $D=0.8$ (b) the dimensionless noise strength $D=0.4$. The sample is the same as in Fig. 1.

IV. CONCLUSION

It has been shown that spectrum harmonics of a bistable system response to periodic driving exhibit noise-induced enhancement. The quality of stochastic resonance has been defined. It has been shown that the quality is larger for harmonics on mixed frequencies. The important dependence of the signals upon the constant force that destroys the symmetry of the potential has been calculated. The theory has been checked on a simple bistable magnetic system—an isolated domain wall pinned between two microdefects.

Low temperature magnetic relaxation and quantum tunneling in nanocrystalline particles (abstract)

X. X. Zhang, J. M. Hernandez, E. C. Kroll,[a] R. Ziolo,[a] and J. Tejada
Department de Fisíca Fonamental, Universidad de Barcelona, Diagonal 647, 08028 Barcelona, Spain

We report measurements of the magnetic relaxation rate versus temperature for ferrofluid and magnetic-glass samples, which are formed by a modification of nanocomposite material consisting of nanocrystalline $CoFe_2O_4$ and polymer.[1] The magnetic properties of the samples have also been studied by using SHE-SQUID at different temperatures (1.8–300 K) with low and high applied magnetic field (−5 T to 5 T). The magnetic relaxation in two samples show a perfect logarithmic dependence on the time, i.e., $M(t)=M(t_0)[1-S\ \ln(t/t_0)]$, in accordance with the ZFC-FC results which indicate that there is wide energy distribution. The temperature independence of magnetic viscosity $S\equiv[1/M(t_0)dM/d]\ln t$ below several Kelvin for the two samples gives clear evidence of macroscopic quantum tunneling of magnetization, in accordance with current theories of quantum tunneling of magnetization. © *1996 American Institute of Physics.* [S0021-8979(96)70108-6]

Giant magneto-impedance effects in different measuring geometries (longitudinal and transverse) of amorphous $Co_{70.4}Fe_{4.6}Si_{15}B_{10}$ ribbons under different field annealing have been studied at various frequencies (0.1 Hz–2 MHz). For suitably annealed samples, rich peak features have been observed in longitudinal MI measurements. For transverse MI measurements, a large effect magnitude has also been found. These results are discussed in terms of the effects of the magnetic annealing and measurement geometries on the effective permeability. © *1996 American Institute of Physics.* [S0021-8979(96)76908-8]

Recently, frequency and field dependent impedance has been observed in amorphous materials with nearly zero magnetostriction.[1–3] The origin of the pronounced magnetoimpedance (MI) effects appears to be the field dependence of the effective transverse permeability, which is better understood in the case of amorphous wires.[2] Very recently,[4] we reported the effects of field-annealing geometry, highlighting the role of transverse anisotropy on the longitudinal MI (LMI). However, many questions concerning the nature of the MI and the rich spectra of the MI effects remain to be addressed. A key question is the role of the measurement geometry on the MI. Early reports for transverse MI (TMI), describe a very insignificant effect.[1,3] We show in this work that the TMI effects not only exist, they have the same order of magnitude as the LMI. We also report on the effect of the field-annealing and measurement geometries of amorphous $Co_{70.4}Fe_{4.6}Si_{15}B_{10}$ ribbons. The dependency of MI on frequency (up to 2 MHz) is also reported.

Samples from adjacent portions of the same amorphous $Co_{70.4}Fe_{4.6}Si_{15}B_{10}$ ribbon were cut into sections of 10×1 mm^2. The average thickness of the ribbon was 20 μm and the resistivity about 115 mΩ cm. Four-terminal MI measurements with In metal contacts were used in the low frequency range (0.1 Hz$\leqslant f\leqslant$100 kHz). Sinusoidal current (up to 20 mA) was provided by a low noise current source, and the signal detected by a dual-channel lock-in amplifier. The results are expressed in terms of the impedance $Z(I_0,f,H)=R(I_0,f,H)+iX(I_0,f,H)=(V_R+iV_X)/I_0$. In the low frequency range, the dc field was provided by an electromagnet with fields up to 5 kOe. For the high frequency (rf range) measurements (100 kHz$\leqslant f\leqslant$2 MHz), a three-terminal method was used. The rf signal was amplitude modulated in order to allow lock-in detection of the signal proportional to the impedance $Z(I_0,f,H)$. The dc field in rf measurements was provided by a long solenoid with a maximum field of 150 Oe and a field uniformity better than 2%. Magnetic annealing ($T_A=300$ °C) was performed in flowing Ar gas with zero or 2 kOe field oriented either parallel to the long direction of the samples (longitudinal annealing) or along the short direction, but still in the sample's plane (transverse anneal). In what follows, the MI effect will be expressed as $\Delta Z/Z(H_{max})$, $\Delta R/R(H_{max})$, and $\Delta X/R(H_{max})$, where $H_{max}=5$ kOe for the low frequency and $H_{max}=150$ Oe for the high frequency range.

In Fig. 1 the longitudinal magnetoimpedance (LMI) results for the samples subjected to different annealing geometries are shown. These measurements were taken at 100 kHz and 20 mA peak value for the probe current. There is a large LMI effect in the as-produced sample [Fig. 1(a)] with two round peaks. Upon annealing at zero field, the magnitude of the effect decreases significantly [Fig. 1(b)], but the two round peaks can still be observable. Longitudinal annealing produces a very small effect [see Fig. 1(c)] and the overall shape is a wide plateau with no resolvable peak. Transverse annealing recovers the large MI effect [Fig. 1(d)] with very

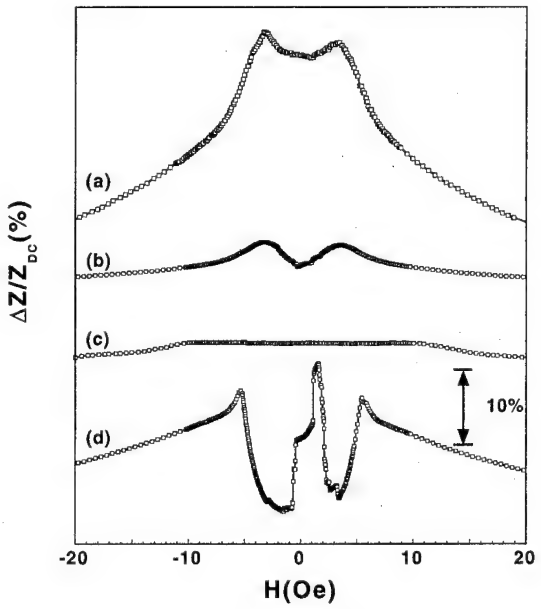

FIG. 1. Longitudinal magnetoimpedance (LMI) results at $f=100$ kHz and 20 mA peak probe current of (a) as-cast sample and samples subjected to different annealing conditions at $T_A=300$ °C: (b) at $H_A=0$, (c) longitudinally annealed at $H_A=2$ kOe, and (d) transversely annealed at $H_A=2$ kOe. The results are expressed as $\Delta R/R(H_{max})$ and $\Delta X/R(H_{max})$. All graphs share the same vertical scale indicated by the 10% mark.

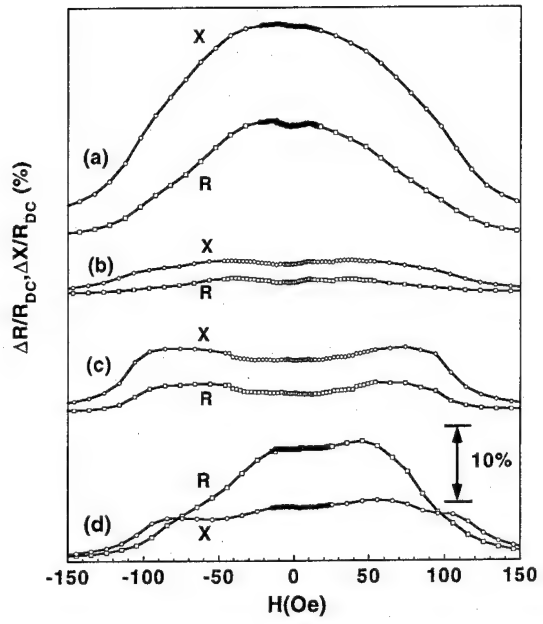

FIG. 2. Transverse magnetoimpedance (TMI) for the same samples shown in Fig. 1.

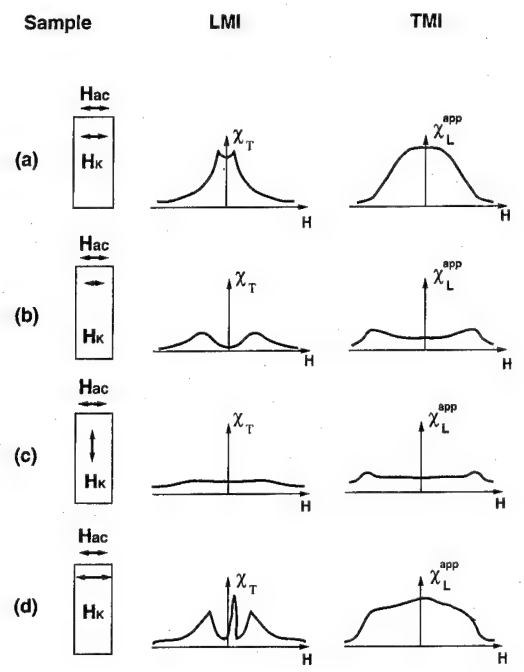

FIG. 3. Schematics showing the effects of annealing, measurement geometries, and induced anisotropies on longitudinal (LMI) and transverse (TMI) magnetoimpedance for (a) as-cast, (b) annealed at zero field, (c) longitudinally annealed, and (d) transversely annealed samples. The relevant transverse susceptibility (second column) for LMI and apparent longitudinal susceptibility for TMI (third column) are also shown. For the LMI the dc field H is parallel to the sample's length and for the TMI the field is parallel to H_{ac}.

well-defined peak structure. It may be noted that LMI occurs in very low fields, in the field range of only ± 10 Oe.

It should be mentioned that in Fig. 1(a), 1(b), and 1(c), the decreasing-field curves (not shown) and the increasing-field curves (shown) are essentially the same. In Fig. 1(d) however, the two shoulder peaks at ± 6 Oe are reversible, whereas the central peak is hysteretic; the central peak at 2 Oe in Fig. 1(d) appears at -2 Oe in the decreasing field curve.

In Fig. 2, the transverse magneto-impedance (TMI) measurements for the same samples of Fig. 1 are shown. A large effect is again observed in the as-cast sample [Fig. 2(a)] which shows a bell-shaped curve without many of the details present in the LMI. For the sample annealed in a zero field [Fig. 2(b)], the magnitude of the effect is much smaller than the as-cast case, in a way consistent with the LMI. For the longitudinally annealed sample [Fig. 2(c)], the TMI shows broad peaks in the resistance and reactance curves. For the transversely annealed sample [Fig. 2(d)], the large effect in TMI is again retrieved, in a manner similar to that of the LMI. Although still showing bell-shaped curves, the R vs H and X vs H curves indicate some peak structure, which contains as many as four broad peaks. As shown in Fig. 2, regardless of the annealing conditions, the MI effect for the reactance part ($\Delta X/R_{dc}$) is usually larger than that of the resistance part ($\Delta R/R_{dc}$), except for the transversely annealed sample.

It should be noted that the principal difference between LMI and TMI is that the field range in TMI is about one order of magnitude *larger* than those of the LMI. If one were guided by the LMI results shown in Fig. 1 and attempted to measure TMI using only small external fields, one would *not* have observed a large TMI effect. This may explain why TMI, with magnitude similar to that of LMI, was not reported earlier.[1,3]

The differences between the LMI and the TMI measurements can be understood in terms of the effect of the annealing and measurement geometry on the effective differential permeability, the underlying quantity responsible for the MI effects. It is well accepted that in LMI, there are different regimes in high permeability materials, depending on the relative values of the sample thickness t and the skin depth length:[2] $\delta_m = c/\sqrt{2\pi\omega\sigma\mu_{\text{eff}}}$, where σ and μ_{eff} are the conductivity and the effective differential permeability of the material, ω the angular frequency, and c is the speed of light. The field and frequency dependence of the permeability $\mu_{\text{eff}}=1+\chi_{\text{eff}}$ play a central role in defining the magnitude of the MI and the peak structure observed.

It is a well-known fact[5] that the as-cast samples already have a small amount of anisotropy induced during the fabrication process, with an effective anisotropy field of H_K', as schematically shown in Fig. 3(a). Upon annealing in the zero field, part of this anisotropy is relaxed, but not eliminated. A perpendicular component of the anisotropy with respect to the probe current is still present in both the LMI and the TMI cases, as indicated in Fig. 3(b). For the longitudinally annealed sample [Fig. 3(c)], a larger part of the anisotropy is parallel to the long direction of the sample, whereas in the case of the transverse-annealed sample [Fig. 3(d)], a larger part of the anisotropy is induced perpendicularly to the long direction of the sample. The geometry of measurement defines which permeability is important for the MI. In all LMI measurements, the field produced by the probe current H_{ac} is perpendicular to the applied dc field H. The magnetization

processes produced by the probe current will then be described by the transverse differential susceptibility χ_T.[6] As a consequence, χ_T will be the relevant susceptibility for the LMI. On the other hand, in TMI, the field generated by the probe current H_{ac} and the applied dc field H are parallel to each other and to the average dc magnetization. In this case the magnetization processes produced by the probe current will be described by the longitudinal differential susceptibility χ_L,[6] which is the relevant one for the TMI.

The details of the field dependence of the susceptibilities, and hence the peak structures in the MI, are the results of the relative orientation of the field generated by the probe current H_{ac}, the anisotropy field H_K, and the applied field H. In the second column of Fig. 3, the expected behavior of χ_T vs H curve, relevant to LMI, is schematically shown for each annealing geometry. The demagnetization field in LMI has a negligible contribution to the internal field because $H_i = H - 4\pi D_L M$, and D_L is small. For TMI, the longitudinal susceptibility χ_L is of relevance. Furthermore, in this case, the demagnetization field has a large effect; it not only influences the internal field via $H_i = H - 4\pi D_T M$, but more importantly, it also places a *limit* for the longitudinal susceptibility χ_L.[7] The apparent susceptibility is $\chi_L^{app} = \chi_L/(1 + 4\pi \cdot D_T\chi_L)$, which is χ_L corrected for demagnetizing effects. In the limit that χ_L is large, the apparent susceptibility will be given by $\chi_L^{app} \approx 1/4\pi \cdot D_T$, which together with the smaller internal field produce the bell-shaped curves for the transverse measurements over a large range of applied field H. The expected apparent differential susceptibility curves for the various samples are schematically represented in the third column of Fig. 3. The demagnetization effects will always be present in the TMI, regardless of the details of the field dependence of the differential permeability or the annealing geometry. The field dependence of the intrinsic χ_L is therefore masked.

The LMI effects, hardly influenced by the demagnetizing effects, provide the actual field dependence of χ_T, with which one can unravel the processes that contribute to the peak structure of the LMI and χ_T. As mentioned earlier, the as-cast sample already has anisotropy.[5] It is well known that after transverse annealing, the transverse susceptibility (χ_T) develops a peak at $H = H_K$.[6,8] We therefore identify the shoulder peaks in Fig. 1(d), located at ± 6 Oe, as H_K.

The central peaks in the transverse-annealed sample can be attributed to a maximum in the permeability associated to the domain wall (DW) motion.[9] This identification is consistent with the fact that the central peaks, located at ± 2 Oe, are hysteretic, as mentioned earlier. The susceptibility can be described as $\chi = \chi_{DW} + \chi_{rot}$, where χ_{DW} is the susceptibility associated with domain wall motion and χ_{rot} is the susceptibility associated with the rotation process. This hypothesis can be tested by high frequency measurements, because these susceptibilities (χ_{DW} and χ_{rot}) have different attenuation constants due to their different nature. In metallic samples, including amorphous materials, DW motion is attenuated at lower frequencies, when compared with the rotation process.

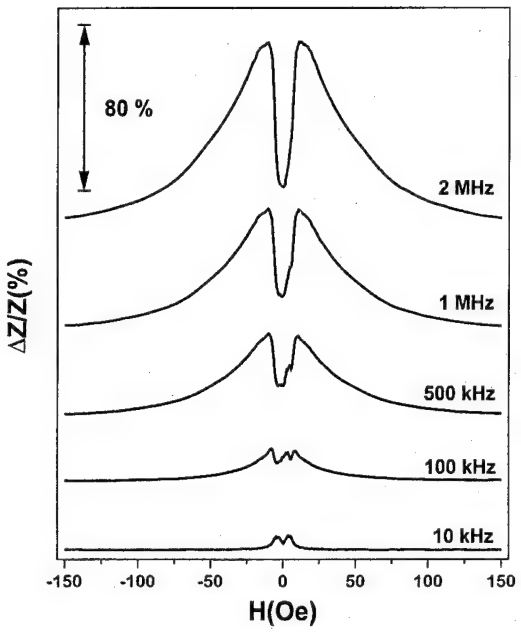

FIG. 4. The results of LMI at 40 mA at various frequencies for the transversely annealed sample.

The LMI vs H curves for the sample annealed under a transverse field are shown in Fig. 4 for various frequencies. Above 100 kHz, while the amplitude of the shoulder peaks increases, the amplitude of the central peaks *decreases* as the frequency increases and vanishes for $f \geq 2$ MHz. Thus the vanishing central peak in this transverse-annealed sample corroborate the assertion that the central peaks are associated with DW motion as proposed[4] and described above. It is also noted that the magnitude of the LMI is very high, increasing as $f^{1/2}$ and reaching more than 150% at high frequencies. The width of the shoulder peaks also broadens with frequency. These results will be described elsewhere.

Size dependence of the magnetoresistance in submicron FeNi wires

A. O. Adeyeye, J. A. C. Bland, C. Daboo, Jaeyong Lee, U. Ebels, and H. Ahmed
Cavendish Laboratory, Madingley Road, Cambridge, CB3 OHE, United Kingdom

The field-dependent magnetoresistance (MR) characteristic and magnetic hysteresis behavior has been studied in 300–500 Å thickness $Ni_{80}Fe_{20}$ wires of variable width (w) in the range from 0.2 to 10 μm. As the width of the wire decreases, a marked increase in the easy axis coercive field is seen for fields applied along the wire axis and the form of the MR characteristic is markedly modified for the in-plane perpendicular hard axis direction with a large field-dependent MR response observed for applied field strengths exceeding the edge demagnetizing field. The low field hard axis results are discussed in terms of an inhomogeneous spin configuration across the width of the wires arising from the spatial variation of the demagnetizing field. © *1996 American Institute of Physics.* [S0021-8979(96)77008-7]

The size-dependence of the magnetization reversal process in submicron structures provides an important opportunity in testing micromagnetic models and in exploring magnetoresistance effects associated with the modified spin ordering arising from the reduced dimensions. Advances in fabrication techniques based on advanced electron lithography together with recent developments in micromagnetic computational techniques have opened new perspectives in this field. An understanding of the magnetization reversal processes and magnetoresistance (MR) response in small ferromagnetic elements is also important for the design and optimization of miniature MR heads for ultrahigh density data storage applications.[1] Whereas the magnetoresistance properties of micron-range permalloy thin films have already been extensively investigated,[2–4] in the present work we present the results of a systematic study of the magnetization reversal process in submicron $Ni_{80}Fe_{20}$ wires fabricated using advanced lithography techniques. We show that striking new effects are observed in the reversal processes, leading to strong variations in the MR response at large fields.

An ultra high vacuum system with a base pressure of 5×10^{-10} Torr was used to prepare continuous film structures of the form 30 Å Au/t $Ni_{80}Fe_{20}$/GaAs(001) with $t=300$ Å and $t=500$ Å. The $Ni_{80}Fe_{20}$ layers were deposited at a rate of 2.5 Å/min. The pressure during growth was 2.5×10^{-9} Torr while the substrate was held at 30 °C. The film was annealed at 120 °C for 30 min to remove the uniaxial anisotropy induced during growth. $Ni_{80}Fe_{20}$ wire arrays of variable width (w) in the range from 0.2 to 10 μm were fabricated using electron beam lithography and optimized pattern transfer techniques based on a combination of dry and wet etching. The separation (s) between wires is 1–10 times the wire width so that the wires are weakly interacting (low s) or well isolated (large s).

The pattern was first transferred to the Au layer by sputtering. The pattern is further transferred to the underlying $Ni_{80}Fe_{20}$ layer using wet chemical etching with a solution of $HCl:HNO_3:H_2O$(1:25:200). This is made possible because of the high etch selectivity between Au and $Ni_{80}Fe_{20}$. Complete removal of $Ni_{80}Fe_{20}$ in the gap between array structures was confirmed using energy dispersive x-ray analysis (EDX). Details of the fabrication process are described in Ref. 5.

For MR measurements, electrical contacts to the arrays were made using standard optical lithography, metallization and liftoff of 20 nm Cr/300 nm Au. The wires are each of length 250 μm and extend over a distance of 250 μm. An initial determination of the device resistance at zero applied field was made and it was found that the resistance scaled approximately inversely with the proportion of metal remaining after etching. A dc current of 1 mA (Ref. 6) was passed along the wires of each grating and the resistance was recorded automatically using a four terminal method as the magnetic field was swept. The magnetic field was applied in the plane of the structures for all the measurements reported since the magnetization of the continuous films lies in plane. MOKE magnetometry measurements were made in the longitudinal geometry using a stabilized HeNe laser source and a focused spot size at the sample of 0.2 mm.

The field-dependent magnetization ($M-H$) loops of the grating structures were measured with the field parallel ($\Theta=0°$) and perpendicular ($\Theta=90°$) to the wire axis in order to investigate the effect of shape anisotropy. Figure 1(a) shows the results of the MOKE measurements on a 300-Å-thick $Ni_{80}Fe_{20}$ grating with $w=0.5$ μm and $s=0.5$ μm. This measurement is compared with that of the reference sample (unstructured material) that went through all the processing steps but which displays almost zero anisotropy. The MOKE measurements on the unstructured material display the same $M-H$ behavior in both orientations as that of the original film prior to fabrication. This shows that the magnetic properties of the film are preserved during processing. There is a marked increase in the saturation field of the $M-H$ loop obtained along the hard axis ($\Theta=90°$) in the 0.5 μm wire, in comparison with the loops obtained along the easy axis ($\Theta=0°$) and for the reference film, due to the magnetic shape anisotropy. A surprising feature of the hard axis MOKE data of Fig. 1(a) is that it is asymmetric with applied field implying that different energy states are explored according to the sense of the field sweep, presumably due to incomplete saturation at the wire edge. Presented in Fig. 1(b) are the easy axis coercive fields derived from experimental hysteresis loops for various wire widths. The increase in the coercive field with reduced width is in qualitative agreement with the results of earlier work.[7,8]

In Fig. 2(a) the magnetoresistance (MR) response to

 0021-8979/96/79(8)/6120/3/$10.00

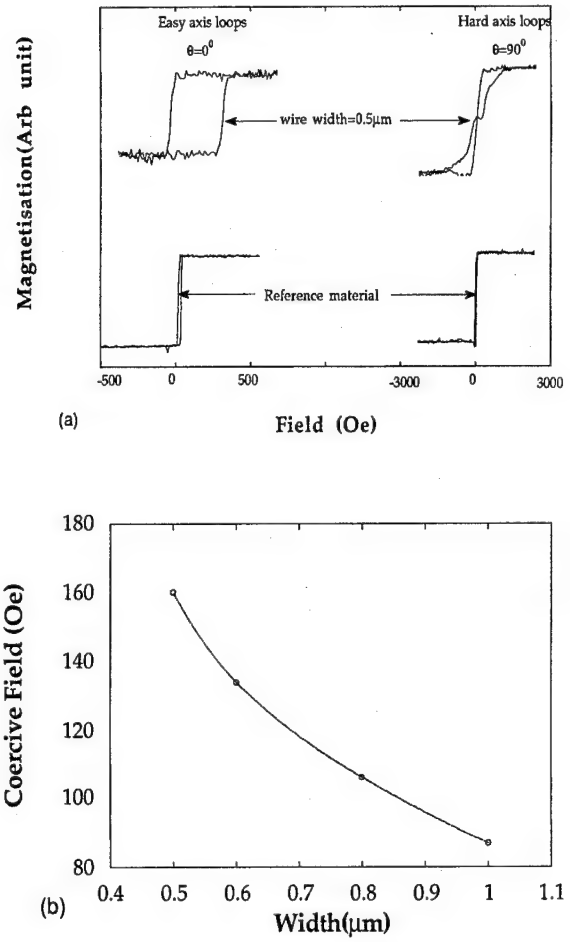

FIG. 1. (a) MOKE loops of a wire array with wire width $w=0.5$ μm and separation $s=0.5$ μm (top) and of the unstructured material (bottom). The thickness of the film is 300 Å. (b) The easy axis coercive fields derived from the experimental hysteresis loops for various wire widths.

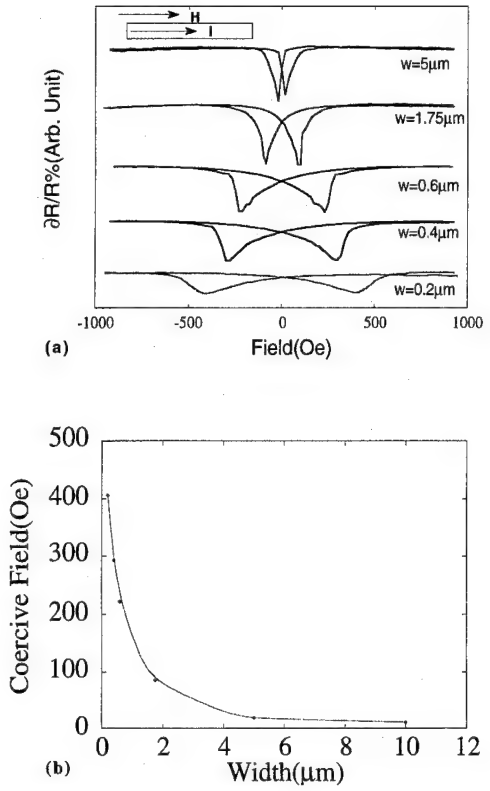

FIG. 2. (a) The magnetoresistance (MR) response to fields applied along the easy axis for a wire grating with film thickness $t=500$ Å and $s=10$ w for various wire widths. (b) The coercive field corresponding to the sharp minima in the MR curves in (a) plotted as a function of the wire width.

fields applied along the easy axis is presented for various wire widths, plotted as a percentage defined as

$$\frac{\partial R}{R}=\left[\frac{R(H)-R(H=0)}{R(H=0)}\right].$$

The sharp minimum in the longitudinal MR curve corresponds to the switching of the magnetization in the wires, and therefore it is taken as the coercive field of the wire. The coercive field corresponding to the minimum of the MR curves is plotted as a function of the wire width in Fig. 2(b). A marked increase in the coercive field H_c with decreasing width is again observed. This has been explained by Kryder[9] as resulting from the buckling of magnetization perpendicular to the length of the wire. This leads to the formation of domain walls perpendicular to the wire. These walls do not move, but block the reverse domain from propagating down the wire because the width of the wire is smaller than the buckling wavelength. Edge wall curling is expected to occur for small w. A related result has been obtained by Smyth *et al.*[10] for small particles where a corresponding transition to a spin vortex process is observed with reduced particle size.

Figure 3(a) shows the MR response to a hard axis field for various wire widths. A near reversible behavior, almost symmetric with field strength is now obtained, indicating that spin rotation processes rather than domain wall motion occur. The dependence of the MR curves on the orientation of the applied field will be described elsewhere.[11] The form of the MR–H curve is greatly changed according to the wire width. A striking feature is the large MR response at high fields exceeding the maximum value of the demagnetizing field M_s which occurs at the edge of the wire (approx. 1T). A reduction in the magnitude of the maximum magnetoresistance ratio with reducing wire width is also observed and we note that the easy axis peak MR also reduces with reducing wire width.

The observed behavior can be attributed to the anisotropic magnetoresistance effect[7] at low field (i.e., beneath the maximum demagnetizing field). The change in response with wire width can be partly explained in terms of the inhomogeneous demagnetizing field across the width of the wires resulting from the spatial variation of the dipolar field due to the edge charges.[7] As the wire width is reduced, a greater proportion of the current flows in the regions in the vicinity of the edges of the wires where the demagnetizing field is large, and hence the response extends to larger applied fields. The average hard axis saturation field can be estimated as[12] (SI units)

$$H_s\approx\frac{3}{2}H_d=\frac{3}{2}\left(\frac{t}{w}\right)M_s,$$

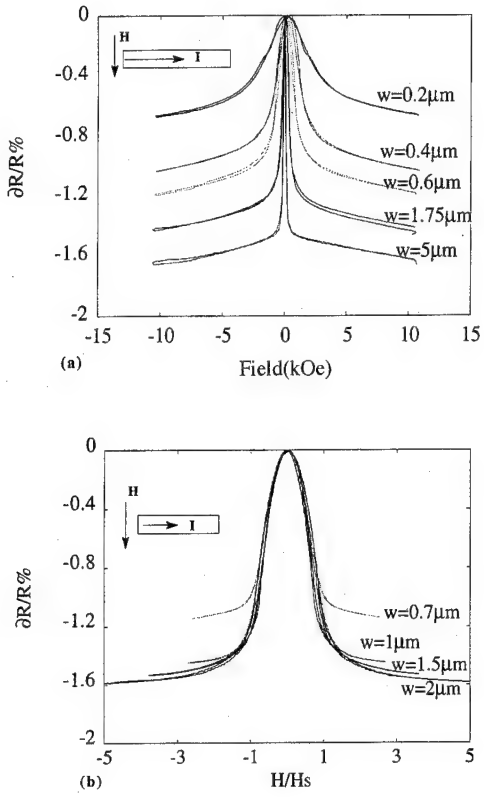

FIG. 3. (a) The MR response to fields applied along the hard axis for various wire widths for a grating structure with $t=500$ Å and $s=10\ w$. (b) MR vs reduced field $h=H/H_s$ as a function of the wire width for a grating structure with $t=500$ Å and $s=w$.

where H_d represents an estimate of the demagnetizing field at the wire center, t is the film thickness, w the wire width, and M_s is the saturation magnetization of the material and the magnetic anisotropy of the constituent film is assumed to be zero. From the results of Fig. 3(a), H_s can be estimated for various values of wire width. Figure 3(b) shows a plot of the MR vs the reduced field (h) as a function of the wire width, where $h=H/H_s$. We find that a near universal, parabolic behavior is obtained for $H_a \leqslant H_s$. This result is expected from a simple magnetostatic model of the MR response for fields applied along the hard axis which assumes coherent rotation of the spins. For fields smaller than the average demagnetizing field only the spins in the interior region of the wire rotate significantly with applied field and the average rotation angle will initially scale with h. For $H_a > H_s$ a significant deviation of the response from the universal curve with reducing wire width is seen. The deviation from the universal behavior at high fields is clearly associated with the spin configuration at the edge regions of the wire where the demagnetizing field approaches the maximum value given by M_s and a scaling behavior is no longer expected. However for fields larger than the demagnetizing field at the edge, the resistance continues to vary with field in an almost linear fashion. It is possible that the spin configuration at the edge of the wire is greatly modified with reducing width, for example due to an edge pinning effect but it is

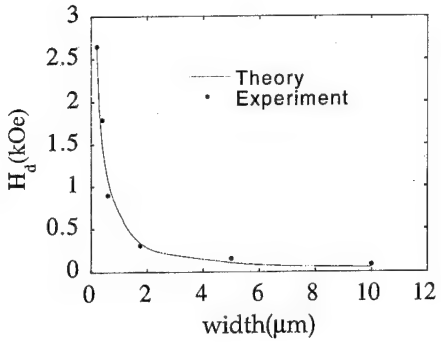

FIG. 4. The experimentally determined and calculated values of the demagnetizing field H_d as a function of the wire width for a grating structure with $t=500$ Å and $s=10\ w$.

also possible that a transverse magnetoresistance effect seen in thick Ni films contributes.[13] The experimentally determined and calculated values of the field H_d are plotted as a function of the wire width in Fig. 4. Reasonable agreement between the calculated and the experimentally determined values is obtained. However in order to understand the origin of the high field behavior, further computational and experimental studies are clearly needed.

In summary, we have studied the magnetization reversal process in submicrometer $Ni_{80}Fe_{20}$ wires of variable width (w) in the range from 0.2 μm to 10 μm using magnetoresistive measurements and MOKE magnetometry. We have observed a marked increase in the coercive field as the width of the wire decreases, in agreement with earlier studies. A striking feature observed is the large MR response at high fields. The departure from a universal form of the low field MR characteristic may be explained in terms of an inhomogeneous spin configuration across the width of the wires resulting from the spatial variation of the demagnetizing field but the origin of the high field behavior is unclear. We hope that these measurements will stimulate accurate micromagnetic simulations of the edge spin configurations.

Effect of interstrip gap on the sensitivity of high sensitivity magnetoresistive transducers

Bharat B. Pant
Solid State Electronics Center, Honeywell Incorporated, 12001 State Highway 55, Plymouth, Minnesota 55441

For high sensitivity magnetoresistive (MR) transducers, the role of interstrip gap is examined as a design parameter. This is modeled using analytic and numerical approximations. As the gap is narrowed the range of linearity of the MR transducer decreases and the sensitivity increases. For gap/width ratio exceeding 1.8 the strips behave essentially as isolated strips. An example using typical design parameters shows that the minimum detectable field is reduced from 6.3 μOe/$\sqrt{\text{Hz}}$ to 3.6 μOe/$\sqrt{\text{Hz}}$ as gap/width ratio is reduced from ∞ to 0.1. © *1996 American Institute of Physics.* [S0021-8979(96)77108-3]

I. INTRODUCTION

Magnetoresistive (MR) transducers for low field applications requiring minimum detectable field ($h_{\min}$) in the range of 1 μOe–1 mOe are typically made of long strips of thin films of MR material (e.g., NiFe) of thickness $t\sim100$ Å, width $W\sim10$ μm, and length $L\sim100$ μm.[1–3] The response of the MR transducer to applied field (sensitivity, range of linearity of the transfer function, etc.) is determined by these dimensional parameters and material parameters—saturation magnetization M_S, anisotropy H_K, easy axis angle γ, and exchange constant A. For easy axis parallel to the long dimension of the strip the field scale $H_S=H_K+H_D$, where demagnetizing field $H_D\simeq4\pi M_S t/W$, plays an important role in determining the performance parameter[3]—range of linearity $\propto H_S$, and sensitivity $\propto 1/H_S$.

Practical transducers requiring low power consumption must pack several such strips in parallel on Silicon (or other substrates) connected electrically in series to obtain a resistance $\sim1k\Omega$ or higher. A typical interstrip gap g is 1–10 μm. The effect of proximity is to reduce the effective demagnetizing field[1] in the strips thus reducing the field H_S. The response curve of the transducer saturates at a lower value of applied field, and has higher sensitivity compared to an isolated strip.

Other investigators[1,2] have modeled the response of parallel arrays of MR strips as part of a more general set of design parameters. In this paper we elucidate the role played specifically by the interstrip gap. Along with the t/W ratio, the g/W ratio emerges as an important design parameter that can be used to tailor the response of MR transducers. Above a certain value of this ratio a parallel array of strips behaves essentially as an isolated strip. We also calculate the improvement in $h_{\min}$ obtained for realistic transducer designs by narrowing the interstrip gap.

II. MODEL

Figure 1 shows three parallel strips subjected to an applied field perpendicular to the long dimension of the strips. The material easy axis is parallel to the long dimension. The magnetization rotates toward the applied field. As the magnetization rotates, lines of north (+) and south (−) poles are created at the upper and lower edges, respectively, resulting in demagnetizing field opposite to the direction of rotation.

Focusing on the central strip, the demagnetizing field inside is the sum of fields from its own edges, plus stray field contributions from the edges of other strips. The edges of the three strips are labeled (0,0′), (1,2), and (1′,2′). The stray field from the bottom edge 1 of the strip above and the top edge 1′ of the strip below is, in opposite direction to and lower in magnitude than, the internal demagnetizing field of the central strip. Moving further out, the stray field from the edges (2,2′) is, in opposite direction to and weaker than, the field from edges (1,1′). In the case of an infinite number of strips parallel to each other the demagnetizing field at any strip is given by the sum of an infinite series whose terms are successively smaller in magnitude, and of alternating sign. The total demagnetizing field is smaller than that of an isolated strip for a given rotation of magnetization. This results in a less stiff behavior of a parallel array of strips compared to an isolated one.

As an initial approximation, we treat the magnetization as uniform across the width of the strip, and use the ellipsoidal approximation which has been shown to be adequate for strips of dimensions $t\ll W\ll L$.[3] The demagnetizing field from the two pairs of edges $(2n,2n')$ and $(2n+1)$, $(2n+1)')$, $n=0,1,...$ is

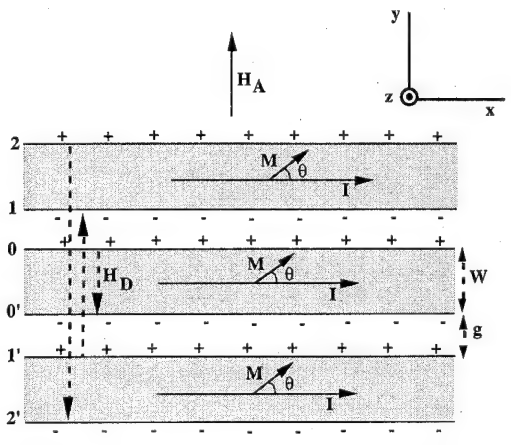

FIG. 1. A parallel array of magnetoresistive strips.

 0021-8979/96/79(8)/6123/3/$10.00

$$H_D = -4\pi M_S \frac{t}{W}\left(\frac{1}{(2n+1)+2nr} - \frac{1}{(2n+1)+(2n+2)r}\right), \tag{1}$$

where $r=g/W$. The sum over infinite array gives

$$H_D = -4\pi M_S \frac{t}{W}\alpha(r),$$
$$\alpha(r) = \frac{2r}{1+2r} + \frac{r}{2(1+r)^2}\left(\frac{\pi^2}{2}-4\right). \tag{2}$$

In arriving at the expression for $\alpha(r)$ the infinite sum over the strips is converted into an integral,[4] which is then expanded to linear order in $r/(1+r)$, ignoring higher order terms.

In the limit of $r\to 0$, the factor $\alpha(r)\to 0$; in the opposite limit of $r\to\infty$, $\alpha(r)\to 1$. The first limit corresponds to the strips coming in physical contact, in which case there is no demagnetizing field, and the second limit corresponds to an isolated strip. In both cases Eq. (2) yields physically sensible limits for the demagnetizing field. Note that for g/W ratio exceeding 3, the proximity effect is negligible; $\alpha(3)=0.94$.

A more exact analysis is performed using numerical methods. In Fig. 1 assume that magnetization **M** varies along the width (y axis) and is constant through the thickness (z axis). We also assume that the strip is infinite along the length (x axis) and the magnetization profile is translationally invariant along this axis. We define a unit length magnetization vector $\mathbf{m}=(m_x,m_y,m_z)$ using $\mathbf{M}=M_S\mathbf{m}$. The strip width is divided into N equal bins. The continuous magnetization profile is approximated by a discrete magnetization profile $\mathbf{m}_i$, $i=1,\ldots,N$. The demagnetizing field in real space is given as the weighted sum over (m_{yi},m_{zi}), $i=1,\ldots,N$, the weighting factors being the pairwise interaction kernels between bins.

Two different representations of these interaction kernels are calculated. For an isolated strip the continuous magnetostatic Greens's function[5] is discretized, integrated along the x axis and averaged over the width of the source bin. For the infinite array of parallel strips we employ the FFT method to calculate the demagnetizing field. Magnetization and interaction kernels are expressed in the Fourier space.[6] The FFT method—computationally much faster than the real space method—is well suited to this problem because of its inherent periodicity.

Energy minimization is performed using conjugate gradient method with gradient information.[7] Instead of the $3N$ variables (m_{xi},m_{yi},m_{zi}) a nonlinear transformation is used to obtain $2N$ variables for use in the minimization. These are N in-plane angles θ_i, $-\pi<\theta_i\leq\pi$, and N out-of-plane tilt variables ξ_i, $-1<\xi_i\leq 1$.

III. PERFORMANCE TRADEOFFS

We use this formalism to calculate the magnetoresistive response of an array of parallel strips of thickness $t=200$ Å, width $W=10$ μm, and gap $g=0.5$–40 μm. The exchange constant $A=2\times10^{-6}$ erg/cm, and $4\pi M_S=10$ kG, $H_K=4$ Oe and the applied field is in the range $-60\leq H_A\leq 60$ Oe. Also calculated is the magnetoresistive response of the corresponding isolated strip. The familiar approximately parabolic curve[3] is obtained whose width decreases as the gap becomes narrower. The half width at half height H_{half} is calculated for all these curves. Figure 2 shows H_{half} vs r for all these strips and the isolated strip. For $r>1.8$ H_{half} is within 94% of value for the isolated strip.

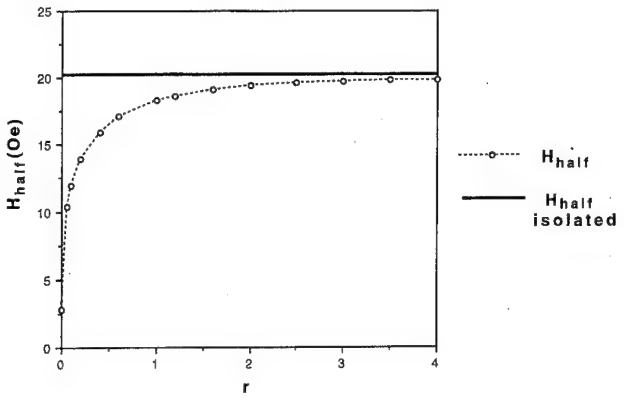

FIG. 2. Half width at half height of the MR response curves as the interstrip gap is varied. The symbols represent actual data points from the numerical calculations, the joining line is used as a guide for the eyes. For comparison the half width for an isolated strip is also shown.

An improved estimate of $\alpha(r)$ than that obtained from the ellipsoidal approximation [Eq. (2)] is made as follows. $H_{\text{half}}=H_K/\sqrt{2}$ for $r=0$. The quantity $H_{D\text{eff}}=H_{\text{half}}-H_K/\sqrt{2}$ is proportional to the demagnetizing field, and is a function of r. From this, one obtains $\alpha(r)=H_{D\text{eff}}(r)/H_{D\text{eff}}(\infty)$, i.e., the ratio of $H_{D\text{eff}}$ to the value calculated for the corresponding isolated strip. Figure 3 shows $\alpha(r)$ vs r for $0\leq r\leq 4$. Note that $\alpha(r)=0.94$ for $r=1.8$. For comparison $\alpha(r)$ calculated from the ellipsoidal approximation is also shown. It shows that as r increases the array of parallel strips approaches the response of an isolated strip more rapidly than that calculated from the ellipsoidal approximation.

As an example we calculate the effect of reducing the interstrip gap on $h_{\min}$. If we construct a barberpole transducer[8] of these strips, with a 2/3 ratio of spacing between the shorting bars and the width, the sensitivity is

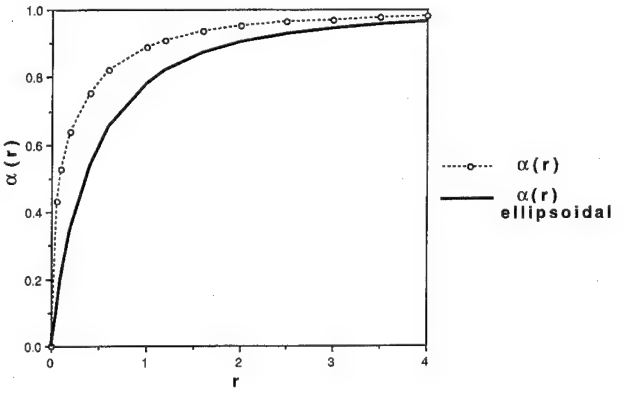

FIG. 3. Demagnetizing field reduction factor $\alpha(r)$ due to the proximity effect. For comparison the ellipsoidal approximation to $\alpha(r)$ is also shown.

$S=0.9(\Delta\rho_{max}/\rho_{ave})(1/H_S)$, where $(\Delta\rho_{max}/\rho_{ave})$ (2.5%) is the total MR effect. For a transducer of resistance R ($1k\Omega$) the rms thermal noise voltage is $V_n=\sqrt{4Rk_BT\Delta f}$, where Δf is the bandwidth of signal conditioning electronics. To the thermal noise power must be added any magnetic noise power. For this estimate we assume that the total noise voltage from all sources is twice the thermal noise voltage. For a supply voltage V_S (10 V), h_{min} is calculated using $SV_Sh_{min}/2V_n=6$.

A transducer made of well separated strips of $t=250$ Å, and $W=10$ μm gives $H_S=29$ Oe, and $S=0.78$ mv/VOe resulting in $h_{min}=6.3$ μOe/$\sqrt{\text{Hz}}$. If the transducer is constructed of the same strips separated by a gap $g=1$ μm, then $\alpha(0.1)=0.5$, $H_S=16.5$ Oe, and $S=1.36$ mV/VOe resulting in $h_{min}=3.6$ μOe/$\sqrt{\text{Hz}}$.

IV. DISCUSSION

The magnetostatic interaction between parallel magnetic strips modifies the magnetoresistive response of these strips compared to an isolated strip. Using analytic and numerical methods, it has been shown that in addition to H_K and t/W ratio, the g/W ratio is an important design parameter affecting the design of magnetoresistive sensors. The FFT method leads to efficient calculation of the demagnetizing field. Because of the inherent periodicity of these structures, FFT method is a natural fit to this problem. The effects of narrowing the interstrip gap are significant in the ranges of design parameters relevant to practical designs. Therefore, these models become useful tools for the design of MR sensors for low field applications.

As $g/W\rightarrow 0$, the range of linearity of the magnetoresistive response curve decreases, and the slope increases. These narrow gaps can be used to advantage in designing high sensitivity transducers. Conversely, for $g/W>1.8$, the effect of the proximity is negligible. Thus, if wide range of linearity is desired it is unnecessary to increase g/W much above 1.8.

An example using typical design parameters demonstrates that reducing the g/W to 0.1 from the isolated strip configuration reduces h_{min} to 3.6 μOe/$\sqrt{\text{Hz}}$ from 6.3 μOe/$\sqrt{\text{Hz}}$. This shows one means of eking out additional sensitivity from a maturing technology for low field applications.

Large magnetic Hall effect in ferromagnetic Fe_xPt_{100-x} thin films

C. L. Canedy, G. Q. Gong, J. Q. Wang,[a] and Gang Xiao[b]
Physics Department, Brown University, Providence, Rhode Island 02912

We have observed a very large extraordinary Hall effect (EHE) in a series of Fe–Pt thin films with various Fe contents. The origin of this remarkable EHE is the large spin–orbit interaction in the Fe–Pt alloys. At certain Fe content, the Hall resistivity can be saturated with a magnetic field less than 2 kG. The large EHE persists to room temperature with little change in magnitude. The EHE, which to our knowledge is the largest among magnetic transition metals, may find potential applications in magnetic sensors and nonvolatile magnetic random access memories. We will present structural analysis of the Fe–Pt films. © *1996 American Institute of Physics.* [S0021-8979(96)77208-X]

The study of magnetotransport in magnetic solids has received an increasing amount of attention recently.[1] The primary driving force behind this study is the potential applications of various novel magnetic solids in information storage devices and magnetic sensors.[1] Most of the research in this area has focused so far on the magnetoresistance aspect, with relatively little attention being paid to the magnetic Hall effect, often called the extraordinary Hall effect (EHE). The EHE arises from the spin–orbit interaction and it can be substantially larger than the ordinary Hall effect.[2] Currently, a large class of magnetic sensors is the semiconductor Hall sensor which offers good field sensitivity and linearity. However, due to a low carrier concentration, the internal resistance of a semiconductor Hall sensor is large and the frequency response narrow. Metallic solids, though having a high conductivity and a broad frequency response, are not suitable for Hall sensors because of the small Hall coefficient resulting from the inherently high carrier concentration. However, it has been suggested in the past that one may take advantage of the EHE of some magnetic solids and apply it to data storage devices or other types of magnetic sensors.[3] In reality, a large EHE generally occurs in rare-earth based magnetic systems where the spin-orbit interaction is strong,[2] but the rare-earth systems tend to have low magnetic transition temperatures (T_c) and are rather susceptible to corrosion.

In this work, we report on a very large EHE uncovered in a transition-metal system of Fe_xPt_{100-x} thin films. The EHE coefficients are roughly three orders of magnitude larger than a typical ordinary Hall coefficient of a metal. The EHE saturates at a couple of kG and remains large at room temperature. We attribute the large EHE to the strong spin–orbit interaction existing in the Fe–Pt alloys.

The Fe–Pt thin films used in this study were deposited on silicon (111) substrates by using the magnetron-sputtering technique. We used the co-sputtering method to obtain samples with varying composition. Two of the collimated cluster guns were loaded, respectively, with an Fe (>99.9%) and a Pt (>99.9%) target. The composition of each sample was controlled by varying the sputtering rates (2–5 Å/s) of the two targets. Before each deposition the background vacuum was better than 7×10^{-8} Torr. The Ar sputtering gas pressure was kept at 4.0 mTorr. All samples were deposited at an ambient substrate temperature. The film thickness was about 2500 Å. The structure of each sample was checked using an x-ray powder diffractometer. The standard photolithography and wet etching were used to pattern samples for transport measurement. The magnetic properties were measured in a superconducting quantum interference device magnetometer.

The equilibrium phase diagram of the Fe–Pt system consists of two face-centered-cubic (fcc) ($FePt_3$ and Fe_3Pt), one tetragonal superstructures (FePt) and a continuous solid solution in the α-Fe-rich side.[4,5] We have made a series of samples with Fe content ranging from 0 to 50 at. %. The high quenching rate inherent in sputtering allows the formation of metastable Fe–Pt solid solutions. Figure 1 shows the θ–2θ x-ray diffraction patterns of the Fe_xPt_{100-x} thin films used in our study. Only the (111) and (222) peaks of the fcc structure

are present, indicating a high degree of (111) textured growth of the thin films. No secondary phases were found in the x-ray patterns. The position of the (111) and the (222) peaks shifts toward high angles as the Fe content is increased (see Fig. 1). The obtained lattice constants (a) are shown in Fig. 2. Note that the value of a decreases monotonically with the Fe content.

All of the samples that we studied are ferromagnetic. For samples with an Fe content larger than 20 at.%, T_c is above 300 K. We have also observed giant Fe moments largely exceeding those in pure Fe. The enhanced moment is caused by the narrowing of Fe d band and the polarization of the Pt d states.[5] Detailed study of this phenomenon is underway and will be presented elsewhere.

In the following, we will focus on the EHE observed in the Fe–Pt system. In general the Hall effect is sensitive to the magnetic state of the material.[2] This is clearly revealed in Fig. 3, where we show the Hall resistivity ρ_{xy} as a function of magnetic field H for a representative $Fe_{30}Pt_{70}$ sample measured at 4.2, 77, and 285 K. The value of ρ_{xy} is defined according to $\rho_{xy}=E_y/j_x=V_yt/I_x$, where E_y, V_y, j_x, and I_y are electric field, voltage, current density, and current, respectively, t is the thickness of the Hall bar. The value of ρ_{xy} consists of two components, i.e.,

$$\rho_{xy}=R_0[H+4\pi M(1-D)]+R_s 4\pi M, \tag{1}$$

where the first term is the ordinary Hall effect (D is the demagnetization factor), and the second term is the EHE which is proportional to the magnetization M. The dependence of ρ_{xy} shown in Fig. 3 follows the magnetic hysteresis curve closely. The large initial increase in ρ_{xy} with H is due to the EHE. Once M is saturated, so is ρ_{xy}. Above the saturation H, ρ_{xy} is nearly independent of H at $T=4.2$ and 77 K. The normal Hall effect is too small to be visible in Fig. 3. At $T=285$ K, the increase of ρ_{xy} with H in the high field region is not due to the normal Hall effect, but rather due to the fact that M remains unsaturated up to 6 T.

In Fig. 4, we plot the EHE term at saturation (i.e., $R_s 4\pi M_s$) as a function of Fe content for the Fe_xPt_{100-x} alloys. The values of $R_s 4\pi M_s$ were obtained by extrapolating

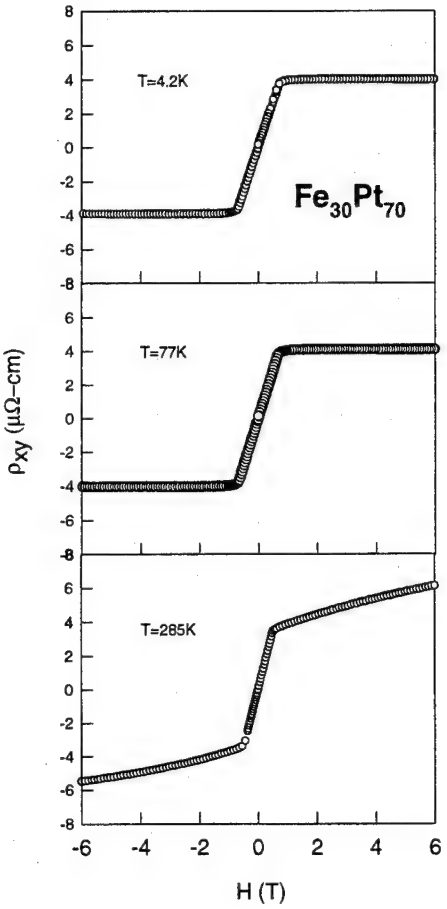

FIG. 3. Hall resistivity, ρ_{xy}, as a function of magnetic field measured at 4.2, 77, and 285 K for $Fe_{30}Pt_{70}$.

the $\rho_{xy}(H)$ curve from high field to $H=0$. At $T=4.2$ and 77 K, the quantity $R_s 4\pi M_s$ peaks at the Fe content of 30%. The initial rise of $R_s 4\pi M_s$ with Fe content is simply caused by the increasing concentration of magnetic scattering centers. However, as the Fe content is increased the spin–orbit coupling strength, mostly resulting from the heavy Pt atoms, becomes less effective. This eventually causes the EHE,

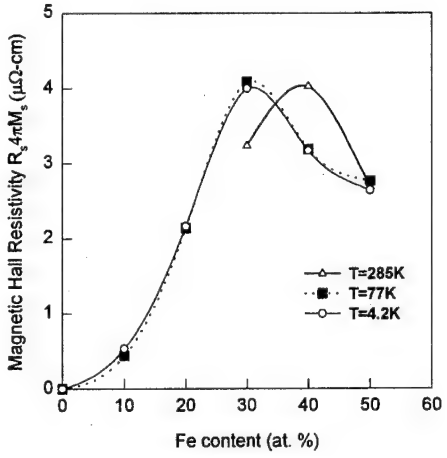

FIG. 4. The extraordinary Hall resistivity, $R_s 4\pi M_s$, measured at 4.2, 77, and 285 K for the Fe_xPt_{100-x} alloys. The lines are guides to the eyes.

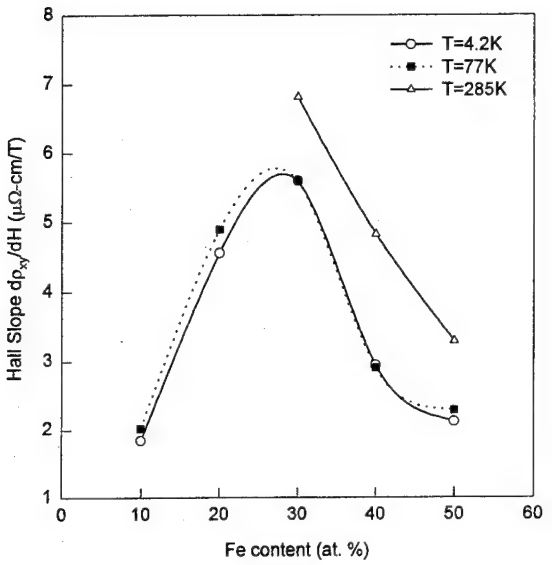

FIG. 5. The initial Hall slope, $d\rho_{xy}/dH$, at 4.2, 77, and 285 K for the Fe_xPt_{100-x} alloys. The lines are guides to the eyes.

originating from the spin–orbit interaction, to weaken when the Fe content exceeds 30%, despite an increasingly larger M. The peak value of $R_s 4\pi M_s$ occurring in $Fe_{30}Pt_{70}$ is 5.5 $\mu\Omega$ cm. This is perhaps the largest magnetic Hall coefficient obtained in transition-metal based magnetic systems. The cause for such a large EHE may be twofold: a strong spin–orbit interaction and a strong polarization of the Pt d states induced by Fe. It is noted that the resistivity of these Fe–Pt alloys is in the range of 20–70 $\mu\Omega$ cm. The Hall angle defined by $\tan\theta = \rho_{xy}/\rho_{xx}$ is also very large.

The compositional dependence of $R_s 4\pi M_s$ at 77 K is rather similar to that at 4.2 K. All samples remain ferromagnetic at 77 K. However, at $T=285$ K, the $x=10\%$ and 20% samples are no longer ferromagnetic, thus suppressing the EHE. The peak of $R_s 4\pi M_s$ shifts to $x=40\%$. This is because the M of the $x=40\%$ sample remains appreciable at 285 K, whereas the M of other Fe-poor samples is substantially reduced. Overall, the EHE remains robust at room temperature for samples with Fe content larger than 20%.

In addition to the quantity $R_s 4\pi M_s$, the initial Hall slope ($d\rho_{xy}/dH$) before saturation is also an important quantity (see Fig. 3). As shown in Fig. 3, the initial ρ_{xy} is linear in H. To achieve a large Hall slope it is preferred to have a small saturation field, which is equal to $4\pi M$, when the magnetic field is perpendicular to a thin film as required for the Hall measurement. The Hall slope is presented in Fig. 5 as a function of Fe content. The maximum Hall slope, 6.9 $\mu\Omega$ cm/T, is found in the $x=30\%$ sample at $T=285$ K. The Hall slope tends to be smaller at low T because of a larger M at low T and, hence, a larger saturation field. From the maximum Hall slope, we can estimate an effective carrier concentration ("n") if the EHE was caused by the normal Hall effect. The value of "n" is about $5\times10^{19}/cm^3$. The large Hall slope observed in the Fe–Pt series is, to our knowledge, among the largest in transition-metal based magnetic systems.[2] Compared with a normal metal such as Cu, the Hall slope in the Fe–Pt alloys is enhanced by three orders of magnitude.[6]

The large EHE in Fe–Pt could be potentially important for applications, such as magnetic sensors and nonvolatile magnetic random access memories (MRAM). In one version of MRAM each memory cell consists of a small Hall bar with a large EHE and a magnetic perpendicular anisotropy. The hysteresis loop is squarelike when the field is oriented perpendicular to the Hall bar. A local current loop switches the M to either an up or down direction yielding a Hall voltage with opposite polarity. The Fe–Pt system has both the metallic conductivity and the large EHE. The magnetic perpendicular anisotropy can be achieved by making either sandwich or multilayer structures involving Fe–Pt.[7] The surface or interface magnetic anisotropy may cause the perpendicular anisotropy.

In summary, we have fabricated a series of fcc–Fe_xPt_{100-x} thin films. Due to a large spin–orbit interaction, the Fe–Pt alloys exhibit a very large extraordinary Hall effect which can be saturated with a field of a couple of kG. Optimal magnetic Hall resistivity and Hall slope at room temperature are found in the sample $Fe_{30}Pt_{70}$, which is a good candidate for applications.

To help clarify the sources of the 67% periodic oscillations in the in-plane saturation resistivity, ρ_S (ρ_S varied from 2.5 to 5 $\mu\Omega$ cm at 4.2 K) of molecular beam epitaxy-grown epitaxial Ni/Co multilayers of total thickness, $t_T \approx 100$ nm recently reported by Gallego *et al.* [Phys. Rev. Lett. **74**, 4515 (1995)] we have measured the in-plane resistivities at 4–5 and 295 K of Ag/Cu, Ag/Au, and Ni/Co multilayers with $t_T \approx 100$ nm, dc sputtered nonepitaxially onto (001) Si. In no case do we see reproducible periodic oscillations, and any variations are always similar at 4–5 and 295 K. Our results show that oscillations of the size seen by Gallego are not simply a consequence of an average multilayer resistivity as low as 3.5 $\mu\Omega$ cm. © *1996 American Institute of Physics.* [S0021-8979(96)77308-6]

INTRODUCTION

Gallego *et al.*[1] recently reported seeing ≈67% periodic oscillations (about the average) in the saturation resistivity, ρ_S, (ρ_S varied from 2.5 to 5 $\mu\Omega$ cm) at 4.2 K of molecular beam epitaxy (MBE)-grown epitaxial Ni/Co multilayers of total thickness, $t_T \approx 100$ nm with fixed Ni(Co) thickness and variable Co(Ni) thickness. They ascribed the oscillations to superlattice effects and suggested that prior multilayers did not show them because they did not have mean-free-paths several times longer than the bilayer spacings (evidenced by low enough average resistivities).

To help clarify the source(s) of their oscillations, we have measured the in-plane resistivities at 4–5 and 295 K of Ag/Cu, Ag/Au, and Ni/Co multilayers with $t_T \approx 100$ nm, dc sputtered nonepitaxially onto (001) Si. The Ni or Ag thicknesses were fixed. Ag/Cu and Ag/Au were chosen: (a) to see if oscillations occur in nonmagnetic metal pairs with total resistivities comparable to those of Gallego *et al.*; and (b) to investigate effects of mutual miscibility of the metal pairs; like Ni and Co, Ag and Au are fully miscible, whereas Ag and Cu are nearly immiscible. Ni/Co was chosen to compare the behavior of sputtered samples with the MBE ones of Gallego *et al.* To check for systematic differences between sputtering runs, two independent runs were made for each metal pair. Measurements were made at both 4–5 and 295 K to examine any temperature dependence of the oscillations, a factor not addressed by Gallego *et al.*[1] Subsequently, however, this group indicated[2] that they observe nearly identical oscillations at room temperature and 4 K. Since any variations that we see at 295 K are also very similar to those we see at 4–5 K, for brevity, we omit our 295 K data and focus on those at 4–5 K.

Our samples were dc sputtered onto substrates maintained below room temperature in an ultrahigh vacuum (UHV) compatible four-gun system that has already been described.[3] The system was lightly baked, pumped to a pressure $\leq 2\times10^{-8}$ Torr (after filling of an internal Meissner trap), and then filled with the Ar sputtering gas to a pressure of 2.5 mTorr. The multilayer constituents were sputtered at rates ranging from 0.9 to 1.4 nm/s through masks shaped to give a standard four-probe current-in-plane geometry with sample width 1.6 mm, voltage lead separation of 5.2 mm and current lead separation of 10 mm. Measurements with a traveling microscope showed that the lengths and widths of the different masks were the same to within a few percent, and variations in lengths and widths over one complete set of samples were less than 5%. We will see below that our reproducibility in ρ from completely independent sputtering runs was typically ±10%. Measuring currents of 0.1, 0.5, and 1 mA were used to check that the resistances were current independent. The Ag/Cu and Ag/Au resistances were measured at room temperature (assumed about 295 K) and at 4.2 K in a helium storage dewar. The Ni/Co saturation resistances were measured at room temperature and at 5 K in a Quantum Design MPMS system with the field in the plane of

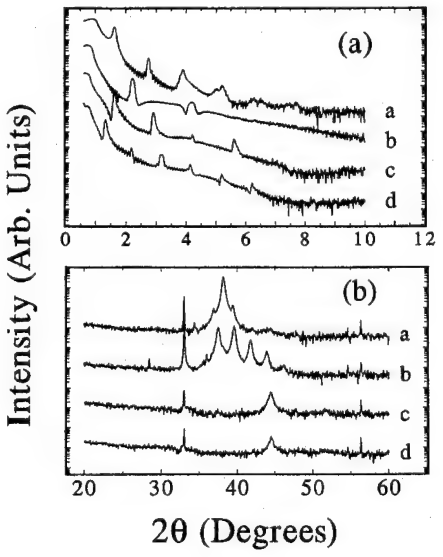

FIG. 1. (a) Low-angle and (b) high-angle Cu $K\alpha$, θ-2θ x-ray diffraction patterns of representative samples at room temperature. In both graphs, each pattern is offset by a factor of 10^2 to 10^3 for clarity. The letters identify the samples: a=[Ag(3.3 nm)/Au(4.5 nm), N=15]; b=[Ag(3.3 nm)/Cu(1.2 nm), N=26]; c=[(Ni(4.2 nm)/Co(2.4 nm), N=15]; and d=[Ni(4.2 nm)/Co(5.0 nm), N=11], where N=number of bilayers.

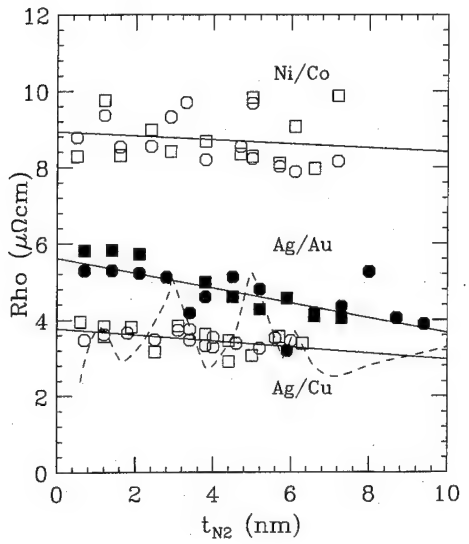

FIG. 2. Resistivity (Ag/Cu—lower open squares and circles—and Ag/Au—filled squares and circles) or saturation resistivity (Ni/Co—upper open squares and circles) vs thickness t_{N_2} for N_2=Cu, Au, or Co, for multilayers with total thickness ≈100 nm. For each metal pair, squares and circles are for multilayers made in completely independent sputtering runs. The solid lines are least squares fits to all of the data for a given metal pair. The dashed curve shows the oscillatory behavior reported in Ref. 1.

the layers and parallel to the current direction. In this geometry we see small positive magnetoresistances like those seen by Gallego *et al.*[4] (i.e., the resistance is a maximum at high fields), with saturation fields comparable to theirs.

Figure 1 shows Cu $K\alpha$, θ-2θ x-ray diffraction patterns of both low-angle superlattice lines and high-angle satellites for representative multilayers. Usually, several low-angle lines are seen, normally with strong Keissic fringes from the top and bottom edges of the films. Rocking curves at the first few lines show very narrow specular spikes (~0.03° in ω for Ni/Co and ~0.05° for Ag/Au and Ag/Cu, where ω is the rocking angle) and low fractional diffuse intensities. All of these facets of the data evidence good layering and are quite comparable to the low angle x-ray data of Gallego *et al.*[5] The high-angle satellites for Ag/Cu and Ag/Au demonstrate strong (111) texture in the plane normal to the layers and good coherence (~24 nm). Rocking curves were ~9° in ω. In contrast, our Ni/Co high-angle scans show no clear evidence of superlattice satellites and the high-angle rocking curves are wide (~20°), indicating that our samples have only modest (111) texture.

Figure 2 shows the resistivities at 4–5 K of two independent runs for each metal pair, calculated using the nominal (intended) layer thicknesses. Using the thicknesses derived from x-ray data would make no significant difference for the Ni/Co and Ag/Cu multilayers, or for the Ag/Au ones from the first run, since those thicknesses typically averaged only a few percent lower than the nominal ones, and did not change the patterns of the data. The situation for the second Ag/Au run is more complex; the x-ray bilayer thicknesses averaged about 8% lower than the intended ones, but also did not change the pattern of the data. The cause of the lower x-ray thicknesses in this case is under investigation. The solid straight lines in Fig. 2 are least-square fits for all data points. For comparison, the dashed curve shows the Co/Ni data of Gallego *et al.*[1]

Ag/Cu

We start with our data for Ag/Cu, which are immiscible and have our lowest average resistivities, similar to those of Gallego *et al.*[1] We see that the reproducibility between our two independent sputtering runs is excellent, with any variations about the average straight line only ±10%, similar to our reproducibility and to that of Gallego *et al.* The peak to peak variation of our data is less than half of theirs, and any reproducible oscillations in our data could not have an amplitude larger than a fourth to a fifth of theirs.

Ag/Au

For Ag/Au, which like Ni/Co are completely miscible, our average resistivities (solid line) are about 50% larger than both ours for Ag/Cu and those of Gallego *et al.*[1] for Ni/Co. Here, aside from one omitted datum,[6] the data from our first run (filled squares) show little evidence of oscillations beyond our minimum reproducibility of ±10% about the average straight line. The second run, in contrast (filled circles) shows a few larger variations that could be fit with a (not completely periodic) oscillation amplitude almost as large as that seen by Gallego *et al.* We thus have two possible interpretations. (1) That the apparent oscillations in the second run are spurious, in which case we can rule out oscillation amplitudes more than about one-fourth of those seen by Gallego *et al.* in Ni/Co. (2) That the apparent oscillations in the second run are real, and arise from some difference in conditions from the first run not yet under our control. We do not see any strong systematic differences between the x-ray scans from the two runs, aside from the shift in the average bilayer thickness already noted.

Ni/Co

For Ni/Co, our average $\rho_S \approx 9\ \mu\Omega$ cm is much larger than those for our other sample sets and for those of Gallego *et al.*[1] The maximum variations in our data (~2 $\mu\Omega$ cm) are almost as large as those seen by Gallego *et al.*, but still within ±10% of our average values. Taken separately, the data for each of our two runs mimics some of the oscillatory structure of the data of Gallego *et al.*, but only their first weak peak at $t_{Co} \approx 1.4$ nm is reproduced in both runs. Taken together, our two data sets do not show reproducible oscillations anywhere near as large as those seen by Gallego *et al.*

CONCLUSIONS

To summarize, we have measured the resistivities of Ag/Cu, Ag/Au, and the saturation resistivities of Ni/Co, multilayers sputtered onto Si. We do not in any case find reproducible periodic oscillations of amplitude larger than our ±10% reproducibility. Our results indicate that mean-free-paths longer than the multilayer period are not enough to see

oscillations. Rather, our data strongly suggest that any such oscillations require additional constraints including, perhaps, epitaxial growth.

[6] We have omitted a filled square for a sample of Ag(3.3 nm)/Au(2.8 nm) for which the resistivity at 5 K increased as the sample was remeasured, from an initial value consistent with the other filled squares to later values much larger. We ultimately found this sample to be cracked, and we do not know if the crack was already present when it was first measured. Several other samples were also remeasured, yielding much smaller changes, if any.

Resonant near-sound reorientation of the domain wall plane in yttrium orthoferrite

M. V. Chetkin, Yu. N. Kurbatova, and A. I. Akhutkina
Department of Physics, Moscow State University, Moscow, 119899, Russia

The dynamic orientation of the moving domain wall (DW) inclined at the static at an angle of about 50° to the surface of the plate of the orthoferrite cut perpendicularly to the optical axis was investigated. In the process of the increase of the domain wall velocity a very sharp decrease of the visible thickness of DW takes place near the transversal sound velocity. The moving domain wall changes its orientation plane and becomes almost perpendicular to the plate. This result may be caused by renormalization of anisotropy or dynamic minimization of domain wall energy. The solitary defection wave can propagate along self-organizing structure in the domain wall as a result of supersonic instability. © *1996 American Institute of Physics.* [S0021-8979(96)77408-2]

I. INTRODUCTION

The canted (weak) ferromagnets—orthoferrites are single magneto-ordered crystals, where the domain wall can move with supersonic velocities.[1,2] The motion of domain walls (DW) with near-sound velocities possesses several interesting peculiarities. During the transition to the supersonic motion, the DW ceases to be one-dimensional object. DW changes its initial plane rectilinear form and becomes tilted to the surface of the sample. The self-organizing periodic structures with singular points are formed on supersonic dynamic DW.[3] The amplitudes of the structures and the visible DW thickness decrease as the DW velocity is approaching the limiting velocity c, which is equal to 20 km/s.[4] This velocity is equal to that of spin waves on the linear part of their dispersion law.[4,5] So, the study of the DW dynamics in the orthoferrites can be useful for determining of the magnon dispersion curves.

II. EXPERIMENTAL PROCEDURE

Most experiments on the domain wall dynamics in the orthoferrites were performed on plates cut perpendicular to the optical axis.[6] In these plates two main types of rectilinear domain walls exist: (1) perpendicular both to the surface of the plate plane and to the a axis, and (2) inclined to the surface of the plate plane at an angle of about 50° and parallel to the a axis. Observed with the help of Faraday rotation, the visible thickness of the domain wall in the last case is equal to 60 μm in a sample having a thickness of 100 μm. Such a single DW in the sample exists in the magnetic fields perpendicular to the surface of the sample with a grad H=2000 Oe/cm. Magnetic moments of almost all orthoferrites can rotate only in the ac plane which is inclined at an angle of about 50° to the surface of the plate. This paper is devoted to the experimental study of the dynamic orientation of the DW at room temperature. It was shown that the visible thickness of the domain wall initially inclined to the plate surface gradually decreases as the domain wall is approaching the limiting velocity. A very sharp decrease of the visible thickness was observed near the transversal sound velocity. The method of double high speed photography was used in the plates of $YFeO_3$ cut perpendicular to the optical axis at room temperatures. The N_2 laser with transversal discharge was used. The thin plate of quartz with a small hole was placed in the discharger of the laser. The discharger was supplied by a sound mutter. These measures provided high temporal stability, a long term and soundless work of the laser. This laser pumped rodamin 6 G dye laser. Pulses of red light of 0.25 ns duration were generated in the same manner as in Ref. 3.

III. EXPERIMENTAL RESULTS AND DISCUSSION

Twofold high speed photography allows to study the domain wall velocities.[6,7] With an increase of the domain wall velocity the slow decrease of the visible thickness of DW have been observed. Near the transversal sound velocity the very sharp decrease of the visible thickness of the moving domain wall up to 8–10 μm was observed (see Fig. 1). The plane of the domain wall abruptly leaves the ac plane and at this velocity becomes almost perpendicular to the surface of the sample. This transition takes place in the range of velocities of 200–300 m/s below of the transversal sound velocity. The minimum visible domain wall thickness existed in the magnetic field range ΔH of about 30 Oe, including the region on the $V(H)$ dependence where domain wall velocity stays at the velocity of the transversal sound. After the transition to the supersonic velocity the visible thickness of moving DW increases again. The non-one-dimensional self-organizing structures arise on the dynamic domain wall of orthoferrite. The similar structures were investigated earlier

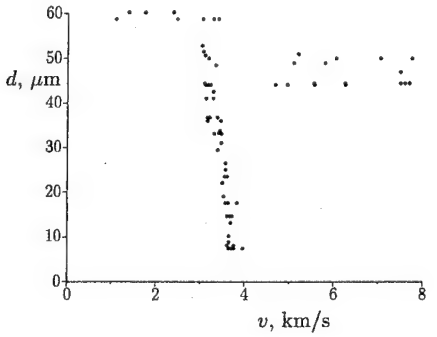

FIG. 1. Dependence of visible thickness of the domain wall of the orthoferrite on its velocity. The static domain wall is tilted with respect to the plate surface.

FIG. 2. Twofold high-speed photograph in the contrast of domain wall of self-organizing structure on supersonic domain wall moving at the velocity 12 km/s. The time delay between two light pulses is 4 ns.

FIG. 3. Twofold high-speed photograph in the contrast of the domains of the solitary wave of the domain wall deflection—of the small kink, moving along domain wall. The domain wall moves from down to up. The black region is the area, which the domain wall passes during the time delay between the two light pulses. Two positions of the kink indicated by arrows.

for the domain walls perpendicular both to the a axis and to the surface of the orthoferrite plate cut perpendicular to the optical axis.[3] In Fig. 2 it is easy to see the almost rectilinear parts of the structures. These parts have been observed only for structures with a large period and amplitude. The intersecting semicircular parts of the structure were also observed under certain condition early.[3,6]

In accordance with a magnetoelastic theory[7] an essential renormalization of the magnetic anisotropy (up to the change of the sign of the anisotropy constant) occurs near the transversal sound velocity if the dissipation of sound is small. This fact can account for the observed domain wall reorientation near the sound velocity. The experimental results of Ref. 8 have shown that the moving domain wall really generates a solitary wave of deformation. Its amplitude increases sharply at the sound velocity. This deformation is small and cannot be observed at room temperature. But its amplitude sharply increases at 2 K and this deformation has been observed using the double Doppler shift of frequency with the help of a high-contrast spectrometer based on Fabry–Perrot five-pass interferometer.[8] It is obvious, that in the interpretation of the experimental results it is necessary to take into account the high dissipation of sound, especially at room temperature. If the renormalization of anisotropy really takes place near sound velocity, the generation of the vertical Bloch lines on the domain wall in orthoferrites and its motion under the influence of magnetic field and gyroscopic forces are possible. But this issue is a separate subject. The observed change of DW orientation can also be a result of an increased rigidity of the DW near the sound velocity. The similar situation can also occur near the limiting velocity. Increased rigidity of DW in these cases has also been confirmed by the results of experiments on relaxation of non-one-dimensional disturbance on DW, moving at near-sound and near-limiting velocities.[6] The decrease of the area of DW moving at near-sound and limiting velocities may be caused by dynamical minimization of its energy for domain walls of any orientation in the plate of the orthoferrite.

Small regions of the domain wall perpendicular to the plate surface and regions inclined to the sample surface coexist in the DW during supersonic motion (Fig. 3). The right part of the domain wall in Fig. 3 has not overcome the sound barrier and moves in the initial direction on sound velocity. On almost rectilinear tilted part of the supersonic structure one can see a solitary deflection wave of a small amplitude—a small kink moving along the domain wall. The velocities of the domain wall v and the one of the kink along the DW u are equal to 12 and 16 km/s respectively. So $u^2+v^2=c^2$, is valid in accordance with predictions of quasirelativistic theory of domain wall dynamics in weak ferromagnets.[5,6] This small kink arises on the domain wall after a short-time fast decrease of the amplitude of the pulsed magnetic field driving the domain wall. The small kink has a sharp front, moves along the domain wall from the left to the right and is similar to the one accompanying the VBL in a garnet film moving by a gyroscopic force.[6,9] Instability of the supersonic domain wall motion and the absence of the hysteresis on the dependence of v on H near the sound velocity could be responsible for the generation of the small kink.

Approach to the anhysteretic surface

M. J. Sablik

R. A. Langman
University of Tasmania, P.O. Box 252C, Hobart, Tasmania, Australia 7001

In this paper, we have investigated experimentally the approach to the anhysteretic surface in $M-H-\sigma$ space. In particular, for a 0.5 wt% carbon steel specimen, we have applied 73 MPa tension and a bias field H and determined the end flux density after superimposing an ac field of amplitude gradually decreasing to zero. We find that the point on the anhysteretic curve for 73 MPa tension and field H is not approached unless the initial amplitude of ac field is sufficiently large to overcome domain wall pinning, which restrains redistribution of the domains. A similar experiment in which stress is cycled was also done. Stress was cycled discretely between 0 and 140 MPa, with the discrete changes about 73 MPa eventually decreasing to zero in bias field H. It was found that the loci of (B,H) end points did not approach the anhysteretic, suggesting that larger amplitude changes in stress and perhaps more continuous changes are needed to overcome domain wall pinning.
 [S0021-8979(96)77508-9]

I. INTRODUCTION

The magnetic anhysteretic curve is a locus of points giving the (M,H) values which correspond to thermodynamic equilibrium points for a given ferromagnetic material. It has been stated many times[1–3] that the anhysteretic curve can be reached experimentally for a particular magnetic bias field by superimposing an ac field on the bias field and allowing the ac amplitude to decrease to zero. In this work, we shall demonstrate experimentally that whether the anhysteretic is actually reached is dependent upon the initial ac amplitude.

Recently a number of authors[4–7] have suggested or implied that there is more than one anhysteretic curve for a given magnetic material depending on the amount of external stress σ that is applied to the material.[5,7] We have observed that the reason for this multiplicity of anhysteretics is that the anhysteretic is actually a surface and not a curve. In particular, the anhysteretic is a surface in $M-H-\sigma$ space where M is magnetization and H is magnetic field intensity. This is the same concept as in $P-V-T$ space, where the ideal gas equation is a locus of thermodynamic equilibrium points that corresponds to a $P-V-T$ surface, where P is pressure, V is volume, and T is temperature.

Figure 1 shows a schematic anhysteretic surface that would be expected in $M-H-\sigma$ space. Three $M-H$ sections are shown for constant stresses σ_0, 0, and $-\sigma_0$. The anhysteretic curves for the corresponding stresses are shown for each section. These curves are simply sections of the anhysteretic surface. Also shown on the $M-H$ sections corresponding to stress σ_0 and $-\sigma_0$ are initial magnetization curves to field H_0. In the $M-H$ section for constant positive stress is shown a schematic zig–zag path to the anhysteretic followed by the magnetization in response to a decreasing ac magnetic field intensity. We shall see later that the actual picture is not quite so simple.

Jiles and Atherton suggested[8] that similar movement toward the anhysteretic occurs when the stress is changed, regardless of the sign of the stress. Thus, it would seem that application of an alternating stress on a bias stress σ and allowing the amplitude of the alternating stress to be decreased to zero also ought to be a way to approach the anhysteretic surface. This would seem to be consistent with the cyclic stress behavior discussed in Refs. 4–7.

Figure 1 shows a schematic path for magnetization at constant field H_0 and negative (compressive) bias stress $-\sigma_0$ when an alternating stress is applied with decreasing amplitude about the bias stress. This would be the analog of the other zig–zag path for alternating ac magnetic intensity at a mean H_0 and constant σ_0. Again, we shall show experimentally that the real situation is not quite this simple.

Domain wall pinning is the major reason why the actual approach to the anhysteretic surface is more complicated

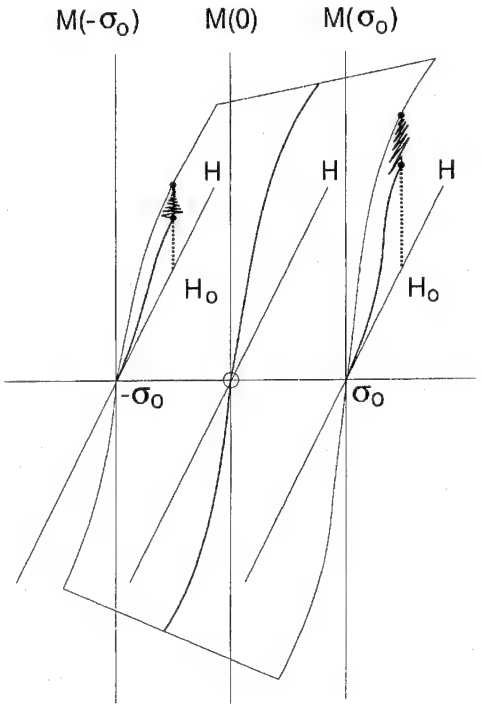

FIG. 1. Depiction of a schematic anhysteretic surface in $M-H-\sigma$ space. Details are discussed in the text.

 0021-8979/96/79(8)/6134/3/$10.00

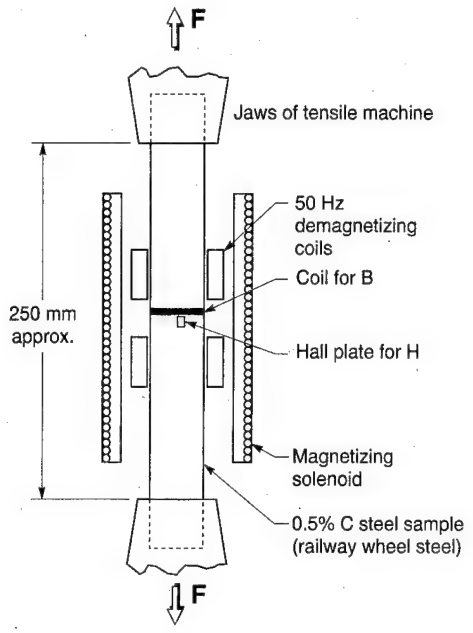

FIG. 2. Diagram of experimental setup.

than in the above description. The pinning must first be overcome in order to sufficiently redistribute the domains so that the anhysteretic is actually approached. The experimental consequences of this will be discussed below.

II. EXPERIMENTAL RESULTS AND DISCUSSION

Measurements were made on a 0.5% C steel specimen, cut from an Australian railway wheel, with coercivity approximately 1000 A/m. Figure 2 shows the experimental setup. A secondary coil was wrapped about the middle of the specimen, and a ballistic method was used to obtain the flux density when the current in the primary magnetizing coils was reversed. A Hall probe next to the secondary coil measured H. Different stresses were applied to the ends of the specimens. Applied force was known from the dial of the testing machine and applied stress was calculated from that. The specimen had a cross section of 40×8 mm. Errors of uncertainty were estimated to be ±2% for H, ±2% for B, and ±5% for stress σ.

Figure 3 shows $B-H$ curves obtained for a specimen under +73 MPa of stress (tension) when different initial amplitudes of 50 Hz decreasing amplitude ac current are superimposed on the quasi-dc bias field H. Curve 1 is for when zero ac amplitude is superimposed—i.e., it is the initial magnetization curve. Each other curve is for a different amplitude of ac current and each other curve is the locus of flux densities $B(H)$ obtained for different bias fields H when the superimposed ac field amplitude is allowed to slowly go to zero. Each of the experimental points on curves 2–6 is obtained after a sequence of starting from the demagnetized state, then applying the quasi-dc bias field H, then applying the 50 Hz ac field amplitude, then gradually decreasing the 50 Hz field amplitude to zero and measuring the resultant flux density from the emf in the secondary coil at the end of this process to obtain the point (H,B).

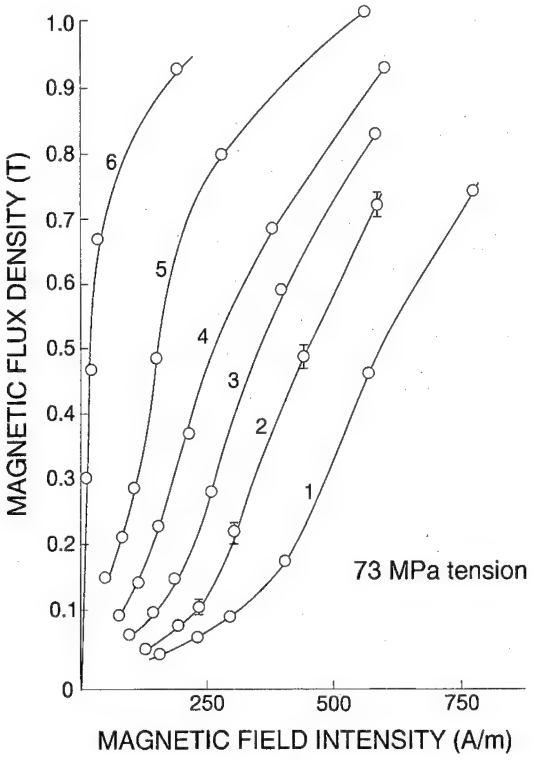

FIG. 3. Loci of $B-H$ points obtained for various bias field H and for 73 MPa of tension σ for different initial amplitudes of a 50 Hz ac field decreasing gradually to zero. Curve 1, zero ac field; curve 2, 40 A/m ac; curve 3, 80 A/m ac; curve 4, 160 A/m ac; curve 5, 320 A/m ac; curve 6, 800 A/m ac.

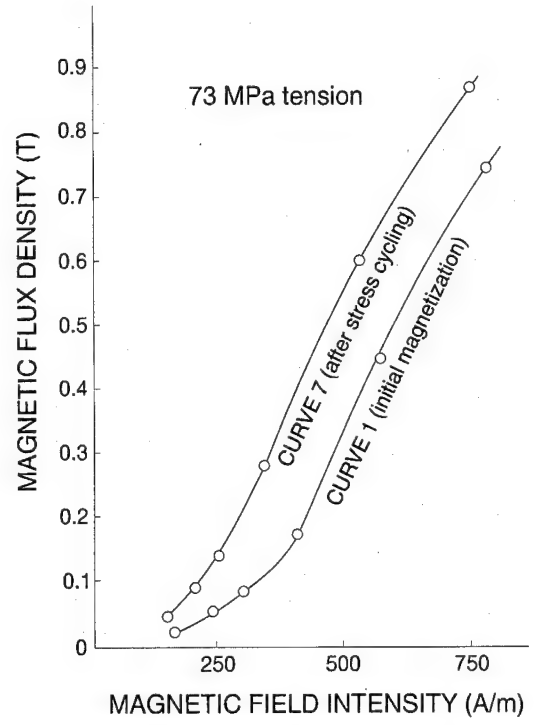

FIG. 4. Loci of $B-H$ points obtained for various bias fields H and for 73 MPa of bias tension. Curve 1 corresponds to curve 1 in Fig. 2. Curve 7 is for a cyclic stress application cycling between 0 and 140 MPa of gradually decreasing amplitude. The stress changes are discrete, rather than continuous.

It will be noted that the end product of decreasing the ac field to zero in a bias field H and under stress σ is not necessarily a point on the anhysteretic curve for stress σ (see curves 2–5). When the ac amplitude gets large enough the overcome almost all the domain wall pinnings, then the resulting $B-H$ curve has the familiar shape of an anhysteretic curve (curve 6), in this case requiring as much 800 A/m of ac field to approach what is considered to be almost the true anhysteretic.

Figure 4 is the corresponding $B-H$ curve (curve 7) for 73 MPa tension, but after stress cycling 73 MPa→140 MPa→0→120 MPa→20 MPa→100 MPa→40 MPa→80 MPa→60 MPa→73 MPa. Curves 2 and 7 are very similar. One would conclude that a roughly 70 MPa cycling amplitude of stress is not enough to approach the anhysteretic.

Different patterns of stress cycling at a bias field of about 500 A/m were also tried, but generally speaking, there was little difference in the final flux density (falling in a range from 0.54 T to 0.6 T).

Cullity[9] has also discussed the approach to the anhysteretic and has asserted that the initial ac amplitude superimposed on the bias field ought to be enough to saturate the specimen. Our results showing an anhysteretic shape at 800 A/m but not at approximately half that value confirms the conclusion that the initial ac amplitude must be sufficiently large. Whether the ac amplitude must be large enough to saturate the specimen is unanswered by our work, but it would seem that to reach the anhysteretic, the amplitude must be large enough to extend to an H regime where domain wall translation is minimal—i.e., beyond the knee of the initial magnetization curve.

III. CONCLUSIONS

The results, both of field and stress cycling at constant (σ_0,H_0), indicate that the approach to the anhysteretic thermodynamic surface is complicated. Cycling needs to be done with an initially sufficiently large amplitude that domain wall pinning could be overcome sufficiently to redistribute all the domains.

In the case of stress cycling, more work needs to be done to see if a sufficiently large cyclic stress amplitude can be applied so that the anhysteretic can indeed also be approached.

Studies of remanence in granular Ni–SiO_2 films

Y. Xu,[a] B. Zhao, and X. Yan
Department of Physics, The Hong Kong University of Science and Technology, Clear Water Bay, Kowloon, Hong Kong

We have studied microstructure and remanent magnetization of the granular Ni–SiO_2 films. Both analysis of the transmission electron microscope images and that of the particle size distribution via remanence studies support the hypothesis that both superparamagnetic and ferromagnetic components coexists in the nearly percolating films. © *1996 American Institute of Physics.* [S0021-8979(96)77608-5]

I. INTRODUCTION

For conventional ferromagnetic or ferrimagnetic materials, the remanent magnetization will remain in the same direction as the saturated one, following that of the applied external magnetic field. For antiferromagnetic, superparamagnetic or spin glass materials, there will be a zero or slightly positive remanent magnetization. An opposite magnetic response is often associated with a diamagnetism, which will leave zero response upon removing the applied magnetic field to zero. A clockwise $M-H$ loop is closely related to the negative remanence, or the opposite remanence upon removing the applied field to zero, and is not expected from a magnetic response of a homogeneous system.[1] Related phenomenon such as the reverse thermal-remanent magnetism has been observed in geomagnetic materials[2] and were explained in terms of two components having different Curie temperatures,[3] and a hysterisis loop shifted with respect to the origin has been observed in amorphous[4] and certain multilayered materials[5,6] and was explained either in terms of interface exchange interaction[5,6] or exchange anisotropy.[7] However, a complete understanding of this phenomenon in inhomogeneous materials is still lacking due to the lack of systematic studies of both the microstructure and the remanent magnetization. Recent observation of the negative remanence in systems with nearly percolating magnetic nanostructures[8] provide this opportunity.

In this article, we describe studies of microstructure and remanent magnetization in granular (Ni,Fe)–SiO_2 films. Analysis again supports the hypothesis[8] that the negative remanence observed in nearly percolating magnetic nanostructures is likely due to the coexistence of both superparamagnetic (SPM) and ferromagnetic (FM) components, and magnetostatic interactions that can favor the opposite alignment between the two components.

II. EXPERIMENTS

Granular $(Ni,Fe)_x-(SiO_2)_{1-x}$ films were prepared using a Denton magnetron rf sputtering system, where pure Ni target with a few small Fe pieces and SiO_2 target were mounted on two separate sputtering guns. The structure of the films were studied via x-ray diffraction and transmission electron microscope (TEM), and the chemical analysis, via x-ray photoelectron spectroscope and energy dispersive x-ray spectroscope (EDX). dc magnetization was measured for all those films between 5 and 300 K using Quantum Design's SQUID Magnetic Property Measurement System for the magnetic field applied parallel to the plane of the film.

III. MICROSTRUCTURE CHARACTERIZATION

Figure 1 shows the TEM bright field images (center), electron diffraction patterns (right), and TEM dark field images (left) of the films for (a) $x=0.3$, (b) 0.4, (c) 0.5, and (d) 0.6, respectively. The bright images display microstructure characteristic of typical granular metal films, containing small metallic particles of spherical in shape. From (a) to (d), it is not difficult to see that the average particle size (its diameter) increases smoothly from 3 nm for $x=0.3$ to 6 nm for $x=0.6$, going smoothly through the percolation threshold between 0.55 and 0.6, corresponding to x' of 0.6 according to the resistivity measurements.[9,10] By tilting the sample holder, no preferred orientation of the particles was observed

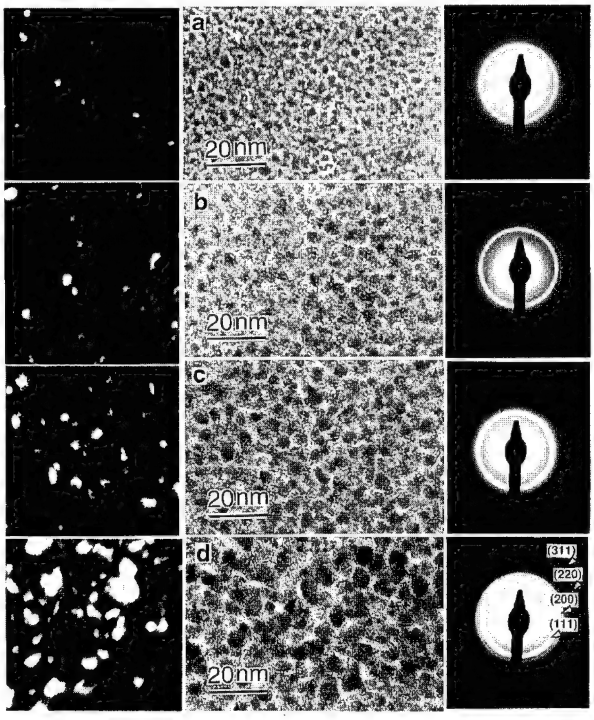

FIG. 1. Bright field TEM images (center), electron diffraction pattern (right), and dark field TEM images (left) of $(Ni, Fe)_x(SiO_2)_{1-x}$ for $x=0.3$ (a), 0.4 (b), 0.5 (c), and 0.6 (d).

TABLE I. Some parameters for $(Ni,Fe)_x(SiO_2)_{1-x}$.

Nominal magnetic volume fraction, x	0.3	0.4	0.5	0.6
Measured magnetic volume fraction, x'	0.336	0.427	0.518	0.650
Fe/Fe+Ni (%)	29	20	14	11
Mean particle size (nm) from TEM	3.5	5.4	6.1	7.9
Mr/Ms (%) at $T=200$ K	0.53	−1.0	−4.0	5.5
Mr/Ms (%) at $T=5$ K	34.6	36.9	36.2	

for all of the samples. The electron diffraction patterns were taken from an area of about 0.5 μm indiameter. The diffraction patterns display rings characteristic of an fcc crystalline structure of a lattice constant closer to that of bulk nickel. Table I shows the magnetic volume fraction x' and the fraction of Fe in Ni–Fe evaluated by EDX, and the granular particle size d as evaluated by TEM bright field images. Note that no diffraction rings of bcc Fe or that of silicides can be revealed in diffraction patterns. Therefore, the system can be considered as fcc Ni–Fe alloy particles of a few nanometer size mixed with the insulating SiO_2 amorphous phase.

Dark field TEM images were taken by using one large aperture which covers about a quarter of the major diffraction rings (111, 200, and 220) for films with $x=0.3$, 0.4, 0.5, and 0.6. It is seen from Fig. 1(a) that particles were well separated for x well below the percolation threshold. Starting from (b), some particles are connected with bottlenecks, while others remain isolated separated by amorphous SiO_2 bridges. The microstructure with such bottlenecks may be termed "labyrinth structure." Such a bottleneck was evident by a white arrow in Fig. 1(d). As x increases, both the size and the volume fraction of the labyrinth structure increase. Above the threshold ($x\geqslant 0.6$), great number of particles are connected by small bottlenecks, and the size of the labyrinth structure diverges and approaches to the sample size. One can see that particles are getting better connected to each other from (a) to (d) in Fig. 1. Thus, it is reasonable to suggest that as x increases, particles start from well isolated ($x\leqslant 0.3$), through partially isolated and partially connected ($0.4\leqslant x\leqslant 0.55$), to well connected ($x\geqslant 0.6$).

IV. STUDIES OF REMANENCE

Figure 2 show the thermoremanent magnetization, $Mr(T)$, which was measured at zero field after removing a positive field of 10 kG, for various x's. Upon increasing temperature, $Mr(T)$ decreases sharply from a large positive value and either changes to negative for $x=0.40$, 0.50, and 0.55, or to zero for $x=0.15$ and 0.30. Note that for the film with $x=0.55$, $Mr(T)$ changes to a negative value at about 100 K and reaches the minimum at about 200 K. In the same temperature regions, zero field cooled susceptibility χ has a broad maximal.[8] Similar negative remanence was also observed in the $M-H$ loop at 200 K for these films with $x=0.4$, 0.5, and 0.55, but not in those with $x=0.15$, 0.3, and 0.6, as shown in Table I for Mr/Ms at 200 K. In contrast, Mr/Ms at 5 K remains to be positive for all films. The

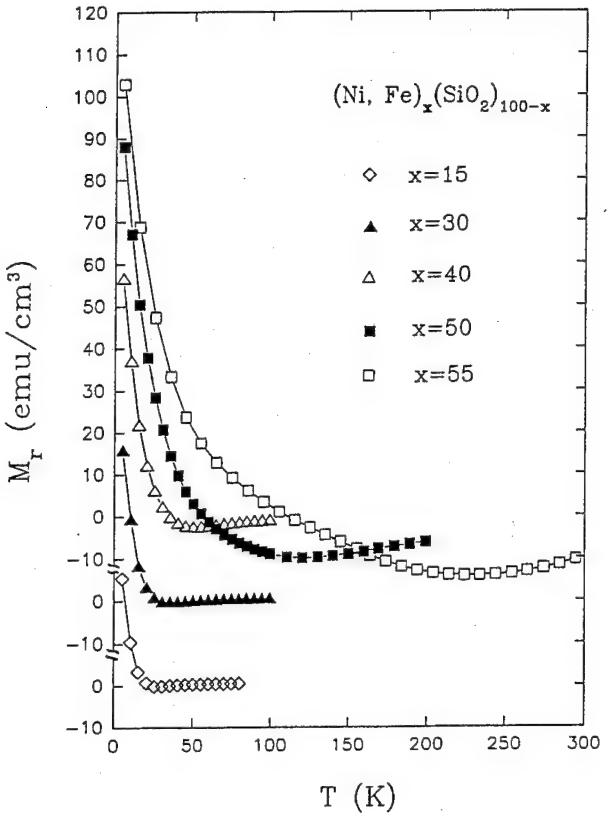

FIG. 2. $Mr(T)$ for $x=0.15$, 0.3, 0.4, 0.5, and 0.55.

appearance of the negative remanence only for the nearly percolating films ($0.4\leqslant x\leqslant 0.55$) indicates the importance of the finite sized labyrinth structure where there are some connected ferromagnetic (FM) particles in addition to the isolated superparamagnetic (SPM) particles.

Let us now examine the hypothesis of the existence of both SPM and FM components in the nearly percolating granular films by studying the remanent magnetization after removing positively saturated field to zero at temperature T, $Mr'(T)$, where $'$ is used to defer it from Mr. It is known[11] that $Mr'(T)$ is a measure of the relaxed magnetization at a given temperature T in a given measurement time which is in the order of 100 s for our SQUID measurement. Such a relaxation process is thermally activated associated with an energy barrier. When the energy barrier has a distribution function $f(E_a)$, Mr' will decrease gradually as increasing temperature. A positive Mr' thus indicates that a fraction (Mr'/Ms) of the system can not reverse its magnetization with the help of the thermal energy. Following Ref. 11, $Mr'(T) = Ms(T)\int_{E_a^{\rm crit}}^{\infty} f(Ea)dEa$, where $E_a^{\rm crit}$ is a critical energy barrier below which thermal activation may induce magnetization reversal. Since Ea is proportional to T_b, $f(E_a)$ is proportional to the blocking temperature distribution $f(T_b)$, which may be obtained by numerical derivative of "$Mr'(T)/Ms(T)$" with respect to temperature. Assuming that the energy barrier is entirely due to the volume dependent anisotropy constant, $f(T_b)$ represents the distribution of the volume of the magnetic particles.

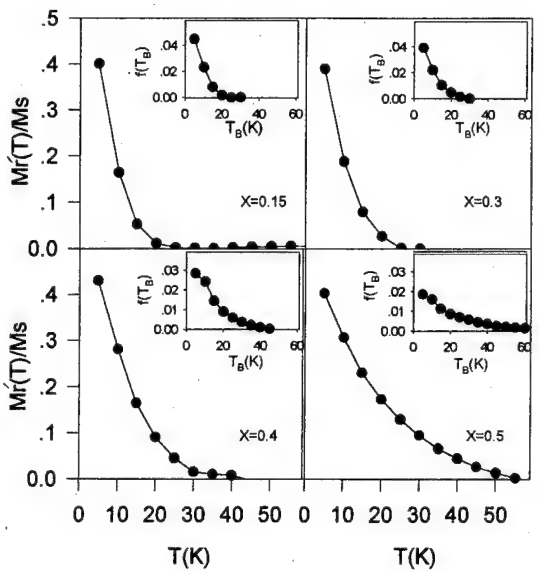

FIG. 3. $Mr'(T)/Ms(T)$ for x=0.15, 0.3, 0.4, and 0.5. Inserts show the corresponding blocking temperature distribution function f(Tb).

Figure 3 shows $Mr'(T)/Ms(T)$ vs T for samples with x=0.15 (a), 0.3 (b), 0.4 (c), and 0.5 (d), respectively. Note that only the temperature region with positive $Mr(T)$ is included due to the difficulty of this method in treating negative remanence.[8] Inserts in Fig. 3 show the blocking temperature distribution $f(T_b)$ which was obtained by numerical derivative of Mr'/Ms with respect to T. Note that upon increasing x, both the mean value and the uncertainty of the energy barrier increases. The larger uncertainty in the energy barrier for a larger x also indicates a larger uncertainty of the particle volume, which is consistent with more extended labyrinth structure observed in the dark field TEM images. Magnetic particle size distribution was also studied via ac susceptibility as functions of temperature and frequency for different x's.[12] Similar trend of increased particle size distribution with increasing x was concluded.[13] Thus both analysis of the TEM images and that of the particle size distribution via remanence and ac susceptibility studies support the hypothesis of the coexistence of both the superparamagnetic and ferromagnetic components in a given temperature.

V. SUMMARY

We have studied microstructure and remanent magnetization of the granular Ni–SiO_2 films. Both analysis of the TEM images and that of the particle size distribution via remanence studies support the hypothesis that both superparamagnetic and ferromagnetic components coexist in the nearly percolating films at a given temperature.

[13] There is a discrepancy between ac and remanence measurements in terms of the particle volume by a factor 5 or so. We feel that this is likely due to a small remanent magnetic field in the remanence measurement due to the past magnetic history, causing error in obtaining particle size distribution. Since ac measurements were done with no prior history for both the magnet and the sample, and is therefore more reliable.

Observation of giant Hall effect in granular magnetic films

A. B. Pakhomov,[a] X. Yan, and Y. Xu
Department of Physics, Hong Kong University of Science and Technology, Clear Water Bay, Kowloon, Hong Kong

The Hall effect in granular co-sputtered ferromagnetic metal–insulator films was found to increase dramatically as the magnetic volume fraction decreases toward the metal–insulator transition. The saturated Hall resistivity is up to 160 $\mu\Omega$ cm at $T=5$ K, that is almost four orders of magnitude greater than that in a pure magnetic metal sample. Close to the metal–insulator transition, both magnetoresistivity and the saturated Hall resistivity decrease with increasing temperature. Correlations of the Hall resistivity with resistivity and magnetoresistivity are discussed. © *1996 American Institute of Physics.* [S0021-8979(96)77708-1]

The discovery of giant magnetoresistance (GMR) in magnetic multilayers[1,2] and granular magnetic—nonmagnetic metal alloys[3] revived the interest to studies of magnetotransport in nanostructured inhomogeneous magnetic solids. Along with GMR, the extraordinary Hall effect was studied for transition metal granular solids. The values of the saturated Hall resistivities ρ_{xys} of up to 1 $\mu\Omega$ cm, that are greater than the typical values for pure ferromagnets, were observed.[4] The granular co-sputtered composite films studied in this work are different from those in Refs. 3 and 4 in that the nonmagnetic component is insulating, so a metal–insulator transition is observed at certain critical volume fraction of metal. Such systems have been widely studied before. Some works on Ni–SiO_2 films are listed in Ref. 5. But to the best of our knowledge, no experimental studies of extraordinary Hall effect in magnetic metal–insulator composites have been reported in the literature prior to Refs. 6 and 7. In this work we show that ρ_{xys} as large as 160 $\mu\Omega$ cm can be achieved near the metal–insulator transition. This is a factor of 4×10^3 enhancement compared to that in a metallic ferromagnet. By analogy with the "giant" magnetoresistance effect,[1–3] we call the observed phenomenon "giant" Hall effect.

The composite films of about 1 μm thick, with the different metal volume fractions x in the range $0.5<x\leqslant1$, were prepared on rotating glass substrates in a Denton magnetron co-sputtering system, with magnetic metal [$Ni_{85}Fe_{15}$ (Ref. 8)] and insulator (SiO_2) targets mounted on two separate guns. Near the metal–insulator transition, the samples consist of 5–8 nm metal grains imbedded in amorphous insulating matrix.[8] The magnetic metal volume fraction x was determined by energy-dispersive X-ray spectroscopy using a Philips EDAX XL30. The resistance and the Hall resistance were measured in the temperature range between 5 and 300 K, in the fields $|H|\leqslant2.15$ T. Magnetization was measured on a Quantum Design SQUID with magnetic field perpendicular to the film plane.

The Hall resistivity ρ_{xy} of ferromagnetic metals is a sum of two terms, of which the ordinary Hall resistivity, due to the Lorentz force, is proportional to the field. The second, extraordinary part, is attributed to spin–orbit interactions during scattering of the magnetically polarized conduction d electrons on impurities or phonons, and hence is proportional to magnetization.[9] If the extraordinary Hall coefficient is much greater than the ordinary one, the plots of the Hall resistivity against field look like magnetization curves. A small finite slope at fields over saturation is due to the ordinary Hall effect. A qualitatively similar shape was also observed for all our samples with magnetic volume fractions $x>0.53$. Shown in Fig. 1 are the field dependencies of the magnetization M, the resistivity ρ_{xx}, and the Hall resistivity ρ_{xy} for a sample with $x\approx0.61$, at $T=5$ K [Fig. 1, column (a)] and $T=300$ K [column (b)]. As the ordinary Hall effect is relatively small, the values of ρ_{xy} at $H=2$ T are referred to as the saturated Hall resistivity ρ_{xys} in this work. It can be seen that both ρ_{xys} and magnetoresistivity decrease with increasing temperature.

In Fig. 2 we show ρ_{xys} and ρ_{xx} as functions of x, at $T=5$ K. For x in region 1 shown in Fig. 2, the samples are metallic. At high temperatures the temperature coefficient of resistivity (TCR) is positive. However, below certain temperature which depends on x, the TCR crosses over to negative, which has been attributed[6,7] to the effect of electron–electron interactions.[10] Below that temperature, the dependence of ρ_{xx}

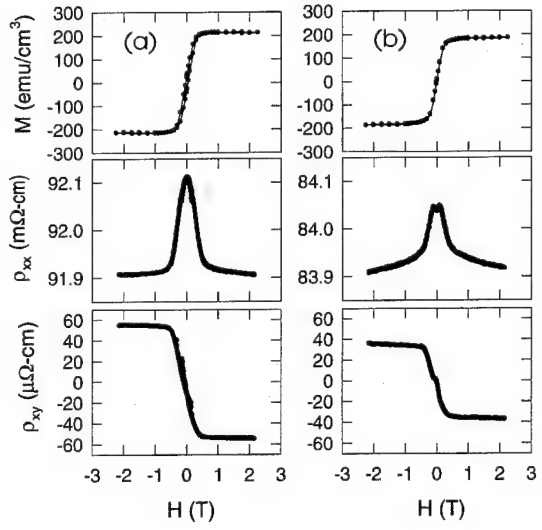

FIG. 1. Field dependencies of the magnetization M_x, the resistivity ρ_{xx}, the Hall resistivity ρ_{xy} for the sample with $x=0.61$ at (a) $T=5$ K and (b) $T=300$ K. The magnetic field is perpendicular to the sample plane.

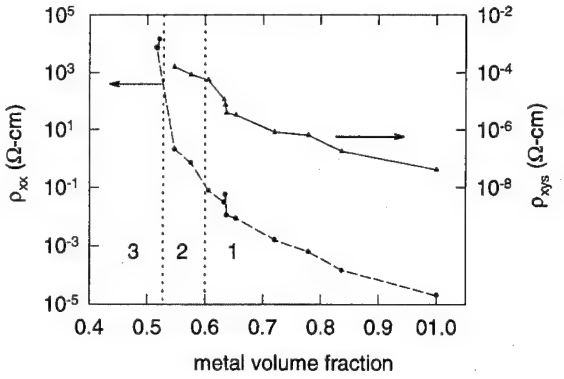

FIG. 2. Resistivity and the Hall resistivity as functions of the metal volume fraction x at $T=5$ K.

on temperature is approximately logarithmic.[10] An example of a ρ_{xx} vs T plot for the same sample as in Fig. 1 ($x=0.61$) is shown in Fig. 3. At the metal–insulator transition (region 2 in Fig. 2), the TCR is negative in the whole temperature range of 5–300 K, and the temperature dependence of resistivity is stronger than logarithmic.[6,7] In the dielectric region 3 conductivity is thermally activated.[6,7] The value of ρ_{xys} increases greatly with decreasing x, and reaches a maximum at $x\approx 0.55$, which is as large as 160 $\mu\Omega$ cm. The corresponding Hall coefficient defined as ρ_{xy}/H being $\sim -4\times 10^{-4}$ Ω cm/T for $H\leqslant 0.4$ T, compared to -7.7×10^{-8} Ω cm/T for $x=1$. Fitting the data for resistivity and Hall resistivity to the percolation relations $\rho_{xx}\propto[(x-x_c)/x_c]^{-t}$, and $\rho_{xys}\propto[(x-x_c)/x_c]^{-g}$,[11,12] was attempted.[7] At any reasonable choice of x_c, the fits gave the critical exponents t and g greater than those predicted by discrete percolation models [$t\approx 2$ and $g\approx 0.4$–0.5 (Refs. 11 and 12)].

To gain insight on the mechanisms of magnetotransport, in Fig. 3 we plot the saturation magnetization M_s, the

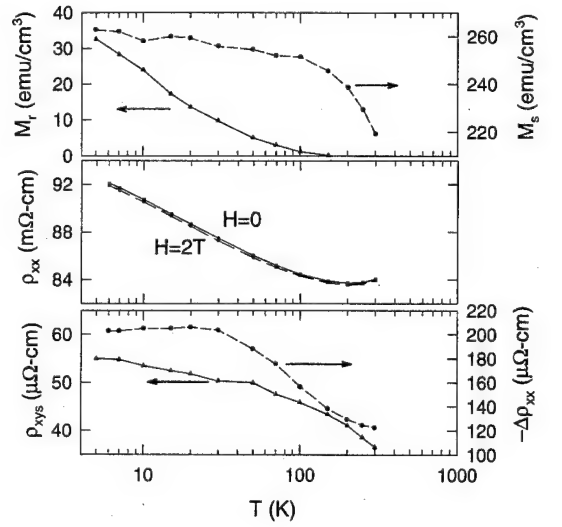

FIG. 3. Saturation magnetization (M_s) as defined in the text, remanent magnetization (M_r), resistivity ρ_{xx} at $H=0$ (squares and solid connecting line) and at $H=2$ T (triangles and dashed connecting line), magnetoresistivity $-\Delta\rho_{xx}=\rho_{xx}(0)-\rho_{xx}(2\text{ T})$, the Hall resistivity ρ_{xys} at $H=2$ T vs logarithm of temperature for the same sample as in Fig. 1, $x=0.61$.

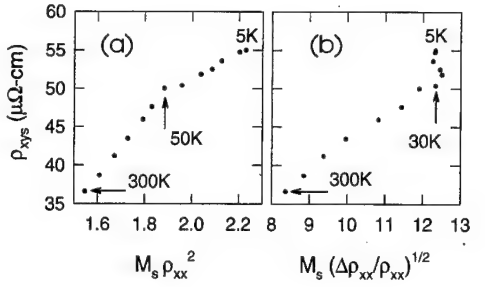

FIG. 4. This figure shows the correlations of the Hall resistivity with ρ_{xx}^2, and, at high temperatures, with $(\Delta\rho_{xx}/\rho_{xx})^{1/2}$. Temperature is an implicit parameter.

remanent magnetization M_r, as well as the resistivity ρ_{xx} at the fields of both $H=0$ and $H=2$ T, the magnetoresistivity—$\Delta\rho_{xx}=\rho_{xx}(0)-\rho_{xx}(2\text{ T})$, and the Hall resistivity ρ_{xys} defined above as functions of temperature for the same representative sample as in Fig. 1 ($x=0.61$). In this work we use the values of M at $H=2$ T for M_s, which was measured at a fixed field with temperature varying from 5 to 300 K. The remanent magnetization was measured by first setting the field to 3 T at 5 K, then setting it to zero and measuring the moment with stepping up temperature from 5 to 300 K. The temperature scale in Fig. 3 is logarithmic, primarily to demonstrate the logarithmic temperature dependence of resistivity at low T. We notice that the difference in resistivity at $H=2$ T and at $H=0$ is very small compared to the temperature dependent logarithmic correction, suggesting that the negative TCR is not associated with the change in spin-dependent scattering rates. The correction due to electron–electron interactions[10] being a probable reason. On the other hand magnetoresistivity, which is of the order of 0.2% of resistivity, was found to be negative for longitudinal, transverse and perpendicular geometries. This appears to suggest that the mechanism is likely to be spin-dependent scattering of conduction electrons on granular boundaries. Scattering decreases at saturation, when the directions of magnetization in different grains are more correlated. The variation of $|\Delta\rho_{xx}|$ below ~30 K is small, while between 30 and 300 K, it drops by roughly a factor of 2 (Fig. 3). We relate the crossover at 30 K to the onset of superparamagnetism,[14,15] corresponding to the blocking temperature determined by a single particle size. From the measurements of M_s and M_r vs T (Fig. 3) all particles are free to rotate above $T\sim 100$ K, which is likely to be related to the blocking temperature of the clustered particles.[8]

Only a small change in the slope of the ρ_{xys} vs $\log T$ curve around 50 K can be seen in Fig. 3. The crossover becomes more obvious from a plot of ρ_{xys} vs the product $\rho_{xx}^2 M_s$, with T an implicit parameter [Fig. 4(a)]. The scaling predicted by the side jump theory of extraordinary Hall effect[9] seems to hold, but the slopes are different below and above 50 K. Besides, the mechanisms developed for metals may not be valid for the system under investigation. It has been noted in Refs. 13 and 16 that the GMR and the extraordinary Hall effect in a Co–Ag granular system should be correlated. On the other hand, we assume that in a percolating ferromagnet the extraordinary Hall effect is due to scat-

terings of polarized conduction d electrons with spins aligned with the field, the number of these electrons being proportional to magnetization,[9] while magnetoresistance is due to scatterings of all electrons. A scaling in the form $\rho_{xys} \propto (\Delta\rho_{xx}/\rho_{xx})^n M_s$, where n is an unknown exponent, is examined. As shown in Fig. 4(b), the high temperature behavior can be successfully described by the latter relation for n of 1/2, but no correlation is observed at low temperatures. We admit that the particular value of n is not justified, and the choice of $n=1/2$ is arbitrary.

The giant Hall resistivity in the percolating granular magnetic system points out a number of interesting applications for Hall sensors. It may be used as a magnetic field sensing element in a read head of magnetic recording devices, in magnetic switching devices or in a magnetic random memory. The main advantages are that the Hall element will be sensitive to the direction of the magnetic field and will not require a bias field which is necessary in sensors based on the magnetoresistance or spin valve effect. The high resistivity may be a limitation. The initial achievement of the saturation Hall resistivity of over 100 $\mu\Omega$ cm in our best percolating films is already considerably larger than the largest extraordinary Hall effect reported so far for magnetic granular systems which is ~ 1 $\mu\Omega$ cm.[4,16]

To conclude, we found a giant enhancement of the extraordinary Hall effect in magnetic metal–insulator granular films, as the metal volume fraction in the composite decreases from 1 to 0.55. The enhancement is greater than that predicted by the percolation theory. Correlations of the Hall resistivity with both resistivity $\rho_{xys} \propto M_s \rho_{xx}^2$ and magnetoresistivity $\rho_{xys} \propto M_s (\Delta\rho_{xx}/\rho_{xx})^{1/2}$ are investigated with temperature being an implicit parameter. The latter relation holds for high temperatures where both magnetoresistivity and the Hall resistivity may be dominated by magnetic disorder via spin-dependent scattering.

Freezing of the extended state in the random local field theory of Ising spin glasses with long range interactions

B. E. Vugmeister[a)]

D. Nowakowski
Department of Physics, Harvard University, Cambridge, Massachusetts 02138

D. L. Huber
Department of Physics, University of Wisconsin-Madison, Madison, Wisconsin 53706

The onset of spin glass freezing in dilute Ising systems with long range interactions is investigated within the framework of a random local field approach (previously developed for disordered ferromagnets and ferroelectrics) with the use of numerical simulations. The problem reduces to the diagonalization of an $N\times N$ random matrix, N being the number of spins in the simulation, whose elements depend on the spin–spin interaction and temperature. We identify the onset of spin glass freezing with the temperature at which this boundary eigenvalue separating localized and extended states is equal to one. Numerical simulations give a reasonable value of the freezing temperature for dilute RKKY spin glasses and reproduce its linear concentration dependence in agreement with the scaling relation. © *1996 American Institute of Physics.* [S0021-8979(96)23108-3]

We consider Ising spin glasses with the Hamiltonian

$$H=-\frac{1}{2}\sum_{ij} J_{ij}S_iS_j, \quad S_i=\pm 1, \tag{1}$$

where J_{ij} is the interaction between spins separated by the distance r_{ij}. For RKKY interactions

$$J_{ij}=A\,\frac{\cos(2k_Fr_{ij})}{r_{ij}^3}. \tag{2}$$

The goal of the present article is to give an estimate of the spin glass freezing temperature T_g based on Eqs. (1) and (2). In particular, we will show that the dependence of T_g on spin concentration c in a very dilute limit is in agreement with the scaling relation[1] $T_g\sim c$. Until recently there has been no proof given for the validity of the scaling law directly from Eqs. (1) and (2). For example, the approach followed in recent papers leads to $T_g\sim c^{1/2}$ as $c\to 0$.[2]

In its application to dilute Ising spin glasses with RKKY interactions, the present article follows the approach[3] of averaging first over thermal fluctuations before averaging over configurational disorder. First of all, we consider a fixed configuration of the spins and perform the thermal averaging, using the so called random local field approach that has been originally developed for dilute Ising ferromagnets and ferroelectrics, where it was found to be a significant improvement over conventional mean field theory.[4]

In applying the model to dilute systems with long range interactions, additional complications are encountered due to the existence of localized states. In order to find a characteristic boundary (or "mobility edge") between localized and extended states and to estimate the freezing temperature of the extended states, we performed the configurational average of the microscopic equations using computer simulation techniques, numerically diagonalizing random matrices that corresponds to RKKY interactions, between spins randomly occupying sites on a three-dimensional simple cubic lattice. The analogous approach based on local mean field equations has been reported recently.[5]

In the development of random local field approach we start from the identity[6]

$$\langle S_i\rangle=\left\langle \tanh\left(\frac{H_i}{T}\right)\right\rangle, \tag{3}$$

where

$$H_i=\sum_j J_{ij}S_j \tag{4}$$

is the local field acting on every spin due to interaction with its neighbors. Equation (7) can be written in the form

$$\langle S_i\rangle=\int dH\,\tanh\left(\frac{H}{T}\right)f_i(H), \tag{5}$$

where

$$f_i(H)=\langle\delta(H-H_i)\rangle=\frac{1}{2\pi}\int d\rho e^{i\rho H}f_{i\rho}, \tag{6}$$

in which

$$f_{i\rho}=\langle\exp[-i\rho H_i]\rangle=\langle\Pi_k[\cos(\rho J_{ik})-iS_k\,\sin(\rho J_{ik})]\rangle. \tag{7}$$

In order to calculate the spin glass transition temperature, it is sufficient in Eq. (7) to keep only terms linear in $\langle S_i\rangle$. We also neglect correlations between different spins

[a)]Present address: Department of Chemistry, Princeton University, Princeton, New Jersey 08544.

 0021-8979/96/79(8)/6143/3/$10.00

$k,k'\ldots$, interacting with spin i, which is equivalent to making a pair approximation. When this is done, the expression for $f_{i\rho}$ assumes the form

$$f_{i\rho}=\Pi_k \cos(\rho J_{ik})-i\sum_j \Pi_{k\neq j}\cos(\rho J_{ik})\sin(\rho J_{ij})\langle S_j\rangle. \tag{8}$$

We make the replacement

$$\Pi_{k\neq j}\cos(\rho J_{ik})\approx\overline{\Pi_{k\neq j}\cos(\rho J_{ik})} \tag{9}$$

based on the fact that the cosine function partially suppresses the effect of fluctuations in J_{ij} that originate from the variable sign interactions. Equation (9) is the exact result for the infinite range SK model with $J_{ij}=\pm J/(N^{1/2})$, N being a number of spins.

In dilute systems in which the randomness in the interaction stems from the random occupation of the lattice sites, the result of the configurational average in Eq. (9) can be written in the form $\exp[-F_1(\rho)]$, where for $c\ll 1$ $F_1(\rho)$ is given by

$$F_1(\rho)=c\sum_j (1-\cos[\rho J(r_{ij})]), \tag{10}$$

where the summation in Eq. (10) is taken over all lattice sites. Using Eqs. (6) and (8) in Eq. (5) we obtain the equation[4(b)]

$$\langle S_i\rangle=\sum_j \phi_{ij}^{\mathrm{RLF}}(T)\langle S_j\rangle, \tag{11}$$

where

$$\phi_{ij}^{\mathrm{RLF}}(T)=T\int_0^\infty \frac{d\rho\,\exp[-F_1(\rho)]\sin(J_{ij}\rho)}{\sinh(\pi\rho T/2)}. \tag{12}$$

Equation (12) is the fundamental equation of the random local field approximation. Note that Φ_{ij}^{RLF} remains finite as $T\to 0$.

Before considering the application of Eq. (11) to realistic models, it is worthwhile seeing the consequences for the SK model. Under these conditions, $F_1(\rho)=\rho^2J^2/2$, while $\sin(J_{ij})$ can be approximated by its argument. The matrix Φ_{ij}^{RLF} then assumes the form

$$\phi_{ij}^{\mathrm{RLF}}(T)=\left\{T\int_0^\infty \frac{d\rho\,\exp[-\rho^2J^2/2]\rho}{\sinh(\pi\rho T/2)}\right\}J_{ij}. \tag{13}$$

We note that for infinite range interactions all eigenvectors of the random matrix Φ_{ij}^{RLF} are delocalized,[3,7] and the transition temperature can be identified with the temperature at which the largest eigenvalue of the matrix Φ_{ij}^{RLF} is equal to one. Since the largest eigenvalue of Eq. (13) is equal to the expression in braces multiplied by $2J$,[3] one obtains an expression for T_g by numerically evaluating the integral. The result is $T_g=1.48$ J, which is halfway between the mean field and exact results, and, thus, is a significant improvement over the former. Since the random local field approximation gives a rather good account of the effect of fluctuations in the SK model, it is likely to be a reasonable first step in the estimation of T_g in the RKKY model.

The main difference between the SK model and the model given by Eqs. (1) and (2) is the existence of localized states, the latter associated with small clusters of spins. It is clear, however, that localized states are not responsible for the collective behavior of the system which is the property of delocalized, extended states. The crossover between localized and extended states has been extensively studied (see, for example, Refs. 8–10) in connection with the problem of Anderson localization. It has been shown that the boundary between localized and extended states is usually rather sharp, and the characteristic eigenvalue of the effective interaction matrix for which a relative variance in the distribution of eigenvalues is equal to 1/2 can be considered as a simple criterion determining the crossover between localized and extended states. The relative variance (that is the ratio between the variance and the distribution function) approaches 1 for Poisson statistics, that are a characteristic of localized states, and is much less than 1 for extended states. We have performed the numerical solution of Eqs. (1) and (2) using computer simulation techniques (with $k_F=3$). We randomly distributed approximately $N=900$ Ising spins on a simple cubic lattice with periodic boundary conditions, where the size of the lattice had been adjusted to the spin concentration. We then calculated all eigenvalues E_k $(k=1,\ldots,N)$ of the matrix Φ_{ij}^{RLF}.

In order to calculate the distribution function of the eigenvalues we divided the interval $[-R,R]$ into 200 subintervals and collected the number $n(E)$ of eigenvalues in each subinterval. This was repeated for 100 different random configurations of the spins and the results averaged. The distribution function was written as

$$\sigma(E)=\frac{1}{M}[n(E)]_{\mathrm{av}}, \tag{14}$$

where M is the normalizing coefficient.

In the same manner we calculated the variance of the eigenvalue distribution

$$\mathrm{var}(E)=\frac{1}{M}([n(E)^2]_{\mathrm{av}}-[n(E)]_{\mathrm{av}}^2). \tag{15}$$

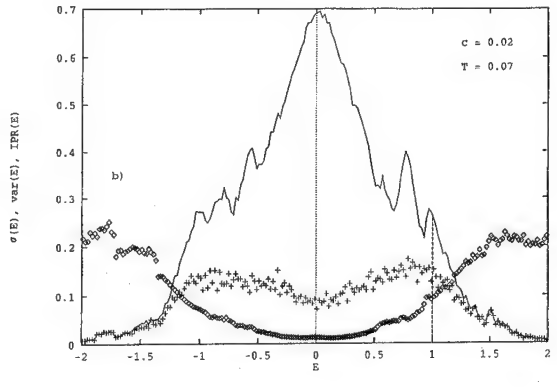

FIG. 1. Eigenvalue distribution function, $\sigma(E)$ (solid line), variance, $\mathrm{var}(E)$ (crosses), and inverse participation ratio $\mathrm{IPR}(E)$ (diamonds) corresponding to matrix Φ_{ij}^{RLF} for $c=0.02$ and $T_g=0.07$ (in units $|A|/d^3$).

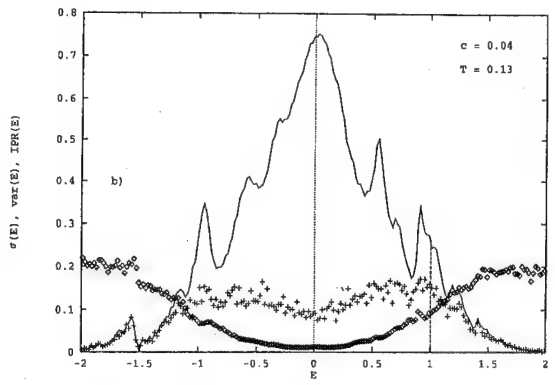

FIG. 2. Eigenvalue distribution function, $\sigma(E)$ (solid line), variance, var(E) (crosses), and inverse participation ratio IPR(E) (diamonds) corresponding to matrix Φ_{ij}^{RLF} for $c=0.04$ and $T_g=0.13$ (in units $|A|/d^3$).

We have tested the effect of finite lattice size by comparing the results obtained for 900 spins with those for 1300 spins. No noticeable difference in eigenvalue distributions was found.

We have also considered another very common localization measure, the inverse participation ratio, IPR(E), for the eigenvalue E, defined as

$$\mathrm{IPR}(E)=\sum_j \psi_j(E)^4, \tag{16}$$

where $\psi_j(E)$, $j=1,\ldots,N$, are the corresponding eigenvector components. Because $\Sigma_j\psi_j^2=1$, the IPR should be very small, i.e., proportional to $1/N$ for very delocalized states, and approaching one only in the opposite limit of extreme localization.

In order to find the estimate for the T_g we have performed numerical simulations using the values of Φ_{ij}^{RLF} matrix at different temperatures and found the temperature for which $E_m=1$.[11] E_m is the crossover eigenvalue separating localized and extended states (see Figs. 1 and 2). This temperature corresponds to the freezing temperature T_g of the extended states. We found $T_g\approx 0.07\pm 0.01$ for $c=0.02$, $T_g\approx 0.1\pm 0.01$ for $c=0.03$, $T_g\approx 0.13\pm 0.01$ for $c=0.04$ (in units $|A|/d^3$, d is the lattice constant). One can see that T_g scales practically linearly with concentration in agreement with scaling relation and can be written as

$$T_g^{\mathrm{RLF}}\simeq 3c\,\frac{|A|}{d^3}. \tag{17}$$

Note that the values of T_g given by Eq. (17) are approximately one-half of the corresponding values for T_g in the mean field approximation.[5]

From a comparison of the numerical values of T_g obtained here with the results of mean field simulations[5] and with the presented above analyses of the SK model one can conclude that the effect of thermal fluctuations on RKKY spin glasses is as crucial as for the SK infinite range interaction model, a result which is consistent with the long range nature of the RKKY interaction. Such a correspondence between the effect of fluctuations in RKKY and SK Ising spin glasses allows us to estimate T_g in RKKY Ising spin glasses as $T_g\simeq 2C|A|/d^3$.

Criticality of the fully frustrated *XY* model: A study using Monte Carlo hard-spin mean-field theory (abstract)

James E. Tesiero and Susan R. McKay
Department of Physics and Astronomy, University of Maine, Orono, Maine 04469-5709

The number and types of phase transitions occurring in the two-dimensional fully frustrated *XY* model have remained controversial in spite of over a decade of attention. In this study, we have developed a Monte Carlo hard-spin mean-field[1] approach for models with a continuous spin variable and applied it to this system. From our calculations of the chirality, helicity modulus, specific heat, and sublattice magnetizations, we find that reflection and rotational symmetries are broken at the same temperature. The chirality, order parameter for the reflection symmetry breaking, exhibits power-law dependence on $T-T_c$ with a critical exponent of 0.246 ± 0.006. This result is decisively different from the mean-field value of 0.500, which would be obtained for a transition in the Ising universality class using this method. This finding enables us to rule out the possibility of two separate transitions, too closely spaced in temperature to be resolved by our calculation. The magnitude of the magnetization on each sublattice also shows power-law behavior as a function of temperature in the critical region, with a critical exponent of 0.126 ± 0.002. We present direct current (dc) magnetization $M(T,H)$ and alternating current (ac) susceptibility $\chi_{ac}(T,H,f)$ data for the quasi-one-dimensional molecule-based ferrimagnet $[MnTPP]^{\cdot+}[TCNE]^{\cdot-}\cdot 2PhMe$ (TPP=*meso*-tetraphenylporphyrinato, TCNE=tetracyanoethylene). Static scaling of the real part χ' of the ac susceptibility and data collapse of $M(T,H)$ over a limited reduced temperature range above $T_c \approx 13$ K lead to the critical exponents $\gamma \approx 1.6$, $\beta \approx 0.5$, and $\delta \approx 4.2$. Below T_c, χ_{ac} depends sensitively on frequency and exhibits a striking double-peak structure similar to that found in reentrant spin glasses. Possible models for the frequency dependence of the peaks observed in χ_{ac} are discussed. © *1996 American Institute of Physics.* [S0021-8979(96)23208-X]

INTRODUCTION

Interest in molecule-based magnets has expanded rapidly as materials with novel physics and technological potential continue to be realized.[1] The first molecular systems possessing bulk magnetization at room temperature were the disordered, organic-based compounds $V(TCNE)_x \cdot y$(solvent) (TCNE=tetracyanoethylene).[2] More recently, magnetism in the vicinity of room temperature has also been observed in the $M[M'(CN)_6]\cdot nH_2O$ Prussian Blue class of materials.[3]

The relative ease of synthesis of molecule-based magnets also yields unique opportunities for studying low-dimensional magnets. In the one-dimensional case, the properties of integral vs half-integral spin chains,[4] alternating quantum-classical ferrimagnetic chains,[5] and low-dimensional spin glasses[6] are currently of great theoretical interest.

The class of metalloporphyrin-TCNE electron-transfer compounds is of interest for its unusual structural and magnetic properties.[7,8] The parent compound, $[MnTPP]^{\cdot+}[TCNE]^{\cdot-}\cdot 2PhMe$ (TPP=*meso*-tetraphenylporphyrinato) is comprised of chains of alternating [MnTPP] ($S_1=2$) and [TCNE] ($S_2=1/2$) molecular units with direct metal-CN bonds similar to those in V(TCNE).

In this paper, we present detailed measurements of direct current (dc) magnetization $M(T,H_{dc})$ and alternating current (ac) susceptibility $\chi_{ac}(T,f,H_{ac},H_{dc})$ for $[MnTPP]^{\cdot+}[TCNE]^{\cdot-}\cdot 2PhMe$. A state of long-range ferrimagnetic order builds up as T is decreased below ~20 K toward a critical temperature of $T_c \approx 13$ K as determined from a static scaling analysis. The broad temperature region of incipient ferrimagnetism above T_c may result from the presence of highly anisotropic coherent clusters of spins and the effects of disorder. At lower temperatures ($T<10$ K), a distinct second peak appears in the out-of-phase ac susceptibility, indicative of the "reentrant" transition to a spin-glass "phase" which coexists with ferrimagnetic order in the field-cooled state. The frequency dependence of this lower-temperature peak, however, is stronger than that observed in the canonical spin glasses[9] as well as known reentrant alloys.[10] The field dependence of the low-temperature state is similar to that of a metamagnet: spins of disordered ferrimagnetic chains reorient coherently over a temperature-dependent critical field range $[\Delta H_c(T)]$ to a state with saturated ferrimagnetic order. These results are compared to the expectations of a model of anisotropic, interacting superparamagnetic clusters.

EXPERIMENT

The preparation of [MnTPP][TCNE] has been described earlier.[7] The dc magnetization was measured with a Quantum Design MPMS5 superconductory quantum interference device magnetometer in the ranges $2 \leqslant T \leqslant 400$ K and $0 \leqslant H_{dc} \leqslant 5$ T. The ac susceptibility was measured via the mutual inductance technique with a LakeShore 7225 ac Susceptometer/dc Magnetometer in the ranges $4 \leqslant T \leqslant 30$ K and $0 \leqslant H_{dc} \leqslant 1$ T. The real and imaginary components of the linear susceptibility were recorded for an ac field of 0.1 Oe and a range of frequencies (5 Hz$\leqslant f \leqslant$40 kHz). The dominant source of uncertainty in determining the magnitude of the molar susceptibilities was the sample mass, estimated to be accurate to within 2%.

RESULTS

The temperature dependence of the zero-field cooled (ZFC) molar magnetization of $[MnTPP]^{\cdot+}[TCNE]^{\cdot-}\cdot 2PhMe$ for different applied fields is shown in Fig. 1. The lowest temperature state is demagnetized (M is near zero at 5 K). The magnetization goes through a broad maximum centered between 8 and 11 K depending on field. As T increases above 15 K, M drops quickly; the intermediate temperature ($100<T<250$ K) $M(T)$ data (not shown) follow Curie–Weiss behavior with $\chi_{dc}=M/H=C/(T-\theta)$, with $\theta=+61$ K. At room temperature, $C \approx 3.1$ emu K mol^{-1}, consistent with molecular units with $S_1=2$ (MnTPP) and $S_2=\frac{1}{2}$ (TCNE). The large negative Curie–Weiss temperature $\theta<-100$ K for $T>250$ K indicates antiferromagnetic coupling between adjacent spins. The inset of Fig. 1 shows field cooled (FC) and

 0021-8979/96/79(8)/6147/3/$10.00

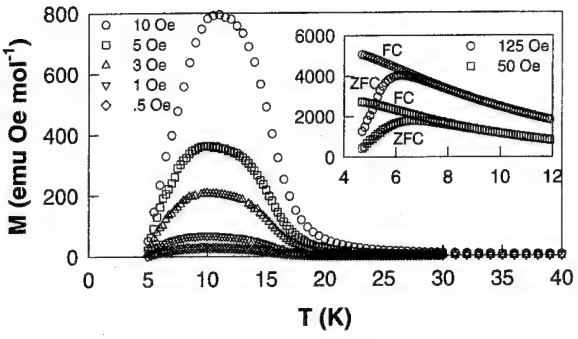

FIG. 1. Temperature dependence of zero-field cooled (ZFC) magnetization at small applied fields. Inset: FC vs ZFC magnetization at 50 and 125 Oe.

ZFC magnetization data at two fields. While the ZFC curves are only obtained on warming, the FC magnetization, which lies above the ZFC magnetization at low temperatures, is reversible at the sweep rate of ~ 0.1 K min^{-1}. The point where the FC and ZFC data merge is taken as the irreversibility temperature $T_f(H)$.

Isothermal magnetization data were recorded in a ZFC state (initial curves) for several temperatures $2 \leq T \leq 35$ K (Fig. 2). The saturation magnetization ($H > 4$ T) is $M_S \approx 17\,000$ emu Oe mol^{-1}, consistent with the expected value ($M_S = 16\,755$ emu Oe mol^{-1}) for a ferrimagnet of net spin $\frac{3}{2}$ per repeat unit. The S-shaped approach to saturation occurs at lower fields as T increases from 2 K.

The zero dc field susceptibility data are presented in Fig. 3. The real χ' and imaginary χ'' parts of χ_{ac} were recorded on warming from a ZFC state. An ac field of amplitude $H_{ac} = 0.1$ Oe was applied in a sequence of frequencies (5 Hz $\leq f \leq$ 40 kHz). Due to the small ac amplitude, a low signal-to-noise ratio was obtained at certain frequencies. A limited frequency range (20 Hz $\leq f \leq$ 1 kHz) is included in Fig. 3 to maximize clarity. The real part χ' becomes strongly frequency dependent below ~ 14 K. In addition, a distinct shoulder appears in χ' at lower temperatures. This feature is isolated in the imaginary part χ'' as a separate peak. The "double-peak" structure in these data is discussed below.

DISCUSSION

The results of the static scaling analysis are presented in Fig. 4. The Kouvel–Fisher[11] scaling function $X_{KF}(T) = -\chi'(d\chi'/dT)^{-1}$ [Fig. 4(a), left axis], obtained from the real zero-field ac susceptibility χ', has the linear (scaling) form $X_{KF}(T) = (T - T_c)/\gamma$ only above ~ 16 K. The critical temperature $T_c \approx 12.5$ K and average susceptibility exponent $\gamma \approx 1.6$ are obtained from the T intercept and inverse slope of X_{KF}, respectively. The fact that χ' does not obey a power law in $|t|$ within ~ 3 K above T_c may reflect the presence of strong spatial anisotropy ($J_{inter}/J_{intra} \sim 10^{-2}$)—the buildup of long-range intrachain correlations is particularly sensitive to defects and disorder, possibly leading to the formation of quasi-one-dimensional (1D) "domains" well above T_c. Consequently, the "core" (3D) critical region is not probed in this measurement and the observed γ is expected[11] to be enhanced over its true value. The effective exponent $\gamma(T) = (T - T_c)/X_{KF}$ [Fig. 4(a), right axis] elucidates the presence of a region ($T < 16$ K) where χ' does not scale, below an unusually wide range where $\gamma(T)$ is fairly constant, falling off slowly as T increases.

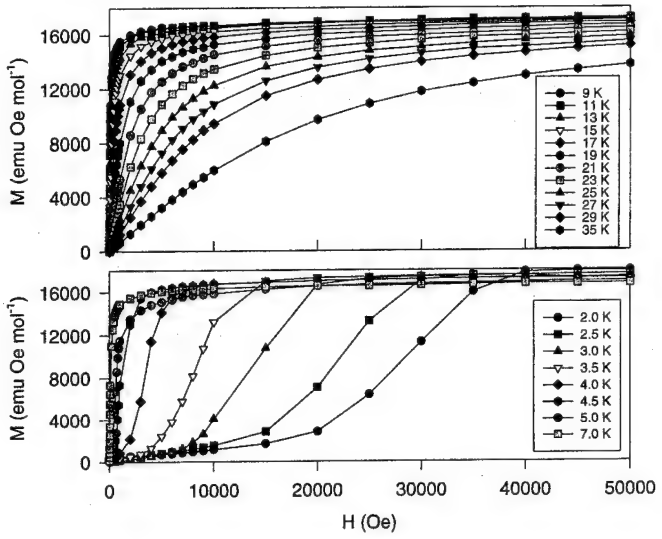

FIG. 2. Zero-field cooled (initial) isothermal dc magnetization.

The value $\gamma \approx 1.6$ is used to restrict the parameter space (β, δ) in the scaling of $M(T,H)$ [Fig. 4(b)] through the Griffiths–Rushbrooke relation[12] $\gamma = \beta(\delta - 1)$. The trial critical temperature T_c^{tr} for which the $M(T)$ data appear to coalesce for the three smallest applied fields (over a limited reduced temperature range above T_c^{tr}) is independently found to be $T_c \sim 13$–13.5 K. It is estimated that $\beta \sim 0.5$ and $\delta \sim 4.2$, though the accuracy and precision are limited by the relative insensitivity of the analysis to the choice of β and δ, and that the (possibly enhanced) γ is obtained from data above 16 K. The T_c value obtained is significantly lower than that ob-

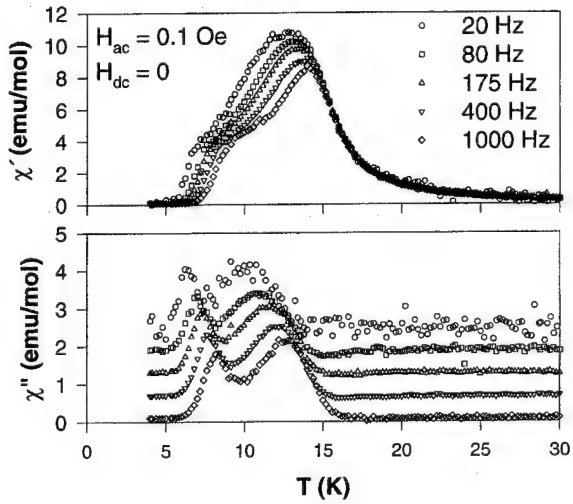

FIG. 3. Real (χ') and imaginary (χ'') parts of the ZFC ac susceptibility in zero bias field H_{dc} and 0.1 Oe excitation field H_{ac}. χ'' data are shifted for clarity; high temperature values show the approximate baseline for each curve.

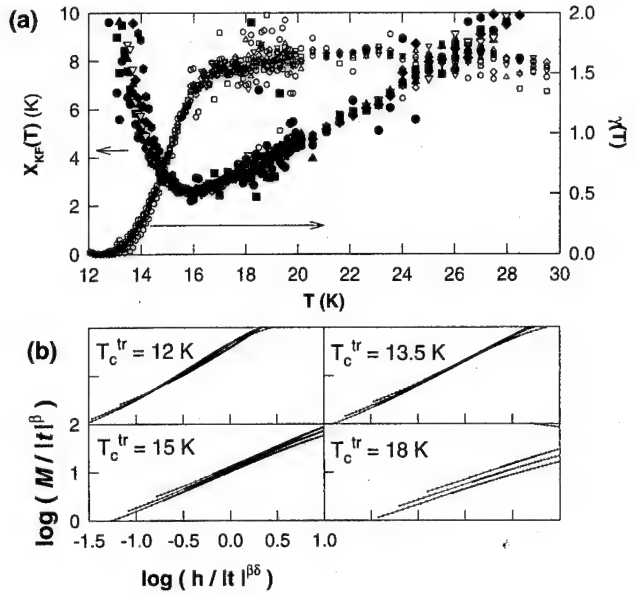

FIG. 4. (a) Kouvel–Fisher scaling function $X_{\mathrm{KF}}(T)=-\chi'(d\chi'/dT)^{-1}$ (left axis) and temperature-dependent effective critical exponent $\gamma(T)=(T-T_c)/X_{\mathrm{KF}}(T)$ (right axis). (b) Scaling of dc magnetization $M(T,H)$ above T_c^{tr} for $\beta=0.5$ and $\delta=4.2$, where $h=H/T$. See the text.

tained by extrapolating the maximum slope[8] of the low-field $M(T)$ curve to $M=0$, which gives $T_c\approx 18$ K.

As mentioned above, the experimental observation of a "slow" transition to long-range ferrimagnetic order in $[\mathrm{MnTPP}]^{\cdot+}[\mathrm{TCNE}]^{\cdot-}\cdot 2\mathrm{PhMe}$ reflects the quasi-1D magnetism in this system. In chainlike magnets, significant long-range longitudinal spin–spin correlations build up well before 3D order is established. For instance, specific heat studies reveal that a very high fraction of the magnetic entropy of quasi-1D magnets lies above T_c.[13]

The low-temperature isothermal magnetization $M(H)$ and the appearance of the "reentrant" transition may be interpreted as resulting from the behavior of interacting, anisotropic superparamagnetic clusters. Superparamagnetism (SPM) describes the behavior of well separated, classical (large S) spin clusters which behave paramagnetically at high temperatures, but due to internal shape or dipolar anisotropy energy barriers are "blocked" from undergoing global spin flips below a characteristic temperature T_b. SPM leads to broad maxima around T_b in $M(T)$ and χ_{ac}, with the latter following an Arrhenius frequency dependence $\omega=\omega_0\exp(-E_a/k_BT)$, where E_a is a characteristic anisotropy energy. In contrast, [MnTPP][TCNE] is a magnetically concentrated system, so intercluster interactions are likely very important, and may be responsible for the spin-glass-like behavior.

The S-shaped crossover in $M(H)$ from low-M to saturation occurs in a range $\Delta H_c(T)$. If $H_c(T)$ is defined as the midpoint of the crossover, it is seen that both H_c and ΔH_c decrease as T increases from 2 to 7 K. The ΔH_c trend favors a disordered, spin-glass-like state at low T and H rather than a pure antiferromagnetic one as in the ideal metamagnetic case. Due to a strongly spatially anisotropic exchange J, spin clusters in [MnTPP][TCNE] are expected to be elongated. The increase in ΔH_c as T decreases indicates the presence of a broadening distribution of barriers to the rotation of spin cluster moments.

The appearance of a second, lower temperature peak in χ_{ac} is similar to that seen in "reentrant" spin-glass (RSG) alloys.[14] However, the frequency dependence of both lower (T_1) and upper (T_2) peak temperatures is quite strong, suggesting that [MnTPP][TCNE] lies somewhere between traditional RSGs and pure SPM. The fractional shifts in peak temperature per decade of frequency are $(\Delta T_1/T_1)/(\Delta \log f)\approx 0.23$ and $(\Delta T_2/T_2)/(\Delta \log f)\approx 0.14$. Fits to pure Arrhenius behavior give $E_{a1}/k_B\approx 112$ K and $f_{01}\approx 940$ MHz ($\tau_{01}\sim 10^{-9}$ s) for $T_1(\omega)$ and $E_{a2}/k_B\approx 247$ K and $f_{02}\approx 420$ GHz ($\tau_{02}\sim 2.4\times 10^{-12}$ s) for $T_2(\omega)$. ($\tau_0=1/f_0$ is the characteristic limiting relaxation time for a given frequency prefactor f_0). The peak positions are relatively close to the "typical" blocking temperatures obtained using $T_b\sim E_a/25k_B$.[10] The applicability of the model of transverse spin freezing[14] to [MnTPP][TCNE] is under investigation.

There is considerable theoretical interest in triangular and stacked triangular lattice antiferromagnets, particularly as regards their phase transitions and the nature of the ground state of quantum systems with spin $S=\frac{1}{2}$. There are, however, no good experimental representatives of the $S=\frac{1}{2}$ triangular lattice antiferromagnet, and indeed there are few good representatives of those with higher spin. Given the diversity of theoretical problems associated with these systems there is a clear need to find appropriate new model materials. We report the discovery of a versatile new series of triangular lattice magnets, the anhydrous alums of general formula $AM(SO_4)_2$, with A=alkali metal, M=Ti,V,Cr,Fe. In these materials the magnetic M ions occupy a regular or very slightly distorted triangular lattice in well-separated layers. All show magnetic ordering effects in the range 2–10 K, the near-neighbor exchange being antiferromagnetic for Ti, V, and Fe and ferromagnetic for Cr. The Ti materials, which we have made for the first time, have $S=\frac{1}{2}$, and may prove to be the best examples of the $S=\frac{1}{2}$ triangular lattice antiferromagnet yet discovered. In general, our ability to control the spin value, spin anisotropy, and exchange anisotropy makes the anhydrous alums a potentially useful series for the investigation of a variety of physical problems. © *1996 American Institute of Physics.* [S0021-8979(96)44008-4]

Finite size effects in thin NiMn spin glass layers

L. Hoines,[a] J. A. Cowen, and J. Bass[b]
Department of Physics and Astronomy and Center for Fundamental Materials Research, Michigan State University, East Lansing, Michigan 48824

Measurements of the normalized spin freezing temperatures, T_f/T_f^b, (T_f^b=bulk spin-freezing temperature) are reported for NiMn/Cu multilayers in which the Mn concentrations are in the spin-glass range and the Cu thickness is held constant at a large enough value (t_{Cu}=30 nm) to magnetically decouple the NiMn layers. The variation of T_f/T_f^b with NiMn layer thickness, t_{NiMr}, is very similar to the variations previously found for CuMn, AgMn, and AuFe. Quasistatic finite size effects in NiMn spin-glass thus appear to be rather similar to those in the more traditional noble-metal spin glasses. © *1996 American Institute of Physics.* [S0021-8979(96)23308-6]

I. INTRODUCTION

There has recently been considerable interest in finite size effects (FSE) in magnetic materials.[1–11] In ferromagnets, deviations of the Curie temperature, T_c, from its bulk value T_c^b do not become large until the ferromagnetic layer thickness, t_F, reaches a few monolayers (ML).[11] In the noble-metal-based spin glasses (SGs), CuMn, AgMn, and AuFe, in contrast, we have shown that the quasi-static spin-freezing temperature, T_f, deviates significantly from its bulk value, T_f^b, by SG layer thickness t_{SG}=100 ML, and reaches 50% of T_f^b by $t_{SG}\sim$20 ML.[1–3] In this paper, we examine the variation of T_f with t_{SG} for a very different kind of SG, NiMn. The issue of interest is the universality of quasistatic FSE in SGs, previously shown to hold for the noble-metal based SG alloys.[1–3]

The noble-metal based SG alloys consist of dilute magnetic impurities in a nonmagnetic host, in which the impurities interact only with each other, primarily via the RKKY exchange interaction.[12] The NiMn alloys of interest, in contrast, contain two magnetic components, neither of which is dilute. All atoms have magnetic neighbors, and the dominant interaction is short range exchange, with competition between ferromagnetic Ni–Ni and Ni–Mn and antiferromagnetic Mn–Mn interactions.[13] As Mn is added to pure Ni, ferromagnetism persists until the Mn–Mn interactions disrupt the long-range magnetic order. This disruption leads[14] first (Fig. 1) to a rentrant SG (RSG) regime for 24 at.%>c_{Mn}>22 at.% Mn, that exhibits paramagnetic (P) to ferromagnetic (F) to disordered SG-like transitions with decreasing temperature, and then, for c_{Mn}>24 at.%, to a regime where there is only a P to a more nearly normal-SG transition.[15] It is this latter regime on which we focus in the present paper. Abdul-Razzaq and Wu[16] reported little or no FSE down to t_{RSG}=10 nm in a brief study of NiMn thin films in the RSG regime.

II. SAMPLES AND PREPARATION

To obtain enough SG material for quantitative analysis of FSE, in our previous studies of noble-metal based SG alloys, we sputtered multilayers composed of alternating layers of the SG of interest and one of the nonmagnetic host metals, with the interlayer thickness, t_{IL}, thick enough (typically t_{IL}=30 nm) to make interactions between the SG layers negligible.[2] We found that different noble metal interlayers yielded essentially the same FSE behavior.[2] Since the two constituents of NiMn are both magnetic, we could not use either for the interlayer material in similar multilayers. Based upon our experience with the noble-metal SG multilayers, and because the noble metals sputter well, we decided to use Cu as the interlayer metal with the NiMn. From previous observations that 30 nm of a wide variety of metals magnetically decouples noble metal SG layers,[17] we assumed the same behavior for NiMnSG layers separated by Cu. To test that this assumption was not strongly violated, we checked for a variation in T_f/T_f^b as the Cu thickness was reduced from t_{Cu}=30 to 10 nm for multilayers with t_{NiMn}=4 nm, where $T_f/T_f^b\sim$0.6. The change in t_{Cu} from 30 to 10 nm caused only a small increase in T_f/T_f^b, comparable to the measuring uncertainties.

Because Cu is not a constituent of NiMn, it might perturb the NiMn multilayer data due to boundary intermixing. For CuMn and AgMn, non-noble metal interlayers such as Al, Nb, and V, all gave lower values of T_f than those for noble metal interlayers when the SG layer thicknesses fell below about 4 nm.[17] We attributed these reductions to interface mixing that reduced the Mn contribution to SG behavior, since Mn did not give SG behavior in those other metals. The situation in NiMn is more complex. Since CuMn is a

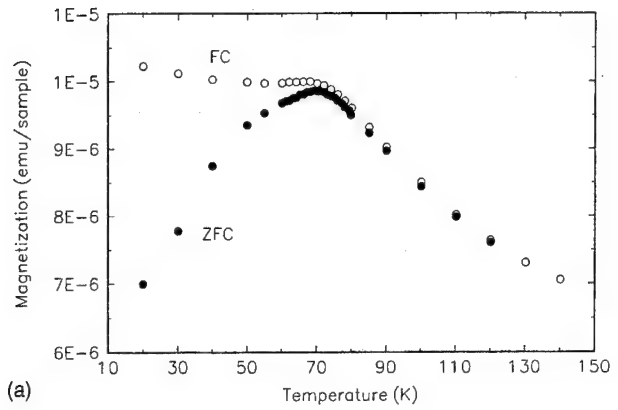

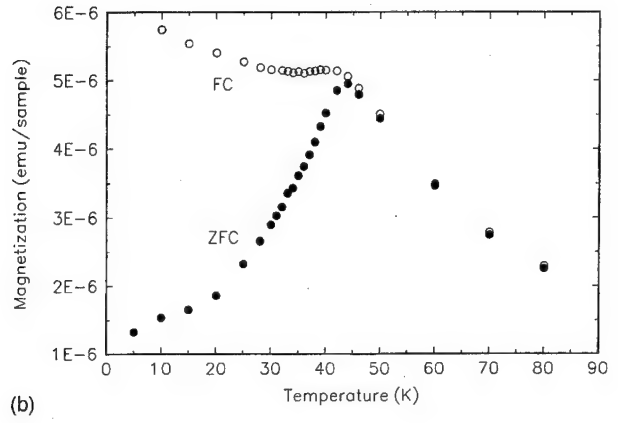

FIG. 2. The field-cooled (FC) (open symbols) and zero-field-cooled (ZFC) magnetizations of (a) a 300 nm thick sputtered single film; and (b) a NiMn [(2 mn/30 nm)×50] multilayer.

SG, dispersal of Mn into the Cu can also lead to SG behavior. Dilute CuNi alloys, in contrast, do not display SG-like behavior.[18] It is thus not clear whether mixing Cu into the edges of a NiMn layer, or spreading some of the Ni and Mn into the Cu interlayer, should drive T_f up or down. In the present study, we assume that the Cu has no net effect on the data. Further studies with interlayers of metals in which both Ni and Mn impurities are nonmagnetic are needed to confirm this assumption.

The multilayers were sputtered in the same system previously used for SG FSE studies in CuMn, AgMn, and AuFe.[2,3] The 1/4 in. thick by 2 in. diam Cu targets were spark cut from 5–9 s pure Cu sheet, while the SG targets were locally fabricated from 3–9 s pure Ni and Mn pellets. Our standard procedure of rf induction melting in a BN_2 coated carbon crucible yielded contaminated samples. We thus developed a procedure in which the NiMn alloy was melted inside an alumina crucible that fit snugly into the carbon crucible. This procedure reduced the maximum diameter of the NiMn targets to 1.5 in.

Aside from the use of smaller targets, the only other important change in sample fabrication was adopted because of the instability of NiMn against possible onset of chemical short-range-order at room temperature.[19] To minimize such effects, the substrates were held at temperatures below −20 °C during the entire sputtering run and the sputtering system was opened while still cold so that the multilayers could be quickly transferred into liquid nitrogen for storage until they were measured.

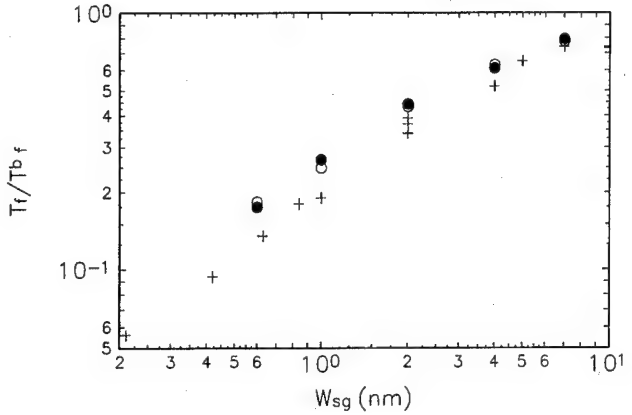

FIG. 3. T_f/T_f^b vs t_{SG} for two sets of (NiMn/Cu) multilayers (open and filled circles) and for CuMn(11 at.%)/Cu and CuMn(14 at.%)/Cu multilayers (crosses).

EDX measurements of the two NiMn targets used in the present study gave Mn concentrations of 29±1 and 31±1 at.% (Fig. 1). These concentrations should be in the SG region.[15] Measurements of T_f^b made on films at least 50 nm thick, that were sputtered alternately with the multilayers, showed that T_f^b was constant to within ±2 K about the average during a single sputtering run.

III. DATA AND ANALYSIS

Figure 2 shows examples of magnetizations M vs T for: (a) a 300 nm thick NiMn film, and (b) a multilayer with 50 bilayers of NiMn/Cu (2 nm/30 nm). Both samples show typical SG behavior—a peak in the zero-field-cooled (ZFC) data (filled symbols), the location of which we define as T_f, and irreversibility between the ZFC and FC (open symbols) data below about T_f.

Figure 3 compares the ratio T_f/T_f^b vs t_{SG} for NiMn/Cu multilayers from our two independent NiMn targets with similar data for CuMn(11 at.%)/Cu and CuMn(14 at.%)/Cu multilayers.[2,20] We see that, although the NiMn data display very similar overall behavior, they lie slightly above the CuMn data. Subject to the caveat noted above—that we assume that the Cu interlayer does not perturb the NiMn data—we conclude that the variation of the ratio T_f/T_f^b with t_{SG} is similar for NiMn and CuMn.

This result leads us to the rather surprising conclusion that FSE in the quasistatic freezing temperature do not appear to be sensitive to whether the dominant interaction between the magnetic impurities in the SG is long range RKKY as in CuMn, or shorter range direct exchange as in NiMn.

A new type of spin glass in spin-density-wave CrMn alloys (abstract)

The temperature dependence of the susceptibility $\chi(T)=M(T)/H$ of $Cr_{1-x}Mn_x$($\ll 0.1<x<8\%$ Mn) alloys in the range $5<T<400$ K and in fields up to 55 kOe, measured with a SQUID magnetometer, and hysteresis of the magnetization $M(H)$ show typical spin-glass (SG) behavior. After zero-field cooling (ZFC), $\chi(T)$ exhibits the low-T maximum typical of a SG, while cooling in the measuring field (FC) gives quite different behavior. In some cases, when measuring at low field, $\chi(5\text{ K})$ is $10\times$ larger in the FC state than in the ZFC state. The temperature of the irreversibility limit decreases with increasing field. All our CrMn alloys show nonlinear field dependence of $M(H)$, with pronounced hysteresis and decay of the remanent M with time. On the other hand, these alloys exhibit properties that are essentially different from those of all other metallic spin glasses: (1) the linear scaling law based on the RKKY interaction between magnetic impurities in a typical SG is not obeyed, and indeed the temperature of the maximum in $\chi(T)$ is essentially independent of Mn concentration, which shows that formation of the SG state does not depend on the distance between the Mn atoms; (2) the maximum in $\chi(T)$ in the alloy containing only a trace of Mn ($\ll 0.1\%$) is at about 40 K, a temperature at least an order of magnitude larger than that in CuMn and other metallic SG with about 0.1% impurity concentration; (3) $\chi(T)$ obeys a Curie–Weiss law above the Neel temperature, but not below, which shows that the Mn moment is frozen in the spin-density-wave (SDW) matrix of Cr. We propose a model to explain this unusual behavior, in which the SG state is formed, not as a result of frustration of the Mn impurity moments, but through the frustration of the moments of the itinerant electrons of the host Cr. At low temperatures the frozen Mn moments pin the SDW, which gives rise to frustration surfaces between adjacent domains having different phase of the SDW. This effect depends only on the T-dependent interaction between the Mn moment and its neighbors, and thus is independent of the Mn concentration. © *1996 American Institute of Physics.* [S0021-8979(96)44108-2]

Departamento de Física, Universidad del Valle. A. A. 25630, Cali, Columbia

E. González and J. M. González
Instituto de Ciencia de Materiales de Madrid—CSIC, Serrano 144, 28006 Madrid, Spain

This work shows preliminary results on the study of $Fe_xMn_{0.6-x}Al_{0.40}$ alloys. It includes measurements of the temperature dependence of the ac susceptibility, zero field cooled magnetization, and Mössbauer spectroscopy. From the results obtained, the occurrence of reentrant spin glass behavior from a spin glass phase to an antiferromagnetic one for $0.2 \leqslant x \leqslant 0.35$ and from a spin glass phase to a ferromagnetic one for the $x = 0.55$ sample is proposed. Also, a normal spin glass transition was detected in the Fe range corresponding to $0.35 \leqslant x \leqslant 0.5$. These results allow us to construct a magnetic phase diagram for the alloy series. © *1996 American Institute of Physics.* [S0021-8979(96)23408-2]

I. INTRODUCTION

Previous theoretical results and experimental works[1–4] on the Fe–Mn–Al system, in particular on the disordered bcc structure of the $Fe_xMn_{0.7-x}Al_{0.3}$ (Ref. 5) series, proved the existence of pure spin glass and reentrant spin glass phases as well as the paramagnetic, ferromagnetic, and antiferromagnetic phases. The competitive ferromagnetic and antiferromagnetic exchange interactions together with the disordered structure make this behavior possible. The transition temperatures for the spin glass phases of the $Fe_xMn_{0.7-x}Al_{0.3}$ alloys are located below 70 K. A study on $Fe_{0.89-x}Mn_{0.11}Al_x$ (Ref. 6) alloys showed a strong dependence of this transition temperature on the aluminum concentration. This series shows reentrant spin glass behavior at $x = 0.4$ and $T = 50$ K. The concentration of aluminum cannot be too high because the disordered bcc structure and the competing exchange interactions do not occur at higher Al content. In the present work, the $Fe_xMn_{0.6-x}Al_{0.40}$ alloys were selected, and their magnetic alternating current (ac) susceptibility measured, to elucidate the different transition temperatures which characterize the magnetic phase diagram.

II. EXPERIMENT

Samples were prepared by melting pure elements in an arc furnace under argon, homogenizing the casts in evacuated sealed quartz tubes for one week at 1273 K and quenching them in ice water. Fe content range was $0.2 \leqslant x \leqslant 0.6$. Samples were characterized using x-ray diffraction (XRD), which showed the desired bcc disordered structure.

Magnetic characterization included the measurement of the temperature dependence of the ac susceptibility, and of the zero field cooled and low field cooled magnetization. The ac susceptibility measurements (pressed powder samples) were carried out in a magnetometer/susceptometer with an ac field of 3 Oe, a direct current (dc) field of 10 Oe and a frequency of 175 Hz. Two temperature ranges 5 K$\leqslant T \leqslant$100 K and 80 K$\leqslant T \leqslant$300 K were selected using liquid helium and liquid nitrogen, respectively. The magnetization was measured in a SQUID magnetometer with a magnetic field of 50 Oe.

III. RESULTS AND DISCUSSION

Figures 1(a) and 1(b) show the ac susceptibility vs temperature curves for 5 K$\leqslant T \leqslant$100 K and 80 K$\leqslant T \leqslant$300 K, respectively. Well defined peaks and also relatively strong changes of curvature can be noted in these curves. Temperatures of the peaks and changes of curvature for the different samples are reported in Table I and are indicated by arrows in Fig. 1.

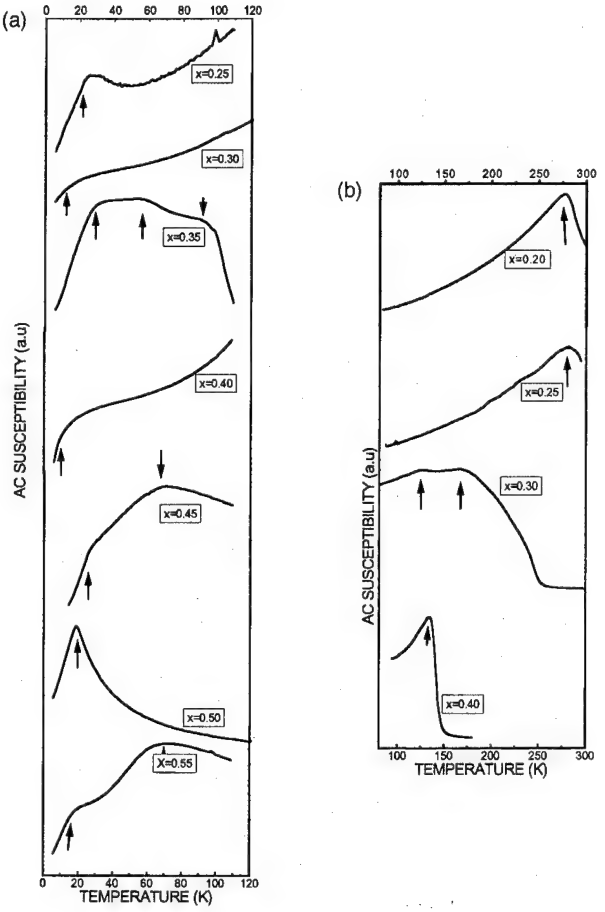

FIG. 1. Alternating current susceptibility vs temperature curves for samples with different Fe content x, (a) for 5 K$\leqslant T \leqslant$100 K and (b) for 80 K$\leqslant T \leqslant$300 K.

 0021-8979/96/79(8)/6155/3/$10.00

TABLE I. Different temperatures, of the maxima and the changes of curvature, obtained from the ac susceptibility curves for samples with different Fe concentrations x.

Sample	Temperatures
$x=0.20$	287
$x=0.25$	24 and 282
$x=0.30$	17, 120 and 167
$x=0.35$	30, 56 and 90
$x=0.40$	12 and 135
$x=0.45$	17 and 61
$x=0.50$	17
$x=0.55$	17 and 73

The magnetization vs temperature curve for an $x=0.30$ sample obtained, using a SQUID magnetometer, by zero field cooling in a field of 50 Oe is similar to its ac susceptibility curve. It can be noted that the sample appears to be magnetic above 17 K. The magnetization vs temperature curve for this sample, using the SQUID magnetometer, by field cooling in a field of 2 T is showed in Fig. 2. It can be noted that there exist high magnetization values until high temperatures. These results do not agree with those obtained by Mössbauer spectroscopy. Figure 3 shows Mössbauer spectra at 17 and 85 K of the $x=0.30$ sample. It can be noted that at 85 K the sample appears to be paramagnetic and at 17 K there exists a slight broadening which can be attributed to some magnetic behavior.

In order to interpret these results it should be remembered that in this system there are different types of magnetic interactions between atoms due the ferromagnetic, antiferromagnetic, and diluted character of the Fe, Mn, and Al atoms, respectively. Thus, it is possible to have ferromagnetic bonds (J_{FeFe}), antiferromagnetic bonds (J_{FeMn} and J_{MnMn}) and diluted bonds (Fe, Mn, and Al with an Al atom). Recent theoretical calculations[7] using the mean field renormalization group on a diluted and random-bond Ising model yielded ferromagnetic phase (region rich in Fe), the antiferromagnetic phase (region rich in Mn), spin glass phase (low temperatures and intermediate Fe and Mn contents), and the paramagnetic phase (high temperatures). The relationship between the exchange parameters also makes it possible to derive the reentrant spin glass phase in this system (see Refs. 4 and 7).

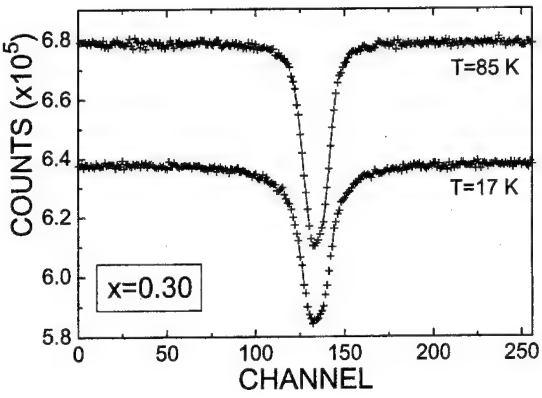

FIG. 3. Mössbauer spectra for the sample with $x=0.30$ for $T=17$ K and $T=88$ K.

According to the previous discussion and the results shown in Figs. 1(b) and 2(b) and Table I, an experimental phase diagram shown in Fig. 4 for the $Fe_xMn_{0.6-x}Al_{0.40}$ series is proposed. In this phase diagram an antiferromagnetic phase appears for $0.20 \leqslant x \leqslant 0.35$ (rich in Mn), a ferromagnetic phase appears for $0.55 \leqslant x \leqslant 0.60$ (rich in Fe), a pure spin glass phase appears for $0.35 \leqslant x \leqslant 0.55$ (intermediate Fe and Mn contents) and a reentrant spin glass phase appears at low temperatures below the antiferromagnetic region. A superparamagnetic region above the spin glass region and near the antiferromagnetic one is proposed. The dashed line represents the variation of the blocking temperature with the composition. The existence of this "superparamagnetic behavior" can be attributed to magnetic clusters of Fe and Mn atoms separated by Al atoms which at very low temperatures behave as a spin glass and for at higher T behave paramagnetic, when the external field is zero, as is shown by Mössbauer spectroscopy. When a little external field is applied, for ac susceptibility or zero field cooling magnetization measurements, the clusters are aligned and thus it is possible to detect the blocking temperature. When high external field is applied, for field cooling magnetization measurement, the clusters are strongly aligned and cannot be detected by the

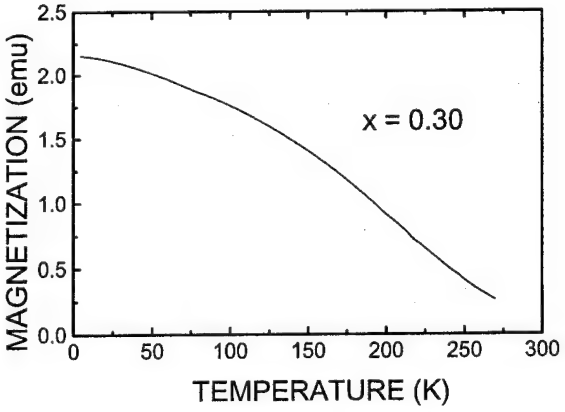

FIG. 2. Field cooling magnetization vs temperature curve using a field of 2 T.

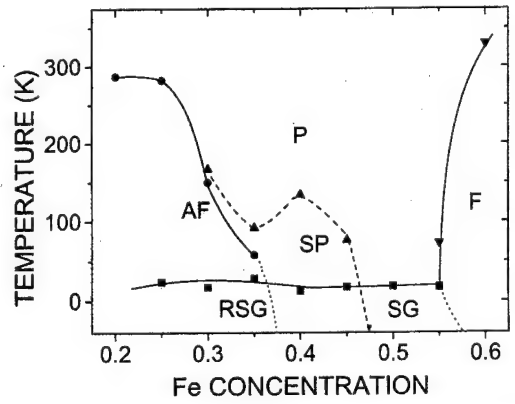

FIG. 4. Proposed magnetic phase diagram according with ac susceptibility curves.

transitions temperatures and the blocking temperature, as can be noted in Fig. 3. It is possible to think that this behavior is due to a ferromagnetic character, but the little Fe content ($x \leqslant 0.45$) is not enough to stabilize this phase as is showed by the Mössbauer spectras in Fig. 2. For alloys rich in Mn, an additional antiferromagnetic region was detected which appears above the spin glass region and below the superparamagnetic region depending on the Mn concentration. The existence of these clusters is possible remembering the structural disorder of the alloy. The experimental point for $x=0.60$, in the magnetic phase diagram, was obtained by Mössbauer spectroscopy and is reported in Ref. 1.

Additional research work is now in progress in order to take Mössbauer spectra with an applied external field to obtain a confirmation of this superparamagnetic behavior.

Hahn-Meitner-Institut, Glienickerstrasse 100, 14109 Berlin, Germany

We determined the paramagnetic critical scattering of the reentrant ferromagnets $Au_{1-x}Fe_x$, with $x=0.2$, 0.18, and 0.16, i.e., close to the threshold ($x_c \sim 0.155$), below which ferromagnetism disappears and a spin-glass state sets in. Following the Ornstein–Zernicke formalism, we derived the inverse critical ferromagnetic correlation length ($\kappa=\xi^{-1}$) and the related magnetic susceptibility. The macroscopic susceptibility $\chi_{q=0}$ of the samples was also determined in a separate experiment with a Faraday balance. The neutron results show the same behavior of critical type with $\chi_{q=0}$ for $x=0.18$ but not for $x=0.16$. We interpret this discrepancy as an indication for a non-well-defined ferromagnetic transition for $x=0.16$. A further comparison of our results with those for Fe shows that the amplitude of the correlation length increase with increasing disorder so that, at the same reduced temperature τ, the correlations are much larger in the disordered samples than in Fe. As a consequence of this, the ferromagnetic correlations in the disordered samples persist well above T_c and lead to a much wider critical region than is the case in Fe and in usual ferromagnets. [S0021-8979(96)23508-9]

INTRODUCTION

Disordered magnetic systems with competing interactions usually show a phase diagram characterized by reentrance: they first undergo a phase transition from the paramagnetic state into a disordered ferro or antiferromagnetic one at a critical temperature T_c and at low temperatures they reenter a magnetic state with spin-glass-like properties. This low temperature spin-glass phase has been the subject of numerous studies in the last twenty years,[1] where strong controversies appeared concerning its nature and the eventual presence of a long range magnetic order. However, little work has been devoted to the influence of the disorder and of the spin-glass phase, which is close in the phase diagram both in concentration and temperature, to the phase transition that takes place at T_c.

The above considerations prompted us to investigate the static and dynamic critical behavior by means of neutron scattering of the archetypal reentrant ferromagnetic system $Au_{1-x}Fe_x$ with $x=0.16$, 0.18, and 0.20, i.e., close to the threshold $x_c=0.155$, below which ferromagnetism disappears and spin-glass behavior sets in.[2]

The quasielastic neutron scattering results on $Au_{0.84}Fe_{0.16}$ and $Au_{0.82}Fe_{0.18}$ and the analysis of the critical paramagnetic scattering of $Au_{0.84}Fe_{0.16}$ were presented elsewhere.[3,4] Here we analyze the critical paramagnetic small angle neutron scattering (SANS) of $Au_{0.82}Fe_{0.18}$ and of $Au_{0.80}Fe_{0.20}$ and deduce the inverse correlation length $\kappa=\xi^{-1}$ and the related critical exponents ν. By comparing the SANS results to the macroscopic volumic susceptibility, we determine for $Au_{0.82}Fe_{0.18}$ and $Au_{0.84}Fe_{0.16}$ the dipolar wave vector q_D and the SANS susceptibility. The qualitative agreement between the macroscopic and the SANS susceptibility is a strong indication in favor of a well-defined ferromagnetic transition for $x \geqslant 0.18$. However, for $x=0.16$, the SANS susceptibility is qualitatively different from the macroscopic one. We interpret this discrepancy as an indication of the breakdown of the ferromagnetic phase transition in the vicinity of the percolation threshold.

SANS RESULTS

Our samples were polycrystalline discs prepared by arc melting of the constituents as described elsewhere.[3] Their homogeneity was tested by microprobe analysis and magnetic susceptibility measurements with a Faraday balance.

The SANS experiments were done with polarized neutrons at the neutron spin echo spectrometer of the LLB (Saclay). The neutron wavelength was 6 Å and the q resolution of spectrometer was equal to 9×10^{-3} Å^{-1}.

The transition temperatures were determined from the peaks of the critical scattering of a depolarized neutron beam. The measurements were done at the lowest q value, which was equal to 1.8×10^{-2} Å^{-1}. We found $T_c=140$ and 180 K for $Au_{0.82}Fe_{0.18}$ and $Au_{0.80}Fe_{0.20}$, respectively. The SANS peaks were not sharp and we estimate the uncertainty in the determination of the critical temperature to be of the order of one degree. As in Ref. 4 this does not affect our analysis because the data vary smoothly with the temperature.

Three-directional neutron polarization analysis[5] was used to separate the magnetic scattering from the structural

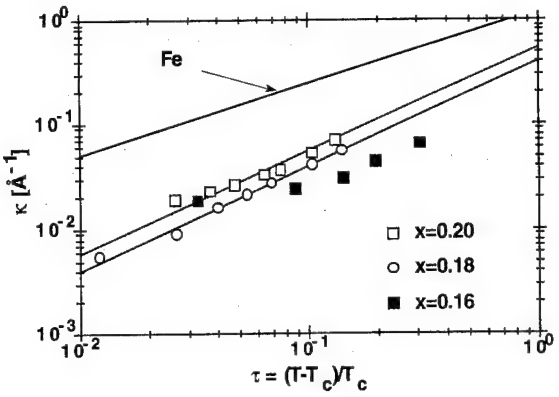

FIG. 1. Log–log plot of the inverse correlation length κ vs the reduced temperature for $x=0.20$ (open circles), $x=0.18$ (open squares), $x=0.16$ (closed squares) and Fe ($\kappa=1.22\tau^{0.69}$). The solid lines represent the power law fits for $x=0.20$ and $x=0.18$ given in the text. The characteristic temperatures are: $T_c=180$, 140, and 93 K for $x=0.20$, 0.18, and 0.16, respectively and $T_c=1043$ K for Fe.

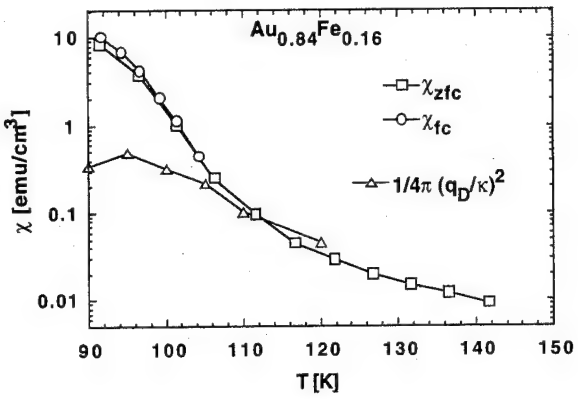

FIG. 2. Zfc (open squares) and fc (open circles) volumic susceptibility of $Au_{0.84}Fe_{0.16}$ measured with a Faraday balance at $H=4$ Oe, as a function of the temperature. The open triangles represent the SANS susceptibility derived by Eqs. (1) and (3). The solid lines are guides to the eye.

small angle contribution. The magnitude of the magnetic guide field at the sample was equal to 4 Oe. The measurements covered the following temperature and q ranges: 203.5 K$\geqslant T\geqslant$184.6 K for $x=0.20$, 159.6 K$\geqslant T\geqslant$141.7 K for $x=0.18$, and for both samples 1.8×10^{-2} Å$^{-1}\leqslant q\leqslant 7.3\times10^{-2}$ Å^{-1}.

The q dependence of the SANS intensity $I_q(T)$ was analyzed using the Ornstein–Zernicke formalism, which neglects the Fisher exponent η at $T\geqslant T_c$:

$$I_q(T)\propto\chi_q(T)=\frac{C}{q^2+\kappa(T)^2}$$

with

$$C=\frac{q_D^2}{4\pi} \qquad (1)$$

(cgs units), where χ_q is the q-dependent volume magnetic susceptibility and q_D is the dipolar wave vector.

Figure 1 shows on a log–log scale the κ values for both the $x=0.18$ and 0.20 samples, as a function of the reduced temperature $(T-T_c)/T_c$. This figure also includes the data of $Au_{0.84}Fe_{0.16}$ (Ref. 4) and Fe (Ref. 6).

According to the predictions of static scaling (the Fisher exponent η is neglected),

$$\kappa=\kappa_0\ \tau^{\nu} \quad \text{and} \quad \chi_{q=0}=\chi_0\tau^{-\gamma}$$

with

$$\tau=(T-T_c)/T_c, \quad \nu=2\gamma. \qquad (2)$$

In three-dimensional Heisenberg systems $\nu=0.69$. For both $Au_{0.80}Fe_{0.20}$ and $Au_{0.82}Fe_{0.18}$, κ is proportional to τ with $\kappa_0=0.53$ Å^{-1} for $Au_{0.80}Fe_{0.20}$ and $\kappa_0=0.40$ Å^{-1} for $Au_{0.82}Fe_{0.18}$. We deduce $\nu=1\pm0.1$, where the estimated error in the value of ν is mainly due to the uncertainty in the determination of the Curie temperatures.

The high value for the exponent ν agrees with previous findings on $Au_{0.83}Fe_{0.17}$ (Ref. 7) and on other disordered systems[8,9] but is not confirmed by $Au_{0.84}Fe_{0.16}$, which is the most disordered of our samples. As seen in Fig. 1, the variation of $\kappa(\tau)$ is slower in $Au_{0.84}Fe_{0.16}$ than in the other samples.

At the same value of the reduced temperature τ, the inverse correlation length κ is significantly smaller in all $Au_{1-x}Fe_x$ samples than in Fe. At $\tau=0.01$, the correlation length of $Au_{0.82}Fe_{0.18}$ is 12.5 times larger than that of Fe and the correlated volumes contain some 350 times more Fe ions in $Au_{0.82}Fe_{0.18}$ than in pure Fe. This astonishing influence of the disorder on the correlations was first seen in $Au_{0.84}Fe_{0.16}$ (Ref. 4) and is confirmed by our susceptibility measurements.

SUSCEPTIBILITY RESULTS

The susceptibility of $Au_{0.84}Fe_{0.16}$ and $Au_{0.82}Fe_{0.18}$ was measured with the Faraday method on the samples used for neutron scattering. The samples were first either zero field cooled (zfc) or field cooled (fc) down to 4 K. The susceptibility was then recorded by increasing the temperature. The magnetic field was equal to 1.33 Oe, 4 Oe, the magnetic guide field of the SANS experiments, and 12 Oe. At all temperatures covered by the SANS experiments the magnetization was linear to the magnetic field and the absolute value of the volume initial susceptibility $\chi_{q=0}(T)$ could be directly determined from the Faraday method. For the demagnetizing field correction we assumed $N=1.102\times10^{-2}$, the factor calculated for a prolate ellipsoid with $m=70$ (ratio diameter/thickness of the samples).[10] Figures 2 and 3 show the volumic susceptibility above T_c measured at 4 Oe for $x=0.16$ and 0.18, respectively.

The relation between the volumic susceptibility and the SANS results is given by the $q=0$ limit of (1): $\chi_{q=0}=(q_D/\kappa)^2/4\pi$. The numerical value of q_D can therefore be determined from the proportionality factor between $\chi_{q=0}$ and κ^{-2}, therefore, $q_D=\kappa$ at the temperature where $\chi_{q=0}=1/4\pi$. We found $q_D=0.041$ Å^{-1} for $x=0.18$ and $q_D=0.05$ Å^{-1} for $x=0.16$. These values are very close to $q_D=0.045$ Å^{-1}, the value found in Fe (Ref. 11).

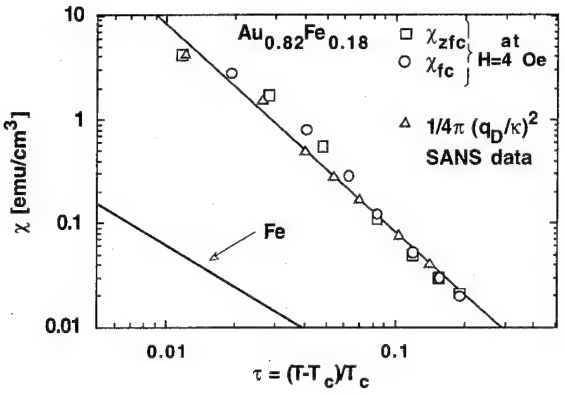

FIG. 3. Zfc (open squares) and fc (open circles) volumic susceptibility of $Au_{0.82}Fe_{0.18}$ measured with a Faraday balance at $H=4$ Oe, vs the reduced temperature. The open triangles represent the SANS susceptibility derived by Eqs. (1) and (3). The solid line represent the power law with $\gamma=2$ (see text). The results on Fe are also included ($\chi=1.35\ 10^{-4}\ \tau^{-1.33}$).

Having determined the proportionality factor between $\chi_{q=0}$ and κ^{-2} we could compare the SANS susceptibility to the macroscopic one. The result is shown in Figs. 2 and 3 for $x=0.16$ and 0.18, respectively.

As seen in Fig. 3, the agreement between the Faraday and the SANS susceptibilities is excellent for $x=0.18$. On the other hand, for $x=0.16$, the neutron susceptibility is systematically lower than the bulk one and the discrepancy between the two curves increases when the temperature decreases (Fig. 2).

DISCUSSION

The behavior of $Au_{0.84}Fe_{0.16}$ is qualitatively different from that of the other two samples, which are more concentrated in Fe. In $Au_{0.84}Fe_{0.16}$, at and above T_c, the spin relaxation rate Γ is proportional to q^2 (Ref. 3), although, in $Au_{0.82}Fe_{0.18}$ (Ref. 3) and in Fe (Ref. 6), $\Gamma \propto q^{5/2}$ as expected for Heisenberg ferromagnets (Ref. 12).

The analysis of the paramagnetic SANS of $Au_{0.84}Fe_{0.16}$ under the assumption of a ferromagnetic phase transition leads to $\nu \sim 0.69$ (Ref. 4) although $\nu=1$ for $x=0.18$ and 0.20. Also the SANS susceptibility deduced in the frame of this analysis is not consistent with the volumic susceptibility measured on the same sample with the Faraday method.

In the light of these results we have to assume that there is no well-defined ferromagnetic phase transition for $x=0.16$. This assumption explains the nonconventional (for ferromagnets) q dependence of the spin-relaxation rate Γ, the strong q dependence of T_c reported in Ref. 4, the low value of the exponent ν as well as the inconsistency between the SANS and the Faraday susceptibility. This inconsistency indicates that the q dependence of I_q is not described by the Ornstein–Zernicke formalism. As seen in Fig. 2, the bulk susceptibility is much higher than the SANS one, which implies that the increase of I_q when q is decreased is faster than predicted by Eq. (1). A similar behavior was observed on the spin-glass $Au_{0.87}Fe_{0.13}$ (Ref. 7), where the $1/I_q$ vs q^2 plots (Ornstein–Zernicke plots) show a marqued downward curvature. In $Au_{0.87}Fe_{0.13}$ this effect was easily seen in the q range covered by the present measurements. In $Au_{0.84}Fe_{0.16}$, the deviations from the Ornstein–Zernicke formalism were not significant. We therefore expect these deviations to become noticeable at $q<0.02$ Å^{-1}.

The qualitative agreement between the SANS and the Faraday susceptibility in $Au_{0.82}Fe_{0.18}$ is a strong argument in favor of a well-defined ferromagnetic phase transition. In the light of the SANS results on $Au_{0.83}Fe_{0.17}$ (Ref. 7) it is reasonable to assume that a ferromagnetic phase transition exists for $x \geqslant 0.17$.

The phase transition that takes place in $Au_{0.82}Fe_{0.18}$ is characterized by different exponents than those found in Fe and more generally in nondisordered 3D Heisenberg systems. This is seen in Fig. 1 but also in Fig. 3. From these plots, we deduce $\nu=1$ and $\gamma=2$ instead of the expected $\nu=0.69$ and $\gamma=1.38$.

Figures 1 and 3 give a consistent picture of the specific features of the phase transition in the disordered ferromagnetic system $Au_{0.82}Fe_{0.18}$. Not only are the exponents different but also the critical amplitudes: at the same reduced temperature the correlation length and the magnetic susceptibility are much higher in the disordered system than in Fe.

Recent results on the insulating system $CdCr_{2(1-x)}In_{2x}S_4$ (Ref. 9) confirmed the existence of larger critical amplitudes $\xi_0(=\kappa_0^{-1})$ in disordered systems than in usual ferromagnets. In Fig. 1 we see that κ_0 decreases when the disorder in increased, which implies that ξ_0 increases with disorder. As a consequence of the large critical amplitudes $\xi_0(=\kappa_0^{-1})$ the ferromagnetic correlations in $Au_{0.82}Fe_{0.18}$ and $Au_{0.80}Fe_{0.20}$ persist well above T_c and lead to a much wider critical region than in Fe and in usual ferromagnets.

Neutron depolarization study of magnetic order in a-Fe_xZr_{100-x} (x=90–93), a-$Fe_{90}Sc_{10}$ and their hydrides

Neutron depolarization measurements have been used to show that ferromagnetic domains exist in a-Fe_xZr_{100-x} alloys for $90 \leq x \leq 93$, and that these domains are not affected by the ordering of transverse spin components at T_{xy}. Domain sizes decrease from 1.1 μm at $x=90$, to 0.08 μm by $x=93$. Measurements in an applied field set an upper limit of ~50 nm for correlations in the transverse components. By contrast, a-$Fe_{90}Sc_{10}$ shows no evidence of ferromagnetic order and is confirmed to be a spin glass. Measurements on deuterium-loaded samples show that all of the a-Fe–Zr and a-Fe–Sc alloys studied here are ferromagnetic with T_c's in the range 380–400 K, and domains ~1 μm in size. © *1996 American Institute of Physics.* [S0021-8979(96)23608-5]

INTRODUCTION

Amorphous iron rich alloys of the form a-Fe_xETM_{100-x} (where ETM=Sc, Y, Zr, Hf, and $x \sim 90$) provide a rich testing ground for models of magnetic order in the presence of exchange frustration as their behavior spans the full range of possibilities from ferromagnet to spin glass with increasing frustration. Two magnetic transitions are observed in partially frustrated systems, the first, at T_c, to a collinear ferromagnetic state, followed at T_{xy} by the ordering of transverse spin components.[1] Earlier neutron depolarization work on a-Fe_xZr_{100-x} ($x=90$–92)[2] confirmed the presence of ferromagnetic order and found large domains for $x \leq 91$, but only weak correlations for $x=92$. However, magnetization and Mössbauer measurements suggest that significant ferromagnetic order persists to $x=93$.[1,3] Our aim here is to extend the neutron depolarization data to $x=93$, to look for possible long-range order in the transverse spin components, and to confirm that the ordering at T_{xy} does not destroy the ferromagnetic order that develops at T_c.

For comparison, we have studied a-$Fe_{90}Sc_{10}$, which is fully frustrated and exhibits a single transition to a spin glass state with no spontaneous magnetization,[1,4–6] although a large magnetization is readily induced by the application of a modest field (~1 T). Since there should be no long-ranged correlations in a spin glass, we expect no depolarization from this material, and it serves in part as an internal test of our procedures.

Finally, we have also investigated the hydrides of these alloys. The lattice expansion associated with the absorption of hydrogen lifts the exchange frustration in both a-Fe–Zr (Ref. 3) and a-Fe–Sc (Ref. 4) converting them to soft ferromagnets with ordering temperatures ~400 K. However, it has been suggested that a-Fe–Sc–H may remain a spin glass,[6] and depolarization measurements provide a direct way to check for this possibility.

[a]On leave from Centre for the Physics of Materials and Department of Physics, McGill University, 3600 University St., Montreal, Quebec, Canada.

EXPERIMENTAL METHODS

The alloys were prepared by arc-melting appropriate ratios of the pure elements (Fe: 99.95%, Zr: 99.8%, and Sc: 99.9% pure) under Ti-gettered argon to yield ~2 g ingots. Melt spinning was carried out under a partial pressure of helium onto a copper wheel at 50 m/s. Ribbons were typically 1 mm wide, 20 μm thick, and several meters long. Thickness variations along the samples used for the depolarization measurements were found to be less than ± 1 μm. Absence of crystallinity was confirmed using Cu–K_α powder x-ray diffraction and room temperature Mössbauer spectroscopy. A LakeShore susceptibility system with a closed-cycle fridge was used to record χ_{ac} vs T down to 12 K. The samples were saturated with deuterium using an electrolytic charging method[7] and final deuterium contents were determined from the mass loss on heating to 300 °C in a Perkin–Elmer TGA-7 Thermogravimetric analyzer. This instrument was also used to determine the magnetic ordering temperature of the deuterides by operating with a small field gradient applied. The TGA was calibrated using alumel and nickel standards.

The neutron depolarization measurements were carried out on the long wavelength polarized neutron spectrometer (LONGPOL) at the High Flux Australian Reactor (HIFAR) operated by the Australian Nuclear Science and Technology Organisation (ANSTO). The incident beam, with a wavelength of 0.36 nm, is polarized vertically by scattering from saturated polycrystalline iron sheets. A similar arrangement is used as an analyzer. Typical beam polarizations were in the range 32%–36%. The instrument has been described in more detail elsewhere.[8] A cadmium plate with a 5 mm×5 mm square hole served as the sample holder. Several ribbons were laid side-by-side to cover the opening, with Cd wire covering the gaps between ribbons. One to four layers of ribbon were used, depending on the depolarization expected. The holder was mounted on the cold stage of a closed-cycle fridge which operates down to 12 K. An air-cooled electromagnet was used to apply fields of up to 80 mT in the sample plane, perpendicular to both the beam and the incident polarization.

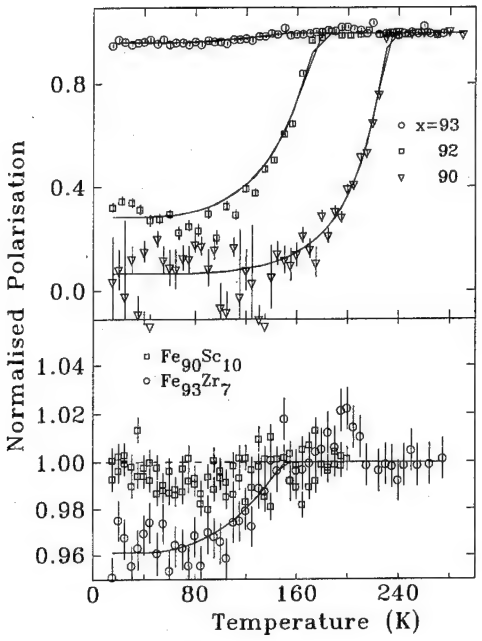

FIG. 1. Normalized depolarization signal for a-Fe_xZr_{100-x} (top) and a-$Fe_{90}Sc_{10}$ (bottom) measured in a guide field of 1 mT. Solid lines are fits assuming a temperature independent domain size. Notice that the a-$Fe_{90}Sc_{10}$ sample does not affect the beam polarization at any temperature.

RESULTS AND DISCUSSION

On passing through a uniformly magnetized region such as a domain, the neutron moment experiences a torque which causes it to precess about the magnetization direction. The total rotation increases with the internal magnetization, the thickness of the domain, and the wavelength of the neutron. If the neutron now passes through many such domains it will undergo many rotations. If the magnetization direction within each domain can be assumed to be a random vector, and the angle through which the neutron moment turns in each domain is $\ll 2\pi$, then the initial polarization is scrambled and decays according to:[9]

$$P=\exp(-\alpha\lambda^2) \tag{1}$$

with

$$\alpha=\tfrac{1}{2}c^2\langle B_\perp^2\rangle d\,\delta, \tag{2}$$

where λ is the neutron wavelength, $\langle B_\perp^2\rangle$ is the mean square domain magnetization perpendicular to the neutron polarization, d is the sample thickness, and δ is the mean domain size. c is a constant which takes the value 4.63×10^{14} $m^{-2}\,T^{-1}$ in S.I. units.

The depolarization signals for all of the samples studied here are shown in Fig. 1. It is immediately apparent that all of the a-Fe–Zr alloys cause a significant depolarization of the beam below their respective T_c's, confirming the presence of ferromagnetic order. The depolarization weakens with increasing iron content as the exchange frustration builds up and the system moves closer to becoming a spin glass. However, even at $x=93$, (shown in the lower half of Fig. 1 on an expanded scale) there is some loss of polarization. By contrast, a-$Fe_{90}Sc_{10}$ has no effect on the beam at any temperature, consistent with the spin glass nature of the order in this alloy and the absence of any ferromagnetic correlations. If we assume that the domains, once formed, do not change size, then the observed temperature dependence of the polarization must result from the normal change in spontaneous magnetization with temperature. Taking the estimated magnetization from Ref. 1, and assuming a simple mean-field temperature dependence, then the data in Fig. 1 can be fitted to Eq. (1) to obtain domain sizes and ordering temperatures. These fits (shown as solid lines on Fig. 1, and summarized in Table I) show that large domains persist to $x=92$ but that beyond this point there is a very rapid reduction in domain size. It is not clear that the 80 nm regions suggested by the fit to the $x=93$ sample are large enough to justify the use of the term "domain" but it is clear that some ferromagnetic correlations are present in this material, and that they are not affected by the ordering of the transverse spin components at $T_{xy}\sim80$ K.[1]

TABLE I. Summary of fitted parameters from data shown in Figs. 1 and 3. $T_c(\chi)$ and T_c(ndep) are ordering temperatures derived from bulk and depolarization measurements, respectively. δ is the mean domain size. * Note: a-$Fe_{90}Sc_{10}$ is a spin glass, so the value for T_c given here is for T_{sg}.

Alloy	$T_c(\chi)$ K	T_c(ndep) K	δ μm
$Fe_{90}Zr_{10}$	240±3	232±4	1.1±0.2
$Fe_{92}Zr_8$	182±2	176±1	1.16±0.07
$Fe_{92}Zr_8D_{13\pm2}$	376±3	362±10	1.4±0.1
$Fe_{93}Zr_7$	145±2	150±5	0.077±0.006
$Fe_{93}Zr_7D_{17\pm2}$	372±3	359±6	0.90±0.05
$Fe_{90}Sc_{10}$	95*	···	0.0
$Fe_{90}Sc_{10}D_{28\pm0.5}$	395±5	390±40	1.0±0.1

The main difference between the results presented here and those of Hadjoudj *et al.*,[2] is that we observe a strong depolarization even at $x=92$ and only the $x=93$ sample shows a weak effect. However, examination of the transition temperatures shown in Ref. 2 allows us to bring the two sets of data into agreement. T_c in a-Fe_xZr_{100-x} is a very strong function of x, decreasing at ~25 K/at.%,[1,3] and thus provides a sensitive check on sample composition. Using this scale, it is clear that their $x=90$ and 91 samples are consistent with typical values, but the T_c of their $x=92$ sample is below 150 K, a value more often associated with $x=93$. With this modified composition, our data and those of Ref. 2 are in full agreement.

At T_c a ferromagnetic state forms with a substantial fraction of each moment oriented perpendicular to the ordering axis. The moments precess rapidly about the ferromagnetic, z, axis, so that the xy components time average to zero, and the system appears to be a collinear ferromagnet. The second transition in a-Fe–Zr is associated with the freezing of the transverse degrees of freedom, and as noted above, does not lead to a destruction of the ferromagnetic order. Since the average magnetization does not increase at T_{xy}, the xy components cannot be correlated over substantial distances, but no limits have yet been placed on their correlation length. Since the neutrons are only sensitive to $B_\perp$ we can eliminate the ferromagnetic contribution to the depolarization signal by magnetizing the sample parallel to the neutron polarization

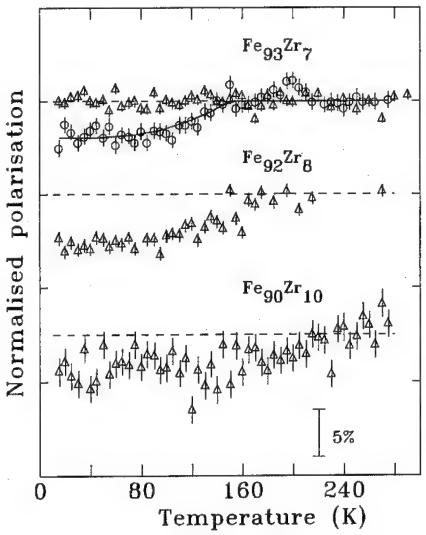

FIG. 2. Normalized depolarization signal for a-Fe_xZr_{100-x} measured in a guide field of 80 mT. The 1 mT data for a-$Fe_{93}Zr_7$ showing a 4% depolarization of the incident beam are repeated for comparison. Dashed lines indicate the base polarization of the beam.

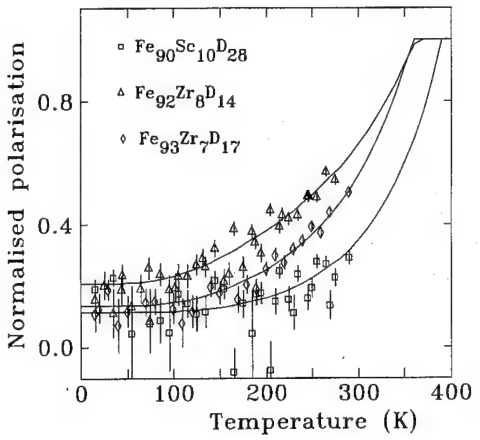

FIG. 3. Normalized depolarization signal for a-$Fe_xZr_{100-x}D_y$ and a-$Fe_{90}Sc_{10}D_{28}$ measured in a guide field of 1 mT. Solid lines are fits assuming a temperature independent domain size.

direction. A simple ferromagnet would then not depolarize the beam even below T_c. In the absence of the ferromagnetic contribution, any correlations in the transverse components should appear as a loss of polarization around T_{xy}. However, Fig. 2 shows that while there is some residual effect from the imperfect alignment obtained in the 80 mT field available, no change can be seen in either the $x=92$, $T_{xy}=46$ K, or the $x=93$, $T_{xy}=78$ K (Ref. 1) samples. Since the change in polarization is much smaller than that seen for the ferromagnetic component of the $x=93$ sample, we are able to rule out correlations in the transverse spin components longer than about half of the 80 nm length scale seen there.

Hydrogen loading is known to convert these alloys into soft ferromagnets,[3,4] and the depolarization behavior of the deuterium loaded samples shown in Fig. 3 is as expected. TGA analysis confirmed that they had ordering temperatures well above room temperature, although the values obtained are only lower limits as the samples lose deuterium rapidly as T_c is approached. Neutron depolarization shows that all of the deuterides are ferromagnetic, and fits to the curves yield ordering temperatures in agreement with the TGA data. Values for domain sizes and ordering temperatures are summarized in Table I. The data for a-$Fe_{90}Sc_{10}D_{28}$ show that it depolarized the beam more strongly than the two Zr samples, leaving no doubt that this material is ferromagnetic. It is not clear why no critical peaks were observed in the susceptibility of a similar sample.[6]

We have performed ac susceptibility and dc magnetization measurements on the diluted magnetic semiconductor $Zn_{1-x}Mn_xTe$. The measurements clearly indicate spin glass behavior. For an $x=0.4$ sample, the data for the imaginary part of the complex susceptibility (χ'') was analyzed according to conventional power-law dynamics and good scaling was obtained with $T_c=13.4\pm0.2$ K, $z\nu = 10.5 \pm 1.0$, and $\beta=0.9\pm0.2$. These values of $z\nu$ and β are consistent with results obtained in other spin glass systems. The scaling of the χ'' data was not as good when analyzed within the activated dynamics model. Magnetization measurements of an $x=0.5$ sample also showed a spin glass-like transition. Scaling of the nonlinear magnetization just above the transition gave $T_c = 20.8 \pm 0.2$ K, and the critical exponent values $\beta=0.8\pm0.2$ and $\gamma=4.0\pm1.0$. This confirms the β value obtained from the ac measurements and the γ value is in fair agreement with reported values for other diluted magnetic semiconductor spin glass systems. We conclude that $Zn_{1-x}Mn_xTe$ and similar systems undergo equilibrium phase transitions to a spin glass state at low temperatures. © *1996 American Institute of Physics.* [S0021-8979(96)23708-6]

I. INTRODUCTION

Diluted magnetic semiconductors (DMSs) are a class of randomly disordered, insulating Heisenberg antiferromagnets with short-range interactions.[1–3] Recently, the archetypal DMS $Cd_{1-x}Mn_xTe$ has been the subject of continued theoretical and experimental investigations in an attempt to firmly establish that this material undergoes a continuous phase transition to a spin glass state.[4–12] If $Cd_{1-x}Mn_xTe$ is a spin glass, then one is led to the question: Are all DMS alloys spin glasses with the same critical exponents? The aim of this article is to shed some light on this question.

Recent studies of the ac susceptibility χ_{ac} in $Cd_{1-x}Mn_xTe$ and $Hg_{1-x}Mn_xTe$ show that these materials have zero-frequency transition temperatures T_c which are >0 K.[6–8] These data also indicate that the spin relaxation time is a power law function of the reduced temperature $\epsilon = (T-T_c)/T_c$. This behavior (critical slowing down) has been found to give a better description of the dynamics in the critical region above T_c than a process of thermal activation over free energy barriers.[4,6,7] These findings indicate that an equilibrium phase transition to a spin glass state exists at finite temperatures in $Cd_{1-x}Mn_xTe$ and $Hg_{1-x}Mn_xTe$. Further, virtually identical critical exponents were obtained in both materials, which led to the speculation that all DMS alloys belong to the same spin glass universality class.

To further test this hypothesis, we have made ac susceptibility and dc magnetization measurements on $Zn_{1-x}Mn_xTe$ alloys close to the spin freezing transition. The ac susceptibility χ_{ac} was measured for frequencies 80 Hz$\leqslant f \leqslant$2300 Hz. Both power-law and activated scaling analyses were applied to the data in order to determine which theory provides the better description of the behavior in the vicinity of the transition. Nonlinear magnetization data were also collected in the region of the transition in order to compare the static scaling behavior of $Zn_{1-x}Mn_xTe$ with that $Cd_{1-x}Mn_xTe$.

II. EXPERIMENTAL DETAILS

The ac susceptibility measurements were performed on a single-crystal sample of $Zn_{1-x}Mn_xTe$, with concentration $x=0.41$. The measurements were carried out with a Lake-Shore susceptometer. Both in-phase (χ') and out-of-phase (χ'') components were measured in an ac field of 12.5 Oe. For each measurement, the temperature was kept stable to within 0.02 K.

The magnetization measurements were made on another single-crystal sample of $Zn_{1-x}Mn_xTe$, with $x=0.506$. These measurements were made with a Cryogenic Consultants Limited superconducting quantum interference device magnetometer. Measurements were taken for fields between 0 and 100 G and for temperatures between 5 and 300 K. Temperature stability was achieved to within 0.01 K.

III. RESULTS AND DISCUSSION

The dynamics of the transition are most sensitively probed by the measurement and analysis of $\chi''(\omega,T)$.[7] Figure 1 shows $\chi''(\omega,T)$ for several different frequencies. There is scatter in the data because of the relatively small out-of-phase signal. Smoothing curves were therefore drawn through the data points to enable us to objectively determine the positions of the peaks, which are needed for the data analysis. An examination of the behavior of $\chi''(\omega,T)$ allows us to discern whether critical slowing down or activated dynamics provides a better description of the dynamical characteristics of the freezing transition in DMS systems.

In the critical slowing down description, $\chi''(\omega,T)$ behaves according to the scaling law[7,13]

 0021-8979/96/79(8)/6164/3/$10.00

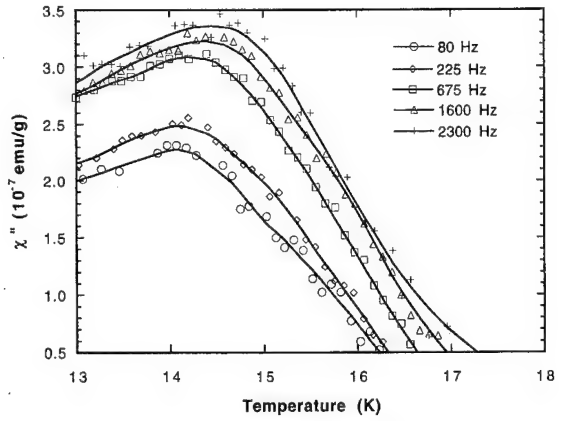

FIG. 1. Temperature dependence of χ'' near the freezing transition. The lines through the data are smoothing curves which enable the positions of the peaks to be reliably ascertained.

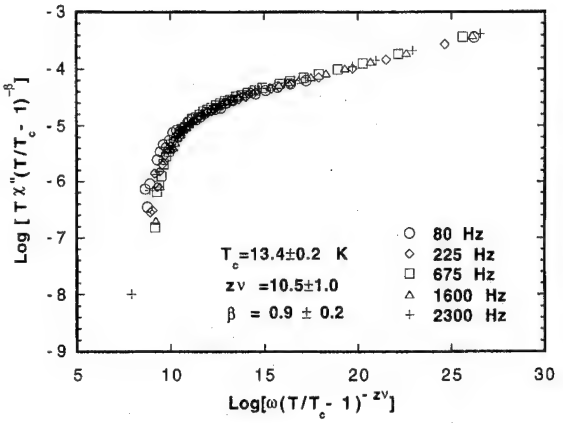

FIG. 2. Power law scaling of $\chi''(\omega,T)$ according to Eq. (1) in the text. The best-fit values of T_c and the scaling exponents $z\nu$ and β are also shown.

$$T\chi''(\omega,T)=\epsilon^{\beta}F(\omega\epsilon^{-z\nu}), \tag{1}$$

where β is the critical exponent for the order parameter and $F(y)$ is a universal function of y. Bertrand *et al.* have argued that the scaling relation Eq. (1) is only valid for temperatures $T > T_p$, where T_p is the temperature at which the peak in $\chi''(\omega,T)$ occurs.[9] We have taken this criterion into account in our analysis of all the $\chi''(\omega,T)$ data, which are shown in scaled form in Fig. 3. The data are well described by a single scaling curve. The best scaling was obtained for the following parameter values: $T_c=13.4\pm0.2$ K, $z\nu=10.5\pm1.0$, and $\beta=0.9\pm0.2$. The uncertainties in these parameters are obtained by ascertaining (by visual inspection) the extremal values of the parameters for which reasonably good scaling is still achieved. The values of the exponents $z\nu$ and β obtained here are consistent with previous results obtained for $Cd_{1-x}Mn_xTe$ and $Hg_{1-x}Mn_xTe$, i.e., $z\nu=9\pm1$ and $\beta=0.8\pm0.1$[6–10] Similar values were also obtained in a non-DMS insulating spin glass.[14] One should note that the range of frequencies used in this study is rather limited, and measurements encompassing a larger frequency range need to be made. Nevertheless, our results for $z\nu$ and β strongly indicate that the same universal critical exponents indeed describe the spin glass transition in all DMS materials.

We have also attempted to interpret the $\chi''(\omega,T)$ data according to the activated dynamics description of the spin freezing transition. In this picture, the scaling relation governing the behavior of $\chi''(\omega,T)$ near the transition can be written as[15,16]

$$\chi''(\omega,T)=\varepsilon^{P}G[-\varepsilon^{Q}\ln(\omega\tau_0)], \tag{2}$$

where P and Q are scaling exponents. If thermally activated excitations do govern the critical dynamical behavior, then one expects the exponents P and Q to be universal.[7] Figure 3 shows the best scaling plot corresponding to Eq. (2) for our $\chi''(\omega,T)$ data. This was obtained using the values $T_c = 13.4 \pm 0.2$ K, $P = 0.5 \pm 0.1$, $Q = 0.4 \pm 0.1$, and $\tau_0 = 10^{-13}$ s. It is clear from Figs. 2 and 3 that the activated scaling form of Eq. (4) provides a less satisfactory description of the data. Further, the P and Q exponents have quite different values from those obtained in other DMS systems and other systems which show a spin freezing transition ($3.65 \leqslant P \leqslant 4.2$, $Q = 0.8$ for $Hg_{0.7}Mn_{0.3}Te$; $3.65 \leqslant P \leqslant 4.2$, $Q = 1.2$ for $Cd_{0.7}Mn_{0.3}Te$; $P = 0.4 \pm 0.1$, $Q = 0.35 \pm 0.05$ for $BaCo_6Ti_6O_{19}$.[7,14] The different values of these exponents clearly indicate a lack of universality, which makes the activated dynamics description less attractive.

We have also made nonlinear magnetization measurements on a $Zn_{0.5}Mn_{0.5}Te$ sample close to the transition in order to examine the static scaling properties in the critical region. In the immediate vicinity of T_c, the universal scaling expression

$$M_{\rm nl}(\epsilon,H)=\epsilon^{(\gamma+3\beta)/2}F(H/\epsilon^{(\gamma+\beta)/2}) \tag{3}$$

applies. Here, $M_{\rm nl}(H,T)=M(H,T)-\chi_{(l)}(T)H$ is the nonlinear magnetization and $\chi_l(T)H$, is the linear contribution near T_c.

The magnetization as a function of temperature was measured in several fixed fields. Near T_c, $\chi_{\rm nl} = M_{\rm nl}/H$ increases as shown in Fig. 4, as would be expected from the well-known divergence of this parameter at T_c for spin

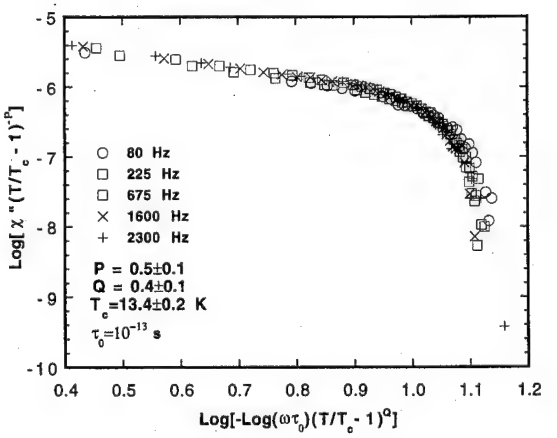

FIG. 3. Activated dynamic scaling of $\chi''(\omega,T)$ according to Eq. (2) in the text. The best-fit values of the T_c, τ_0, and the scaling exponents P and Q are shown as well. Notice that the best scaling in this case is significantly worse than that depicted in Fig. 2.

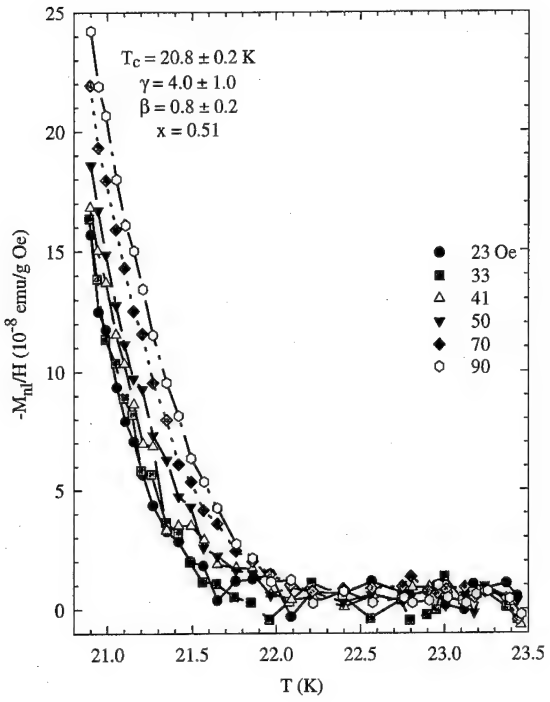

FIG. 4. M_{nl}/H vs temperature T for $Zn_{1-x}Mn_xTe$ for several fixed fields. The data reveal a rapid increase in the nonlinear term near T_c.

glasses. In Fig. 5, the data are plotted according to the universal scaling relation of Eq. (3) using values for the parameters γ, β, and T_c which produced the best scaling. The parameter values which produced the best scaling were $\gamma=4.0\pm1.0$, $\beta=0.8\pm0.2$, and $T_c = 20.8 \pm 0.2$ K. The data collapse onto the single universal scaling curve which covers many orders of magnitude along both axes. For temperatures significantly greater than T_c (lower part of the curve), the slope approaches three, consistent with the first-order term in the expansion of M_{nl}.[11] The scaling plot shows increasing scatter at higher temperatures since the nonlinear magnetization approaches zero as one moves out of the critical region. As T closely approaches T_c from above (upper part of the curve), the slope tends to the proper asymptotic value $(\gamma+3\beta)/(\gamma+\beta)$.[11] These asymptotic limits are shown as solid lines in Fig. 5.

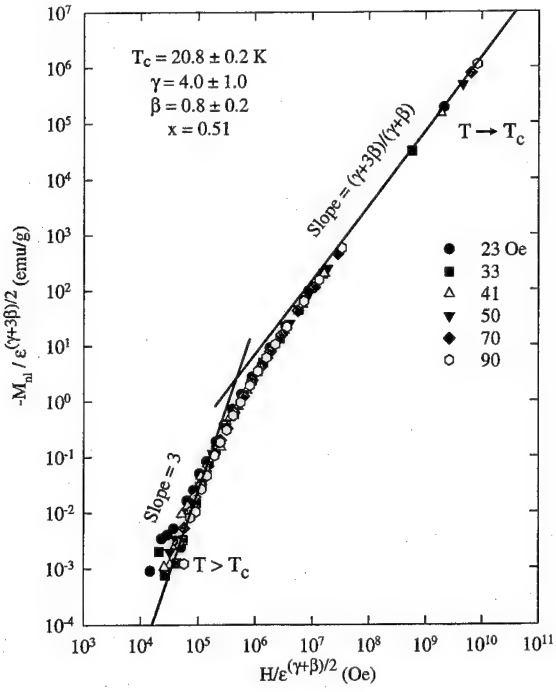

FIG. 5. The nonlinear magnetization data for $Zn_{1-x}Mn_xTe$ analyzed according to a universal scaling model for a spin glass transition. The asymptotic limits, shown by the solid lines, are in agreement with the theory.

The T_c value of 20.8 ± 0.2 K obtained in the static scaling analysis is consistent with that obtained from our zero-field-cooled and field-cooled magnetization data. The value $\beta=0.8\pm0.2$ is in accord with the value obtained from the dynamic scaling analysis discussed above, which reinforces the spin glass picture. Comparing DMS systems, our value of $\gamma=4.0\pm1.0$ for $Zn_{0.5}Mn_{0.5}Te$ is higher than the reported value of $\gamma=3.3\pm0.3$ for $Cd_{1-x}Mn_xTe$ found by Mauger and co-workers.[11] We note that the determination of γ via the scaling plot is very sensitive to slight changes in T_c which explains the large error bars which we quote for our γ value. One should also note that Geschwind and co-workers using novel linear scaling plots found $\gamma=4.4$ in $Cd_{1-x}Mn_xTe$. We conclude that within our experimental error, there is fair agreement between values for the critical exponent γ obtained in $Zn_{1-x}Mn_xTe$ and $Cd_{1-x}Mn_xTe$.

We have observed spin-glass freezing in a nominally pure single crystal of the $S=1$ linear-chain Heisenberg antiferromagnet $Ni(C_2H_8N_2)_2NO_2(ClO_4)$(NENP) by direct current (dc), linear alternating current (ac), and nonlinear ac susceptibility measurements. A possible origin of this spin-glass freezing is discussed. © *1996 American Institute of Physics.* [S0021-8979(96)23808-4]

Stimulated by Haldane's conjecture,[1] linear-chain Heisenberg antiferromagnets (LCHAs) with spin quantum number (S) one have been studied extensively. One of the most interest findings in these systems is the presence of $S=\frac{1}{2}$ degrees of freedom induced at the ends of finite chains. A quasi fourfold degenerate ground state was shown to exist from an exact diagonalization of an $S=1$ LCHA with open boundary conditions.[2] This means that the open chain has a spin $\frac{1}{2}$ degree of freedom at each end. A quantum Monte Carlo calculation on $S=1$ finite LCHAs showed that a staggered moment with $S=\frac{1}{2}$ appears at the ends and decays exponentially with distance.[3] Hagiwara *et al.*[4] demonstrated experimentally the existence of the $S=\frac{1}{2}$ degrees of freedom in the $S=1$ LCHA compound $Ni(C_2H_8N_2)_2NO_2(ClO_4)$, abbreviated as NENP. Many other measurements on $S=1$ LCHA materials have also shown the existence of the $S=\frac{1}{2}$ degrees of freedom.[5–8]

If there is no interaction between the $S=\frac{1}{2}$ degrees of freedom, the system should exhibit paramagnetism down to zero Kelvin. Avenel *et al.*[9] have measured the magnetic susceptibility of a carefully grown single crystal sample of NENP down to 300 μK and found that the susceptibility obeyed the Curie–Weiss law with a very small Weiss constant (6–12 mK). When an interaction between the $S=\frac{1}{2}$ degrees of freedom exists, we expect that the system will exhibit a magnetic ordering at finite temperature. Recently, we have reported the first observation of a spin-glass transition in NENP.[10] In the present paper, we report additional information on a spin-glass freezing in NENP.

NENP crystallizes in the orthorhombic system and belongs to the Pnma space group with lattice constants $a=15.223$ Å, $b=10.300$ Å, and $c=8.295$ Å.[11] The structure consists of $\cdots Ni-NO_2-Ni\cdots$ chains along the b axis which are well separated from each other by ClO_4 anions. The intrachain interaction between Ni^{2+} spins via the nearly 180° $Ni-NO_2-Ni$ bond is determined to be antiferromagnetic ($J/k_B=-55$ K).[12] The interchain interaction is much weaker than the intrachain one ($|J'/J|\cong 10^{-4}$).

The single crystals of NENP used in these experiments were grown from a reaction of $Ni(ClO_4)_2 6H_2O$ (99.99%) with ethylenediamine and $NaNO_2$. Usually, the reaction is controlled so as to proceed slowly. When the reaction proceeded quickly by chance, we obtained the crystals of NENP which show a spin-glass behavior described below.

In the following, we present the results of magnetic susceptibility measurements on the single crystal samples of NENP. The direct current (dc) and linear alternating current (ac) susceptibilities were measured with a SQUID magnetometer (Quantum Design's MPMS2). Special care was taken to reduce the magnetic field at the sample position. The nonlinear ac susceptibility was measured with a Hartshorn-type bridge installed at Chiba University.

Figure 1 shows the temperature dependence of the dc susceptibility (magnetization/applied magnetic field) of a single crystal of NENP for zero-field cooled (ZFC) and field cooled (FC) measurements. The susceptibility of this sample is qualitatively different from that of an ideal one reported before.[12] First, no rounded maximum is observed. Instead, the susceptibility continue to increase with decreasing temperature down to about 15 K for both of ZFC and FC measurements. Second, a marked difference between FC and ZFC measurements is observed below about 15 K. From the chemical analysis of the sample used in the measurement, we found that the concentration of transition elements other than Ni is below 0.01 wt. %. Thus, the increase of suseptibility at

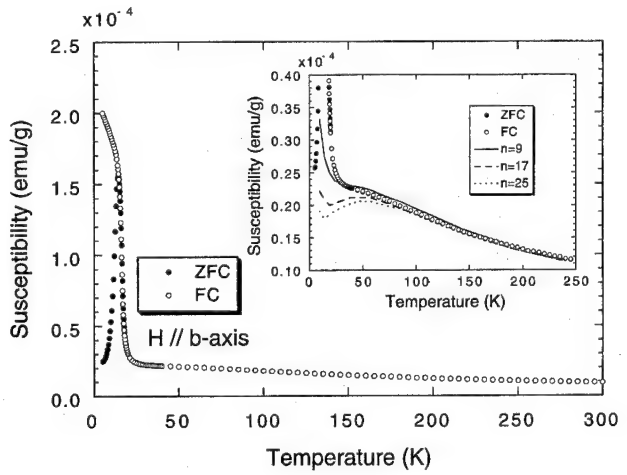

FIG. 1. Temperature dependence of the dc susceptibility in a nominally pure single crystal sample of NENP along the b axis. Inset: Comparison between the experimental data with the result of a Monte Carlo calculation (Ref. 13) in the temperature 20–250 K.

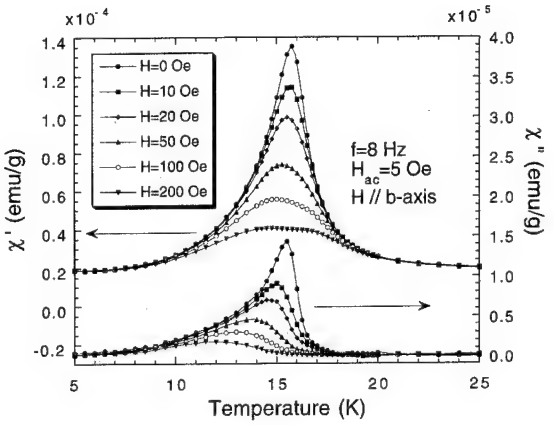

FIG. 2. Temperature dependence of real (χ') and imaginary (χ'') parts of ac susceptibility in the NENP crystal for various dc fields superposed on the ac field. Solid lines are guides to the eyes.

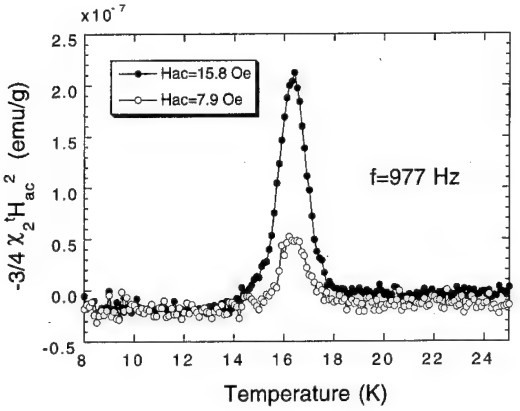

FIG. 3. Temperature vs nonlinear ac susceptibility (χ_2') of the NENP sample.

the low temperatures must come from the $S=\frac{1}{2}$ degrees of freedom at the chain ends. We have compared our data with the results of the Monte Carlo calculation[13] in the temperature range 20 K$<T<$250 K as shown in the inset of Fig. 1. We found that our results can be reproduced if we take an average chain length between 9 and 17 spins (no data are available for the chains between 10 and 16 spins in the literature). The rapid increase in the susceptibility below about 20 K in Fig. 1 means that an interaction between the $S=\frac{1}{2}$ degrees of freedom exists.

Figure 2 shows the temperature dependence of the real (χ') and imaginary (χ'') parts of the linear ac susceptibility for different dc bias fields superposed on the ac field. A cusp is seen in the temperature dependence of χ' in zero dc field as in all the spin-glass materials known to date. The cusp broadens with increasing dc bias field which is commonly seen in spin-glass systems. We have also measured the linear ac susceptibilities for various frequencies.[10] The position of the cusp moves to high temperature side with increasing frequency as commonly seen in spin glasses.

In order to get further evidence for spin-glass transition, we have measured the nonlinear ac susceptibility of this sample. As was predicted theoretically by Suzuki[14] and confirmed experimentally by Chikazawa *et al.*,[15] the second component (χ_2') of the nonlinear susceptibility in spin glasses diverges to $-\infty$ at the freezing temperature (T_f). As is seen from Fig. 3, the temperature dependence of $-\chi_2'$ of our NENP sample shows an anomalous increase when approached to T_f from both sides. From these experimental results, we conclude that a spin-glass transition takes place in the nominally pure single crystal of NENP.

Now we discuss a possible origin of the spin-glass transition in our sample. It is pointed out that the interchain exchange interaction and dipole–dipole interaction alone cannot explain the relatively high freezing temperature. Then, we should take into account the intrachain exchange interaction as an origin of the spin glass. Since our NENP crystals do not contain any detectable magnetic impurities, the moments are induced at the ends of finite chains probably by structural defects. Here, we assume that such defects are created by a displacement of ClO_4 molecules towards the chain that pushes away an NO_2 molecule. Then, there will be a possibility of having a 90° exchange bond between the neighboring Ni atoms in the chain. We expect that this arrangement will give a ferromagnetic exchange interaction[16,17] between the spins at the ends. These ferromagnetic bonds are distributed randomly in the chains. The randomly distributed ferromagnetic and antiferromagnetic bonds in an open chain do not cause frustration in the system. Then, we propose the following mechanism. At the sites where an NO_2 molecule was pushed away, the interchain exchange interaction will be much stronger than that in an ideal sample. Let us consider an example in which frustration is expected to occur. In a short open chain with an even number of spins, the end spins are antiparallel to each other, while they are parallel in a short odd chain. When neighboring even(n) and odd($n+1$) chains interact at the both ends as shown in Fig. 4, a 90° ferromagnetic exchange bond between the neighboring Ni atoms in the chain and a 180° antiferromagnetic exchange bond between the chains exist. This latter exchange bond causes a frustration as shown in Fig. 4.

In conclusion, the dc, linear ac, and nonlinear ac susceptibility measurements on the nominally pure single crystal of NENP show clearly a spin-glass freezing of the moments at the chain ends created by structural defects.

We would like to thank the Chemical Analysis Unit in RIKEN for the chemical analysis. This work was partially supported by the "MR Science Research Program from RIKEN" and by a Grand-in-Aid for Science Research from the Japanese Ministry of Education, Science, Sports and Culture.

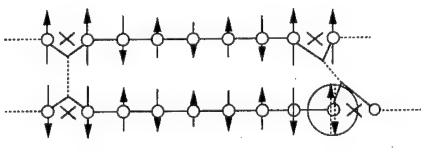

FIG. 4. An example of the arrangement of short chains in which frustration is expected to occur in the NENP crystal. The crosses show the sites where a NO_2 molecule was pushed away.

We have measured the magnetic field and temperature dependence of the nonlinear dc susceptibility, χ_{nl}, of the frustrated pyrochlore antiferromagnet $Y_2Mo_2O_7$ close to and above the temperature, $T_g \sim 22$ K, where this material exhibits irreversible (spin-glass like) magnetic behavior. Our results suggest that the observed irreversible magnetic properties in this material are due to a thermodynamic spin-glass transition signaled by a divergence of the nonlinear magnetic susceptibility coefficient $\chi_3 \sim (T/T_g - 1)^{-\gamma}$ at T_g with $\gamma = 3.3 \pm 0.5$. χ_{nl} shows *two* power-law behavior at T_g, $\chi_{nl} \sim H^{2/\delta}$, with $\delta \sim 2.8$ for $H < 1000$ Oe and $\delta \sim 4.1$ for $H > 2000$ Oe. These values for γ and δ, as well as the crossover behavior of χ_{nl} at T_g, is consistent what is found in common disordered Heisenberg spin glass materials. © *1996 American Institute of Physics.* [S0021-8979(96)23908-4]

The study of magnetic materials with competing, or *frustrated*, antiferromagnetic interactions, inhibiting the formation of a collinear magnetically ordered state, goes back more than forty years.[1,2] However, the past five years have seen considerable increase in the number of systematic experimental, theoretical, and numerical investigations of these systems.[2,3] For example, it has been suggested that the phase transition into a noncollinear spin structure may belong to a "new" chiral universality class different from the universality classes appropriate to collinear magnets.[4] Also, the proposal that large levels of frustration can generate quantum zero-point spin fluctuations sufficient to destroy Néel order at zero temperature even for two and three-dimensional systems, and lead to novel types of magnetic ground states, has attracted much attention.[2,3]

Several families of insulating antiferromagnetic materials with extreme frustration level have been identified.[3] Examples include the kagomé and pyrochlore systems. In the kagomé $SrCr_xGa_{12-x}O_{19}$ (Ref. 5) and $KM_3(OH)_6(SO_4)_2$ (Ref. 6) (M=Cr or Fe) materials, the moment carrying cations (Cr, Fe) reside on stacked, two-dimensional lattices of corner sharing triangles.[5,6] In the $A_2B_2O_7$ pyrochlores (A =Y,Tb; B=Mn,Mo), the A^{3+} and B^{4+} cations, which can be either magnetic or nonmagnetic, sit on two distinct, interpenetrating lattices of corner-sharing tetrahedra.[7–10]

In both the classical kagomé and pyrochlore Heisenberg antiferromagnets, the elementary triangular or tetrahedral plaquettes are highly frustrated, and the classical ground state of the system is determined by the quite unrestrictive condition $\Sigma_{i\in\Delta}\mathbf{S}_{i,\Delta}=0$ on *each* individual plaquette Δ, where $\mathbf{S}_{i,\Delta}$ is a classical spin on lattice site i of plaquette Δ. The number of states which satisfy this local condition increases exponentially with system size, leading to a finite ground state entropy per spin, and a *collective* paramagnetic ground state.[7] In real systems, however, perturbations such as lattice distortions, crystal-field effects, further nearest-neighbor exchange or dipolar coupling can lead to the selection of a classical Néel ordered ground state.[7,8] A mechanism of order-by-disorder via thermal or quantum fluctuations may also be at play, and lead to long-range order.[8] One may therefore expect two generic scenarios for real kagomé and pyrochlore antiferromagnets. They could display long-range Néel order, possibly with a sizeable quantum reduction of the staggered moment due to the "fragility" of the classical order brought about solely by perturbative effects.[8,11] Alternatively, quantum fluctuations may be sufficiently large to destabilize the otherwise classical ground state, and drive the system to an unconventional quantum ground state.[2,11] It is therefore interesting that a large number of kagomé[3,5,6] and pyrochlore[9,10] antiferromagnets fail to display long-range, or even extended short-range, Néel order. Instead, they exhibit magnetic irreversibilities, i.e., spin-glass like behavior, below a glass temperature, T_g.[9,10] This is surprising as a large number of these systems can be prepared with a very high degree of chemical and structural purity.[9,10] The mechanism responsible for this spin-glass behavior is not understood, and is currently the subject of an intense debate.[12] However, irrespective of the origin of the glassiness, one would still like to know: "Does T_g correspond to a true thermodynamic phase transition or, alternatively, is it a dynamical freezing transition?"

$Y_2Mo_2O_7$ is a narrow band gap semiconductor where the Mo^{4+} ions are magnetic, with an antiferromagnetic nearest-neighbor Mo-Mo superexchange, while Y^{3+} is diamagnetic. The 270 mg powder sample of $Y_2Mo_2O_7$ was prepared as described in Ref. 9. Neutron and x-ray powder diffraction studies show that there is no measurable amount of oxygen vacancies or intermixing between the Y^{3+} and the Mo^{4+} sublattices.[9] Any random disorder in that material is therefore below the 1% detectability level. The magnetization was measured using a SQUID magnetometer. The bulk magnetization of $Y_2Mo_2O_7$ becomes hysteretic below $T_g \approx 22$ K: the field-cooled (FC) and zero field-cooled (ZFC) magnetizations measured in fields of 100 Oe show a sharp

 0021-8979/96/79(8)/6170/3/$10.00

breakaway below 22 K.[9] This is a characteristic signature of the freezing transition observed in conventional chemically disordered spin glass materials.[13]

To assess whether or not a true thermodynamic spin-glass phase transition occurs in $Y_2Mo_2O_7$, we have measured the nonlinear susceptibility coefficient $\chi_3(T)$, which is expected to show a power-law critical divergence close to T_g of the type $\chi_3 \sim (T-T_g)^{-\gamma}$ ($\gamma>0$). [13] χ_3 is extracted from the temperature, T, and field, H, dependence of the magnetization, $M(T,H)$,

$$M(T,H)=\chi_1(T)H-\chi_3(T)H^3+\chi_5(T)H^5-\ldots, \qquad (1)$$

where $\chi_1(T)$ is the linear susceptibility. Hence, the temperature dependence of $\chi_3(T)$ allows a determination of T_g and γ.[13] In fact, all the nonlinear terms χ_{2n+1} with $n\geq 1$ must diverge at T_g, since both $M(T,H)$ and H are finite quantities. It is therefore convenient to define a "full" nonlinear susceptibility, $\chi_{\rm nl}$, as

$$\chi_{\rm nl}(T,H)\equiv 1-\frac{M(T,H)}{\chi_1 H}. \qquad (2)$$

Right at T_g, $\chi_{\rm nl}$ has a power law dependence on H:

$$\chi_{\rm nl}(T_g,H)\sim H^{2/\delta}, \qquad (3)$$

where δ is a second critical exponent characterizing the spin-glass transition.[13]

The magnetization data were collected using the SQUID magnetometer under field-cooling conditions; the field H, in the range 100–7000 Oe was switched on at high temperature (70 K$\sim 3T_g$), and kept constant during subsequent slow cooling at a rate 5 mK/s down to the temperature of interest. Because of the irreversible and time-dependent nature of the system's response below T_g only results in temperature range $T_g<T<3T_g$ are included. Our results on the low-temperature dynamical relaxation of the magnetization in $Y_2Mo_2O_7$ will be reported elsewhere.[14] Three consecutive cooling runs for fixed field were performed, with the magnetization data averaged over the three runs.

Figure 1(a) shows the field cooled susceptibility $\chi(T,H)\equiv M(T,H)/H$ for six different cooling fields. Prior to doing any analysis, we dealt with the fact that the interactions do not perfectly average to zero, as evidenced by the fact that $\chi_1(T)$ does not have a simple $\chi_1\sim 1/T$ Curie law. The *leading* corrections to scaling coming from this nonzero averaging of the interactions can be eliminated by fitting $\chi(T,H)$ in powers of $a_{2n+1}(T)\chi_1[\chi_1 H]^{2n}$ for $n\geq 0$, instead of simply $\chi_{2n+1}H^{2n}$, and considering the critical behavior or $a_{2n+1}(T)$ instead of $\chi_{2n+1}(T)$.[13] For each temperature the field dependence of χ at small field was fitted with $\chi=\chi_1-\chi_3 H^2$, giving $a_3=\chi_3/\chi_1^3$, and varying the upper limit of the field range to determine the limit of validity of this restricted fit beyond which higher χ_{2n+1} ($n>1$) corrections become significant. The quality of our magnetization data did not allow us to determine the $a_5=\chi_5/\chi_1^5$ coefficient with precision better than 50%–100%, and these a_5 data are not included here. We show in Fig. 1(b) the full nonlinear susceptibility, $\chi_{\rm nl}(T,H)$, as defined in Eq. (2), with χ_1 extracted from the fit $\chi(T,H)=\chi_1-\chi_3 H^2$, as a function of H^2 for a few temperatures above T_g. These results emphasize the

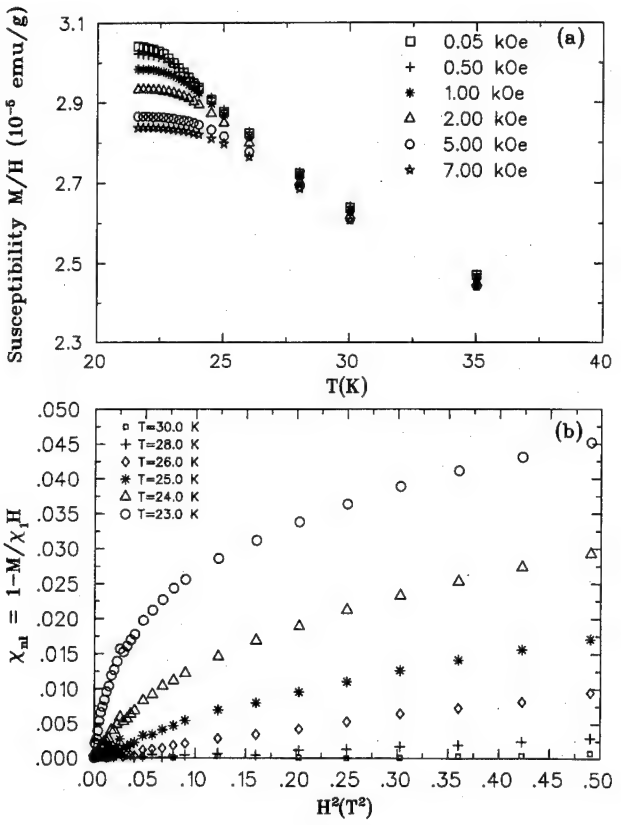

FIG. 1. Panel (a): Raw data, susceptibility M/H vs T for six different cooling fields. Panel (b): net nonlinear susceptibility, $\chi_{\rm nl}=1-M/\chi_1 H$ vs H^2 for the six temperatures indicated.

large increase of the nonlinear susceptibility upon approaching T_g in this material. We also notice that the $\chi_{\rm nl}$ is only linear in H^2 up to a maximum field $H_+(T)$ whose value is rapidly moving to $H_+(T)=0$ upon approaching T_g. This is due to the turning on of the χ_{2n+1} ($n>1$) corrections which diverge at T_g as $(T-T_g)^{(\beta-n[\gamma+\beta])}$.[13]

Figure 2(a) shows a log-log plot of a_3 versus T/T_g-1 with $T_g=21.8$ K. There are two sets of data shown on this figure, the squares and the triangles. The two data sets were obtained with the same $Y_2Mo_2O_7$ sample, but from two separate set of experiments separated by four months. The excellent agreement in the absolute value of a_3 between the two sets of experiments (i.e., no vertical or horizontal shifting of one set with respect to the other was done) gives us an estimate of the precision of our measurements. A power-law fit to the data with square symbols resulted in a fit with minimum χ^2 value for $T_g=21.9$ K, yielding a critical exponent $\gamma=3.3\pm 0.5$. A fit for the triangles give a best fit for $T_g=21.7$ K with a critical exponent of also $\gamma=3.3\pm 0.5$. The power-law divergence of a_3 saturates for $t<0.07$ ($t\equiv T/T_g-1$). A reason for this levelling off of a_3 for $t<0.07$ is that the range of dominance of the term $\chi_3(T)H^2$ to $\chi_{\rm nl}$ falls below the smallest field, $H_{\rm min}$ ($H\sim 100$ Oe), for which reliable data are available to us. The increasingly important diverging higher order terms of alternating signs (χ_5, χ_7, etc) contributing to $\chi_{\rm nl}$ then cause a_3 to be underestimated when $H_+(T)$ becomes less or equal to $\approx H_{\rm min}$. Another possible effect may be the slow but finite cooling rate inhibits the attainment of

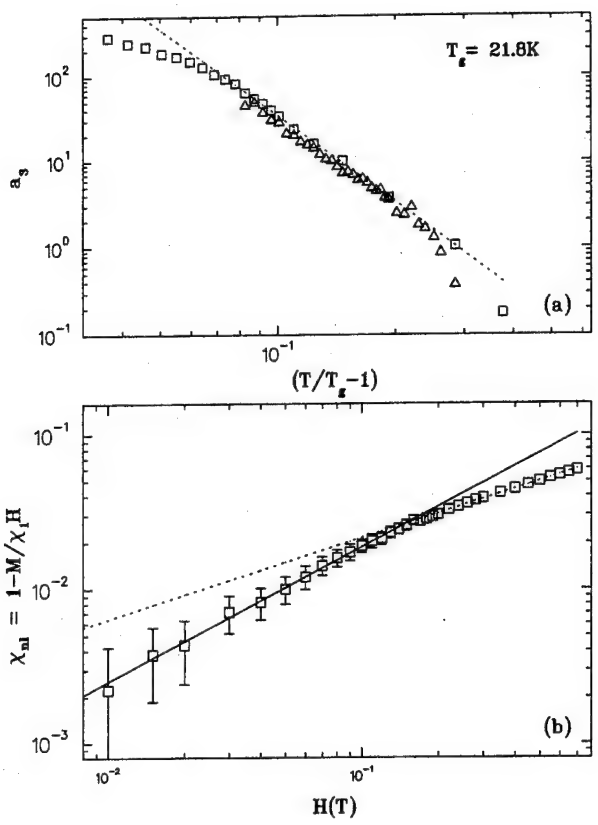

FIG. 2. Panel (a): log-log plot showing the temperature dependence of $a_3(T)$. The square and triangular symbols correspond to two set of independently analyzed experiments. The dashed line shows the power law fit to the square symbols with the average T_g=21.8 K. Panel (b): log-log plot of the net nonlinear susceptibility, χ_{nl}, vs applied field H at T=21.8 K. The dashed and solid lines correspond to power-law fits for fields $H<1000$ Oe and $H>2000$ Oe, respectively (see discussion in text).

the correct equilibrium value of χ_{nl} and this effect is compounded with the previous one, saturating a_3 for $t<0.07$. Figure 2(b) shows a log-log plot of χ_{nl} versus H at T_g=21.8 K for fields H=100–7000 Oe. At criticality, one expects that χ_{nl} will be given by Eq. (3), with a single value of δ for fields $H \ll J$, where J is the rms value of the superexchange interactions. Clearly, we observe two trends in Fig. 3(b), one for small fields and one for large fields, with a crossover field between the two regimes of the order of $H_{co} \approx 1500$ Oe. The value of δ is found to be 2.8 ± 0.5 for $H<1000$ Oe (dashed line) and 4.1 ± 0.1 for $H>2000$ Oe (solid line). Such field induced crossover, with similar values of $\delta(H<H_{co})$ and $\delta(H>H_{co})$ has also been seen in conventional disordered spin glasses.[13]

It is interesting to compare our results for the $Y_2Mo_2O_7$ pyrochlore with those of the $SrCr_8Ga_4O_{19}$ kagomé system (SCGO),[15,16] and for the site-ordered gadolinium gallium garnet magnet $Gd_3Ga_5O_{12}$ (GGG).[17] Ramirez *et al.*[15] found a power-law divergence of χ_3 in SCGO with $\gamma \approx 2.4$, while Martinez *et al.*[16] recently published results where they argue that the freezing at $T_f \approx 3.5$ K in SCGO is *not* associated with a divergence of χ_3 (χ_3 was found to increase by a factor 5 or so in Ref. 16), and that this material does not exhibit conventional spin glass behavior. Schiffer *et al.*[17] found a large increase of χ_3 in GGG (6 orders of magnitude between 0.2 and 5 K), which they ascribe to a spin glass transition. However, the temperature dependence of χ_3 in GGG is qualitatively different than what is found in conventional spin glasses since χ_3 has two maxima in GGG, while it is a monotonic function of the temperature in conventional spin glasses. Hence, from the point of view of nonlinear susceptibility measurements, it appears that the spin glass behavior observed in $Y_2Mo_2O_7$ resembles much more what is found in conventional spin glasses than what has been found in other topologically frustrated antiferromagnets, such as SCGO and GGG.

The magnetic susceptibility of $Ho_2Mn_2O_7$ with a spontaneous rise below about 40 K and a paramagnetic Curie temperature of +39 K suggests a ferromagnetic ordering. Indeed neutron diffraction profiles show strongly enhanced Bragg peaks with a temperature dependence which indicates an apparent $T_c \approx 35$ K. Nonetheless, the magnetic diffraction pattern is not consistent with a collinear ferro or ferrimagnetic ordering of the Ho^{3+} and Mn^{4+} sublattices. Furthermore, specific heat and small angle neutron scattering (SANS) show features which are also incompatible with conventional long-range order. © *1996 American Institute of Physics.* [S0021-8979(96)24008-9]

I. INTRODUCTION

Two necessary but not sufficient conditions for the occurrence of spin-glass-like ordering in a given material are site disorder and magnetic frustration.[1] Recently, some pyrochlore structure materials have been studied extensively as they seem to exhibit spin-glass-like ordering based on magnetic frustration alone, having apparently negligible site disorder.[2–8] The pyrochlore compounds $R_2M_2O_7$ (R^{3+}=rare earth; M^{4+}=transition metal) crystallize in the face-centered-cubic structure with the space group $Fd3m$.[9] Each of the metal atoms in the these compounds forms a three-dimensional network of corner-sharing tetrahedra. Such a topology leads to a very high degree of magnetic frustration if the nearest neighbor interactions are antiferromagnetic.[10]

The series of pyrochlores $R_2Mn_2O_7$ (R=Dy−Lu, or Y) have been reported to show ferromagnetic ordering based upon the observation of positive θ_p values and spontaneous magnetization.[3] Further studies of neutron scattering and heat capacity provided no evidence for long-range magnetic ordering in $Y_2Mn_2O_7$.[4] Small angle neutron scattering (SANS) studies indicated the presence of ferromagnetic clusters of finite size in the temperature range 13–20 K.[6] A variety of studies on a related series of compounds $R_2Mo_2O_7$ (R=Sm, Gd, Tb, or Y) demonstrate the presence of spin-glass-like ordering.[5,7,8] In contrast recent studies of magnetic and electrical along with SANS data on $Tl_2Mn_2O_7$ and $In_2Mn_2O_7$ are consistent with the long-range ferromagnetic ordering below about 120 K in both materials.[11]

$Ho_2Mn_2O_7$ has been reported to show spontaneous magnetization below about 40 K with a paramagnetic Curie temperature, θ_p, of +33 K.[3] To understand the nature of this magnetic ordering, a variety of studies, ac and dc magnetic susceptibilities, specific heat, SANS and powder neutron diffraction were performed and the results are discussed in Sec. III.

II. EXPERIMENT

The polycrystalline powder sample used in the present measurements is the same as that described in Ref. 3. Ac susceptibility, χ', was determined as function of temperature using a Lake Shore 7000 Susceptometer. Dc susceptibility and magnetization were measured with the help of a SQUID magnetometer (Quantum Design, San Diego). The specific heat of the sample, in the form of powder, was measured in the temperature range 2–90 K using a fully automated quasi-adiabatic calorimeter equipped with a Ge thermometer. The SANS experiments were performed at the instrument at the DR3 reactor at Risø National Laboratory. The powder neutron diffraction data, at different temperatures were obtained at the McMaster Nuclear Reactor with 1.3913 Å neutrons.

III. RESULTS AND DISCUSSION

Figure 1 shows the temperature dependence of the real part of the ac susceptibility, χ', of $Ho_2Mn_2O_7$ at 10 G at different frequencies χ' increases rapidly below about 40 K

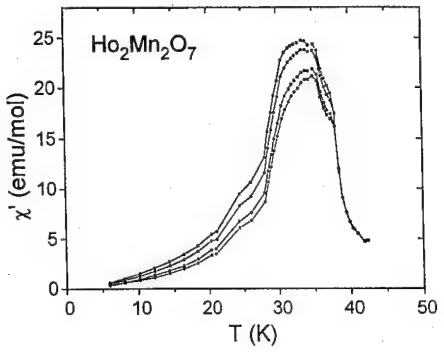

FIG. 1. ac susceptibility, χ', of $Ho_2Mn_2O_7$ at four different frequencies, from top to bottom: (8, 33, 143, and 222 Hz).

 0021-8979/96/79(8)/6173/3/$10.00

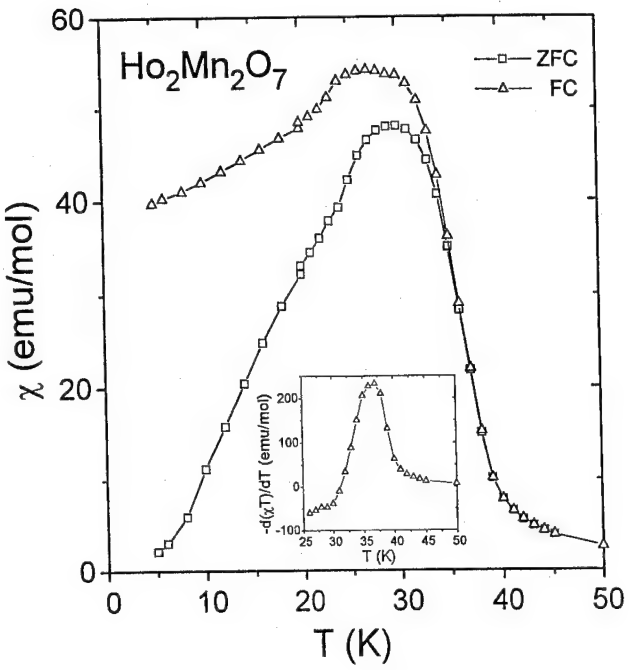

FIG. 2. Zero field cooled (ZFC) and field cooled (FC) dc susceptibility of $Ho_2Mn_2O_7$ measured at 100 G. The inset shows the negative temperature derivative of the product of the FC susceptibility and temperature.

and frequency dependent behavior is seen below 38.0 K with a broad maxima around 33 K. The dc susceptibility, measured at 100 G, is plotted against temperature in Fig. 2. It can be seen that a spontaneous magnetization develops below about 40 K and deviations occur between zfc and fc susceptibilities below 35 K which is expected for a spin-glass transition. A plot of $-d(\chi T)/dT$ against T is generally useful to determine the transition temperature more accurately from the dc susceptibility data. Such a plot given in the inset of Fig. 2 indicates a T_c of 37.1 ± 1.0 K. The magnetization as a function of applied field was measured at 5.0 K. Saturation occurs only above 1.5 T with a value of 12.3 $\mu_B/Ho_2Mn_2O_7$ at 5.0 T. In $Y_2Mn_2O_7$ a magnetic moment of 2.3 μ_B/Mn at 4.0 T was reported.[4] Assuming the same Mn^{4+} sublattice contribution in $Ho_2Mn_2O_7$ leaves a saturation moment of 3.9 μ_B/Ho^{3+} which is very small compared with an expected value of $gJ=10.0$ μ_B per Ho^{3+} free ion ($g=1.25$ and $J=8$

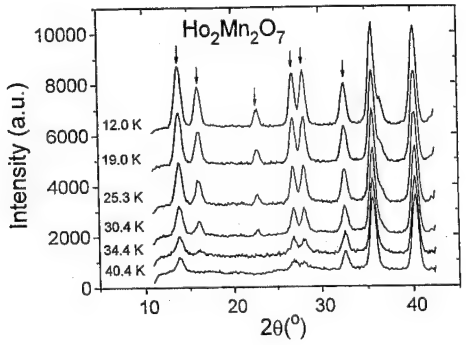

FIG. 3. Powder neutron diffraction profiles at different temperatures for $Ho_2Mn_2O_7$. The base line intensities for different temperatures are shifted arbitrarily for the clarity of the plots.

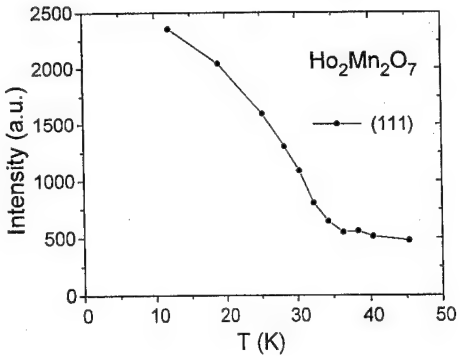

FIG. 4. The intensity of the Bragg reflection (111) against temperature.

for Ho^{3+} with a ground state of $^2I_8$). The significant reduction in Ho^{3+} moment from the expected value suggests the existence of strong crystal field effects. This is consistent with the specific heat data discussed later.

The powder neutron diffraction profiles at different temperatures are plotted in Fig. 3. First, note that the intensity of each nuclear Bragg peak, indicated by the arrows, is enhanced as the temperature is decreased and that there is no apparent change in the peak width. Further the temperature dependence of the intensity of the (111) reflection at 13.85°, as shown in Fig. 4, is consistent with the susceptibility data in suggesting a T_c of about 36 K. The observed magnetic diffraction pattern is not consistent with a collinear ferro or ferrimagnetic structure as found for $Nd_2Mo_2O_7$ or $Yb_2V_2O_7$

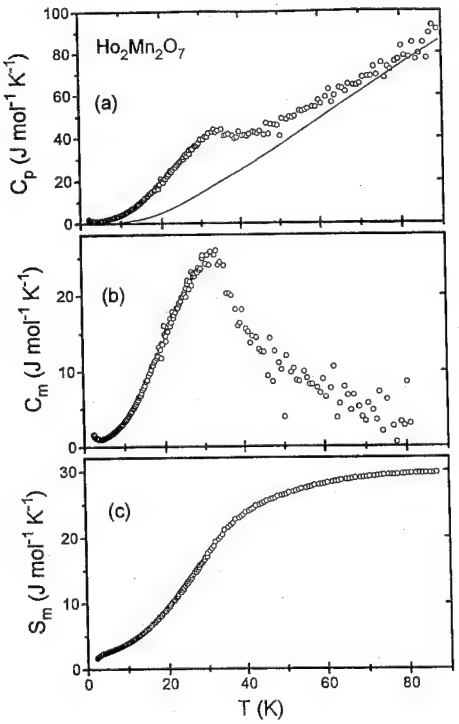

FIG. 5. (a) Measured specific heat, C_p, of $Ho_2Mn_2O_7$. The continuous line represents the estimated lattice specific heat, C_1. (b) Magnetic specific heat, C_m, obtained by subtracting the C_1 from the C_p. (c) Magnetic entropy, S_m, vs temperature.

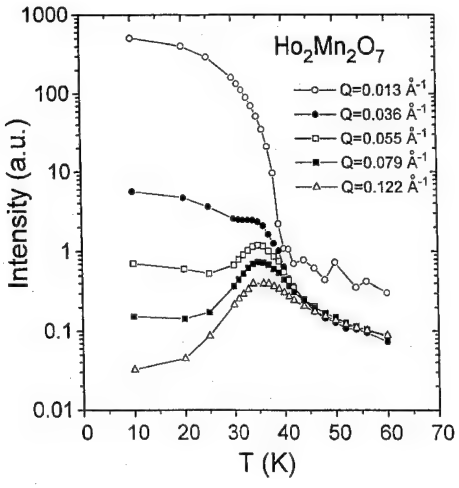

FIG. 6. Small-angle neutron-scattering intensity (in arbitrary units) as a function of temperature at different wave vectors for $Ho_2Mn_2O_7$.

and no solution has yet been found.[5,12] From the resolution of our neutron diffraction data we determine a lower limit for the spin correlation length of ~115 Å.

The measured specific heat, C_p, of $Ho_2Mn_2O_7$ in Fig. 5(a) displays an anomaly at about 35 K. The C_p of insulating $Ho_2Mn_2O_7$ consists of contributions from the lattice specific heat, C_l, and the magnetic specific heat, C_m. The C_l of $Ho_2Mn_2O_7$, represented by continuous line in Fig. 5(a), was evaluated to separate the contribution of C_m. The details of this procedure can be found in Ref. 7. The magnetic specific heat, in Fig. 5(b), shows a broad maximum around 33 K. The absence of a sharp λ-type anomaly and the presence of C_m to temperatures much above the apparent T_c suggests the absence of a conventional long-range magnetic ordering and the presence of short-range correlations. At temperatures below about 4 K there is an up turn in C_m. The magnetic entropy, S_m, involved in the magnetic anomaly is determined as a function of temperature by numerically integrating C_m/T (C_m/T behavior is extrapolated below 2 K). A plot of the magnetic entropy, S_m, versus temperature is displayed in Fig. 5(c). It can be seen that S_m reaches a value of 30 J mol^{-1} K^{-1} at 90 K which is far less than the expected magnetic entropy for $Ho_2Mn_2O_7$ with $J=8$ for Ho^{3+} and $S=3/2$ for Mn^{4+}, $2R\ln(2J+1)+2R\ln(2S+1)=70.2$ J mol^{-1} K^{-1}. This corroborates the reduced saturation moment of Ho^{3+} described above.

Figure 6 displays the temperature dependence of the scattered neutron intensity at different wave vectors, Q. For the highest wave vector (i.e., $Q=0.122$ Å^{-1}), the SANS intensity shows a broad maximum centering about 36 K, which is close to the T_c observed in the previously described experiments, and decreases with the temperature below the T_c. As the Q is reduced down to 0.055 Å^{-1}, the broad maximum and persists but the intensity rises towards the lower temperatures. With a further decrease in the Q, the intensity does not exhibit any peak but a plateau below 36 K and starts increasing below 30 K. For the lowest Q of 0.013 Å^{-1}, the intensity increases sharply below 40 K and continues to increase with the decrease in the temperature. For a long-range ordered material, the SANS intensity observed at low Q as a function of the temperature shows a pronounced cusp at the T_c with a rapid fall off in the intensity both above and below the T_c. The SANS intensity of $Ho_2Mn_2O_7$, at the low Q of 0.013 Å^{-1}, does not show any cusp at the T_c providing evidence for the absence of long-range magnetic ordering. It is of interest here to mention the SANS intensities of $Tl_2Mn_2O_7$ and $Y_2Mn_2O_7$ against temperature.[11] In $Tl_2Mn_2O_7$, the SANS intensity shows a sharp peak at the transition temperature indicating a long-range ordering and consistent with the other experimental evidence. However, in $Y_2Mn_2O_7$ where long-range order is absent, the SANS intensity rises sharply below the T_c. A detailed analysis of SANS data for $Y_2Mn_2O_7$, $Ho_2Mn_2O_7$, and $Yb_2Mn_2O_7$, to be published elsewhere, gives evidence for correlation lengths of the order of 500 Å and greater associated with a random field scattering. It is thus likely that the apparently complex ordering seen in $Ho_2Mn_2O_7$ is not truly long range and thus it is possible to reconcile the neutron diffraction and heat capacity results.

λ-MnO_2, a new frustrated antiferromagnet with the defect spinel structure (abstract)

J. E. Greedan, Guo Liu, and N. P. Raju

MnO_2 exists in a number of crystalline modifications. λ-MnO_2, prepared by electrochemical delithiation of the spine $Li_2Mn_2O_4$, has Mn^{4+}, $S=3/2$, occupying the octahedral (16*c*) sites in $Fd3m$. The magnetic sublattice consists of a pyrochlore-type array of corner-shared tetrahedra and is thus a candidate for frustrated antiferromagnetism. The dc susceptibility data indicate, for very low applied fields of 45 G, a sharp maximum at 32 K but this is smeared to a broad maximum at 25 K for fields as modest as 300 G. Zero-field neutron diffraction data show long range order with $K=(\frac{1}{2}\ \frac{1}{2}\ \frac{1}{2})$ and $T_n=32$ K. Surprisingly, the long range order is robust to applied fields of 1.0 T and higher. Prominent diffuse scattering persists up to greater than 60 K due to short range order which is indicative of frustration. The properties of λ-MnO_2 are compared with those of the spin-glass-like pyrochlore, $Y_2Mn_2O_7$, which has the same magnetic species on the same sublattice. © *1996 American Institute of Physics.* [S0021-8979(96)44208-9]

Nonlinear magneto-optics is a very sensitive fingerprint of the electronic, magnetic, and atomic structure of surfaces, interfaces, and thin ferromagnetic films. Analyzing theoretically the nonlinear magneto-optical Kerr effect for thin films of Fe(001) and at Fe surfaces we demonstrate exemplarily how various electronic material properties of ferromagnets, such as the d-bandwidth, the magnetization, the substrate lattice constant, and the film-thickness dependence can be extracted from the calculated nonlinear Kerr spectra. Furthermore, we show how the substrate d electrons [Cu(001)] affect the nonlinear Kerr spectra even without being themselves spin-polarized and without film-substrate hybridization. We show that the Kerr rotation angle in second-harmonic generation is enhanced by one to two orders of magnitude compared to the linear Kerr angle and how symmetry can be used to obtain the direction of magnetization in thin films and at buried interfaces from nonlinear magneto-optics. © *1996 American Institute of Physics.* [S0021-8979(96)47808-7]

I. INTRODUCTION

Nonlinear magneto-optics for metals[1,2] is a new expanding field the significance of which results from extending electrodynamics to the nonlinear case and from applications. Particularly, an important task of theory was to extend the symmetry analysis to an electronic theory[3,4] since this allowed second-harmonic generation (SHG) to be used as an important new tool for the analysis of surface,[5] interface, thin film, and multilayer[6,7] magnetism. The surface sensitivity results since breakdown of inversion symmetry is necessary for SHG. Thus, it is possible to determine with the help of SHG surface magnetic moments, magnetic anisotropy, domains, magnetostriction, and, in particular, properties of buried interfaces.

Using an electronic theory (with a band structure input) we calculate (i) the material specific nonlinear response function $\chi^{(2)}(\omega,\mathbf{M},\lambda_{so},d)$, depending on magnetization M, spin-orbit coupling λ_{so} and film thickness d, (ii) the nonlinear Fresnel formula for the reflected nonlinear fields $E(2\omega)$, and thus finally, (iii) the complex nonlinear Kerr rotation angle $\Phi_K^{(2)}$. The results, presented in the following demonstrate, in particular, what can be learned (a) from an analysis of the frequency dependence and (b) from the symmetry analysis and the Kerr rotation. Some selected general results obtained previously are shown, but also interesting new results indicating important substrate effects. Remarkably, the calculation[8] and recent experiments[9,10] yield that $\Phi_K^{(2)}$ is larger by two orders of magnitude compared to the linear Kerr rotation.

II. THEORY

A. Nonlinear susceptibility

Using response theory the nonlinear optical polarization is given by

$$P_i=\chi_{ijm}^{(2)}E_j(\omega)E_m(\omega), \tag{1}$$

where P_i is the ith component of the polarizability and where the susceptibility tensor $\chi_{ijm}^{(2)}$ is determined by[1,11]

$$\chi_{ijm}^{(2)}(2q_\parallel,2\omega,\mathbf{M})=\frac{e^3C}{\Omega}\frac{\lambda_{so}}{\hbar\omega}\sum_\sigma\sum_{\mathbf{k},l,l',l''}\left\{\langle\mathbf{k}+2\mathbf{q}_\parallel,l''\sigma|i|\mathbf{k}l\sigma\rangle\langle\mathbf{k}l\sigma|j|\mathbf{k}+\mathbf{q}_\parallel,l'\sigma\rangle\langle\mathbf{k}+\mathbf{q}_\parallel,l'\sigma|m|\mathbf{k}+2\mathbf{q}_\parallel,l''\sigma\rangle\right.$$

$$\left.\times\frac{\dfrac{f(E_{\mathbf{k}+2\mathbf{q}_\parallel,l''\sigma})-f(E_{\mathbf{k}+\mathbf{q}_\parallel,l'\sigma})}{E_{\mathbf{k}+2\mathbf{q}_\parallel,l''\sigma}-E_{\mathbf{k}+\mathbf{q}_\parallel,l'\sigma}-\hbar\omega+i\hbar\alpha_1}-\dfrac{f(E_{\mathbf{k}+\mathbf{q}_\parallel,l'\sigma})-f(E_{\mathbf{k}l\sigma})}{E_{\mathbf{k}+\mathbf{q}_\parallel,l'\sigma}-E_{\mathbf{k}l\sigma}-\hbar\omega+i\hbar\alpha_1}}{E_{\mathbf{k}+2\mathbf{q}_\parallel,l''\sigma}-E_{\mathbf{k}l\sigma}-2\hbar\omega+i2\hbar\alpha_1}\right\}. \tag{2}$$

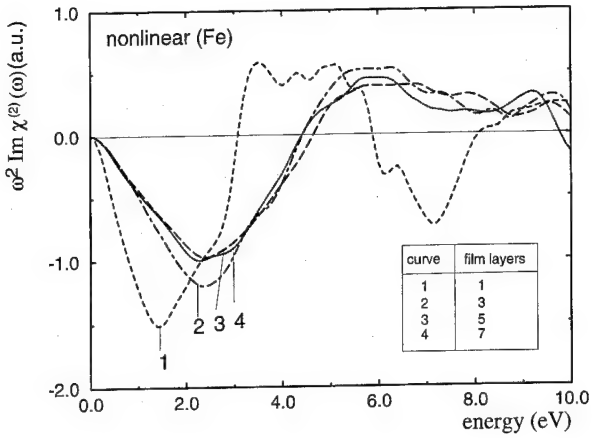

FIG. 1. *Ab initio* calculated nonlinear magneto-optical Kerr spectra of Fe using Eq. (2) for a monolayer (dashed curve—1), and films with 3 layers (dashed-dotted curve—2), 5 layers (long-dashed—3), and 7 atomic layers (dotted curve—4). The second-harmonic response results from the first atomic layer. This SH response is obtained by projecting the wave functions to the first atomic layer yielding the factor C.

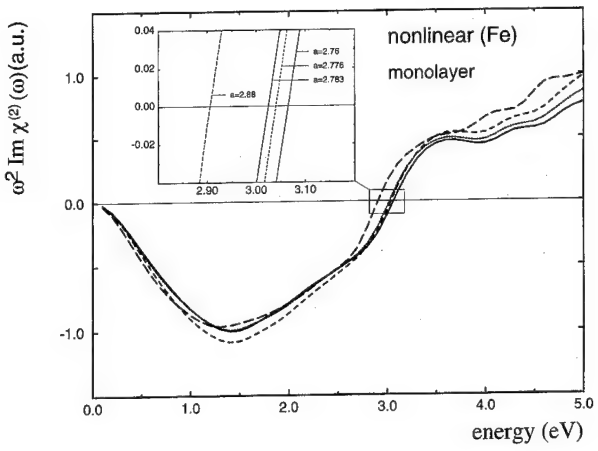

FIG. 2. Film-lattice-constant dependence of *ab initio* calculated nonlinear Kerr spectra of a Fe monolayer. The solid curve refers to the bulk *bcc* Fe lattice constant $a=2.76$ Å, the dashed curve to $a=2.776$ Å (bulk Au), and the dotted curve to $a=2.783$ Å (bulk Ag). The long-dashed curve refers to the experimental $a=2.88$ Å for Fe. Choosing lattice constants a referring to Au and Ag should simulate substrate effects. The inset shows for an enhanced scale the effects of different lattice constants for the zero of Im $\chi^{(2)}$ at $\hbar\omega\approx$ 3 eV and indicate structural effects which should be observable.

Here $E_{\mathbf{k}l\sigma}$ are the electronic energy levels resulting from the band structure calculations, $\langle \mathbf{k}l\sigma|i|\mathbf{k}+\mathbf{q}_\parallel, l'\sigma\rangle$ are the transition matrix elements, which control the symmetry and thus the interface sensitivity. If the matrix elements are treated as constants one has to introduce a cut-off to guarantee the surface sensitivity. This is done by the factor C.[12] Typically, magnetic dipole effects are negligible if the electric dipole contribution does not vanish. λ_{so} is the key parameter for nonlinear magneto-optics. In particular, for determing the Kerr effect it might be useful to decompose $\chi^{(2)}$ in odd and even contributions $\chi^{(2)}=\chi^{(2)}(\mathbf{M})+\chi^{(2)}(M^2)$.

For the application of the general theory thin films are of particular interest. Then, the layer-dependent contributions to $\chi^{(2)}$ reveal interesting film properties and substrate effects. For the thin film calculations we use $C=W_{\mathbf{k}+2\mathbf{q}_\parallel, l''\sigma} W_{\mathbf{k}+\mathbf{q}_\parallel, l'\sigma} W_{\mathbf{k}l\sigma}$, where W_α denotes the weight of the density of state $|\mathbf{k}l\sigma\rangle$ in the Wigner-Seitz cell of the first monolayer. Note, due to the factor C SHG will always result from the surface layer or from the layer at the interface, however the electronic structure of this layer depends on the film thickness. The band structure $E_{\mathbf{k}l\sigma}$ is calculated employing the full-potential linear muffin-tin orbital method (FP-LMTO)[13] for thin Fe(001) films within a symmetric slab calculation.

Results for one, three, five, and seven layers of Fe are presented in Fig. 1. The depth of the first minimum in the spectra scales linearly with the magnetic moment of the top layer while the energy of this minimum reflects the d-band width. As can be seen from Fig. 2, the nonlinear spectra reveal the structural changes induced by different substrates or temperatures. In Fig. 3 we compare the *ab initio* nonlinear Kerr spectrum for the Fe(001) monolayer with tight-binding calculations. From the results of Fig. 3 it becomes obvious that it is necessary to use *ab initio* calculations for the films if only bulk tight-binding parameters are available. However, tight-binding calculations may be adequate if one uses as input parameters those determined from *ab initio* calculations for thin films.

We also generally expect interesting results for $\chi^{(2)}$ at heterogeneous interfaces like Fe/Cu(001). For example, it is of interest to find out how the substrate interferes with the electronic structure of the thin film. For this reason we performed calculations of the Fe/Cu bilayer. Results are shown in Fig. 4. The additional peak structure reveals the electronic influence even of the nonmagnetic Cu on the nonlinear magneto-optic response of thin films. This might be of general significance also with respect to the analysis of quantum well states (tuning of interface properties, λ_{so} in substrate, M in films).

From the results of Figs. 1–4 we learn that the nonlinear

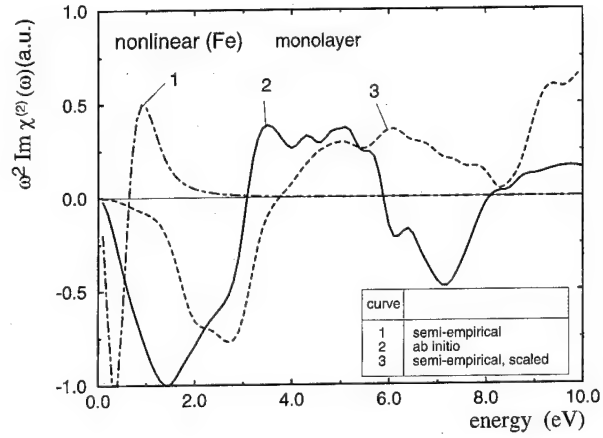

FIG. 3. Comparison of *ab initio* (solid line—2) and semi-empirical calculations of the nonlinear magneto-optical susceptibilities for a Fe monolayer. Semi-empirical calculations are performed for a two-dimensional atomic configuration (dashed-dotted curve—1) and for a three-dimensional one with reduced hopping parameters (dashed curve—3) containing the reduced coordination number of a monolayer compared to the bulk.

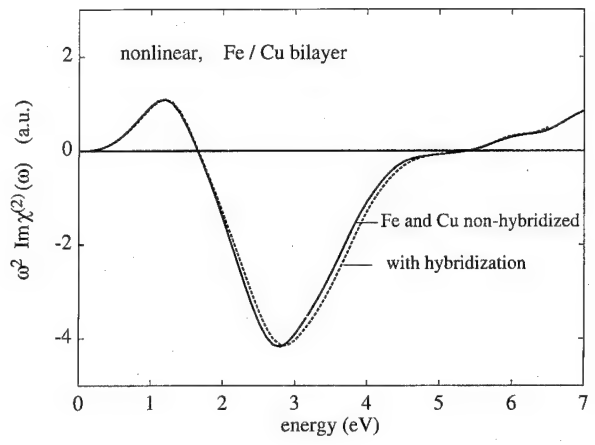

FIG. 4. Nonlinear magneto-optical Kerr-spectrum of a Fe/Cu bilayer system without (solid curve) and with (dashed curve) hybridization between the Fe and Cu layers. Note, the spectrum look rather different from the corresponding one for freestanding monolayers indicating a strong effect of Cu on the optical transitions.

Kerr effect is a sensitive probe of the magnetic and electronic structure at interfaces.

B. Symmetry and Kerr rotation

That SHG is very symmetry sensitive is furthermore particularly demonstrated by its polarization dependence and by the remarkable enhancement of the Kerr rotation. The latter important result was first theoretically derived by Pustogowa *et al.*[8] and later observed in experiments by Böhmer *et al.*[9] and Koopmans *et al.*[10]

First, we note that due to the symmetry sensitivity SHG exhibits a corresponding polarization dependence, which interestingly is very different for transition and noble metals.[3] The latter results, since s and d electrons feel the breakdown of inversion symmetry at the interface differently. This symmetry dependence mainly results from the matrix elements in $\chi^{(2)}$, see Eq. (2). The different possible optical excitations contributing to $\chi^{(2)}$ for noble and transition metals are illustrated in Fig. 5. Obviously, SHG yields interesting information on the electronic structure even for $M=0$ and when no Kerr effect is present. This area needs further analysis and might offer interesting new results.[3]

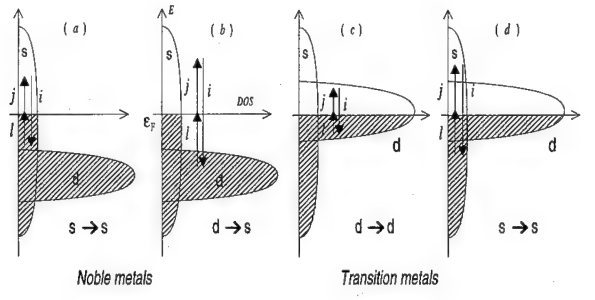

FIG. 5. Illustration of second harmonic generation from noble metals [(a) and (b)] and transition metals [(c) and (d)]. For noble metals, in case (a) no d electrons can be optically excited, which in contrast is possible in case (b). In case (c) for transition metals, predominantly d electrons contribute to the SHG yield, whereas in case (d) the excitation starts from the s band. Note, the cases (a) and (c) refer to low-frequency excitations while (b) and (d) correspond to high-frequency excitation.

Extending the symmetry analysis to the magnetic case we determine the Kerr rotations for different configurations and polarizations. The general analysis can be performed by using for s and p polarization (see Ref. 4)

$$E^{(2\omega)}(\Phi,\varphi)=2i\left(\frac{\omega}{c}\right)|E_0^{(\omega)}|^2\times\begin{pmatrix}A_pF_c\cos\Phi\\A_s\sin\Phi\\A_pN^2F_s\cos\Phi\end{pmatrix}\chi^{(2)}_{ilm}\times\begin{pmatrix}f_c^2t_p^2\cos^2\varphi\\t_s^2\sin^2\varphi\\f_s^2t_p^2\cos^2\varphi\\2f_st_pt_s\cos\varphi\sin\varphi\\2f_cf_st_p^2\cos^2\varphi\\2f_ct_pt_s\cos\varphi\sin\varphi\end{pmatrix},\tag{3}$$

where in the longitudinal configuration the susceptibility tensor is given by

$$\chi^{(2)}_{ilm}=\left(\begin{array}{cccc|cc}0&0&0&0&\chi^{(2)}_{xzx}&\chi^{(2)}_{xxy}\\\chi^{(2)}_{yxx}&\chi^{(2)}_{yyy}&\chi^{(2)}_{yzz}&\chi^{(2)}_{yyz}&0&0\\\chi^{(2)}_{zxx}&\chi^{(2)}_{zyy}&\chi^{(2)}_{zzz}&\chi^{(2)}_{zyz}&0&0\end{array}\right),\tag{4}$$

and in the polar configuration by

$$\chi^{(2)}_{ilm}=\left(\begin{array}{ccc|ccc}0&0&0&\chi^{(2)}_{xyz}&\chi^{(2)}_{xzx}&0\\0&0&0&\chi^{(2)}_{xzx}&-\chi^{(2)}_{xyz}&0\\\chi^{(2)}_{zxx}&\chi^{(2)}_{zxx}&\chi^{(2)}_{zzz}&0&0&0\end{array}\right).\tag{5}$$

Here, Φ and φ denote the angles of polarization of the reflected frequency doubled and of the incident light, $A_{p,s}$ are the amplitudes, $f_{c,s}$ and $F_{c,s}$ are the Fresnel coefficients, and $t_{s,p}$ are the linear transmission coefficients for the fundamental light. Then, from

$$\phi_K^{(2)}\approx\mathrm{Re}\frac{E_\varphi^{(2\omega)}(s-SH)}{E_\varphi^{(2\omega)}(p-SH)}\tag{6}$$

we determine the Kerr rotation for the polar and longitudinal configuration and for s and p polarized incident light. The following results are obtained: For the longitudinal configuration ($M_\parallel$) and p (s) polarized incident light one gets

$$\phi_{K,p}^{(2)M_\parallel}=\mathrm{Re}\frac{E_p^{(2\omega)}(s-SH)}{E_p^{(2\omega)}(p-SH)}=\mathrm{Re}\frac{a_1\chi^{(2)}_{yxx}+a_2\chi^{(2)}_{yzz}}{a_3\chi^{(2)}_{xzx}+a_4\chi^{(2)}_{zxx}+a_5\chi^{(2)}_{zzz}},\tag{7}$$

$$\phi_{K,s}^{(2)M_\parallel}=\mathrm{Re}\frac{E_s^{(2\omega)}(s-SH)}{E_s^{(2\omega)}(p-SH)}=\mathrm{Re}\frac{a_6\chi^{(2)}_{yyy}}{a_7\chi^{(2)}_{zyy}}.\tag{8}$$

For the polar configuration ($M_\perp$) and p (s) polarized incident light one gets

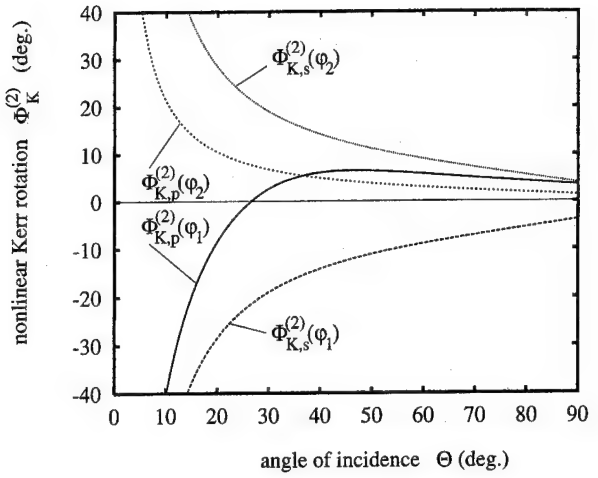

FIG. 6. Nonlinear Kerr rotation angles for p polarized incident light $\phi_{K,p}^{(2)}$ (full and short-dashed curves) and for s polarized incident light $\phi_{K,s}^{(2)}$ (long-dashed and dotted curves) for Fe at 770 nm as a function of the angle of incidence θ in the longitudinal Kerr configuration. The relative phase between $\chi_{zxx}^{(2)}=\chi_{zyy}^{(2)}$ and $\chi_{zzz}^{(2)}$ is $\varphi_1=0.505\pi$ in the full and long-dashed curves and $\varphi_2=1.505\pi$ in the short-dashed and dotted curves.

$$\phi_{K,p}^{(2)M_\perp}=\mathrm{Re}\frac{E_p^{(2\omega)}(s-SH)}{E_p^{(2\omega)}(p-SH)}$$

$$=\mathrm{Re}\frac{a_8\chi_{xyz}^{(2)}}{a_9\chi_{xxz}^{(2)}+a_{10}\chi_{zxx}^{(2)}+a_{11}\chi_{zzz}^{(2)}}, \tag{9}$$

$$\phi_{K,s}^{(2)M_\perp}=\mathrm{Re}\frac{E_s^{(2\omega)}(s-SH)}{E_s^{(2\omega)}(p-SH)}=\mathrm{Re}\frac{0}{a_{12}\chi_{zxx}^{(2)}}. \tag{10}$$

The coefficients $a_1, \ldots, a_{12}$ contain explicitly the whole information about the Kerr geometry (directions of light incidence and polarization, crystal magnetization) and about the linear transmission and reflection (see Ref. 4).

Summarizing the results, we find that generally $\phi_K^{(2)M_\perp}<\phi_K^{(2)M_\parallel}$ and $\phi_{K,s}^{(2)}>\phi_{K,p}^{(2)}$, which is in agreement with the experiment by Koopmans *et al.*[10] Numerical results of our theory using as input parameters the phase ratio of the various different tensor elements from Ni and linear complex indices of refraction are presented in Fig. 6. These results demonstrate clearly that the nonlinear Kerr angle depends sensitively on the direction of the magnetization and the incident beam, as well as on the light polarization. Depending on the experimental conditions the nonlinear Kerr angle might become even as large as 90°. Moreover, also the ellipticity will yield correspondingly large magnetic effects. From these results we conclude that the enhanced nonlinear Kerr rotation allows for the determination of easy axis and canted-spin configurations due to large magnetic contrast of different interfaces.

This selective discussion demonstrates the usefulness of nonlinear magneto-optics as a promising spectroscopy. Our results show that SHG is a new sensitive tool for determining magnetic interface properties such as the interplay of structure and magnetism, magnetic anisotropy, and magnetic reorientation. In contrast to linear optics, which probes characteristic film-averaged features, the nonlinear Kerr effect originates essentially from the surface and interfaces and thus allows the analysis of buried interfaces.

For future studies on the nonlinear magneto-optical Kerr effect it will be interesting to analyze magnetic anisotropy and easy axis, magnetic structure and domains, multilayers, and magnetostriction effects. Nonlinear optics at interfaces is a bulk-background-free technique and therefore, should yield a pronounced visibility of quantum well states and enhanced nonlinear paramagnetic Kerr oscillations in the presence of an external field.

An important future development of the nonlinear Kerr effect might result from femto-second dynamics which is able to follow the charge and spin dynamics of metallic interfaces in real time without involving the lattice.

Second harmonic generation from magnetic materials is shown to lead to a nonlinear magneto-optical Kerr effect that can be orders of magnitude larger than its linear equivalent. The origin of this effect can be found in the differences between the linear and nonlinear solutions of the optical wave equations and in the symmetry properties of the corresponding optical tensors. Applications for the study of magnetic surfaces, thin films, and multilayers will be discussed.
 [S0021-8979(96)13108-X]

I. INTRODUCTION

When linearly polarized light is incident on a magnetic material, the reflected beam will be elliptically polarized, with the major axis of the polarization ellipse rotated with respect to the incident plane of polarization. The origin of this magneto-optical Kerr effect (MOKE) lies in the spin-orbit coupling that leads to a difference in the refraction coefficient for left- and right-handed circularly polarized light. This spin-orbit coupling acts like a magnetic field on the current induced by the electromagnetic field of the incident light.[1] This should also hold for the nonlinear contributions of the induced current, that are the origin of optical second harmonic generation (SHG), leading to a nonlinear magneto-optical Kerr effect (NOMOKE). Based on symmetry arguments, Ru-Pin Pan *et al.* indeed showed that the presence of a magnetization would lead to new, nonzero *surface* contributions to the nonlinear optical response.[2] At the same time, Hübner and Bennemann calculated the nonlinear magneto-optical spectrum of Ni, based on a spin dependent band structure calculation.[3] They showed that this should indeed lead to observable effects, with magnetic contributions to the nonlinear tensor coefficients of more than 10%. First experimental evidence for such a NOMOKE was given by Reif *et al.* for an Fe(110) surface,[4] whereas Spierings *et al.* showed the first NOMOKE results from buried Co/Au interfaces.[5] From a SHG study of $Y_{2.5}Bi_{0.5}Fe_5O_{12}$ films, Aktsipetrov *et al.* reported a nonlinear Kerr rotation between 1° and 4°, that was significantly larger than the linear one.[6] These observations triggered much theoretical and experimental research. Reif *et al.* showed the presence of a magnetic circular dichroism in the SHG reflection from the Heussler alloy PtMnSb, as well as a large nonlinear Kerr rotation of 14°,[7] which is an order of magnitude larger than its linear Kerr angle of 1.1°. Interface and monolayer sensitivity was successfully demonstrated by Wierenga *et al.*[8,9] and nonlinear circular dichroism by Fiebig *et al.*,[10] whereas enormous enhancements of the nonlinear Kerr rotation were observed for a thin Fe/Cr film by Koopmans *et al.*[11] Theoretically, these large enhancements appeared to follow from the differences in the solutions for the Maxwell equations for the nonlinear and linear case,[12] and the differences in the symmetry properties of the linear and nonlinear susceptibilities.[11] In combination with the intrinsic surface and interface sensitivity of the SHG response[13] these large NOMOKE effects are particularly interesting for the study of surface magnetism.

SHG arises from the nonlinear polarization $\mathbf{P}(2\omega)$ induced by an incident laser field $\mathbf{E}(\omega)$. This polarization can be written as an expansion in $\mathbf{E}(\omega)$

$$\mathbf{P}(2\omega)=\boldsymbol{\chi}^{(2)}\mathbf{E}(\omega)\mathbf{E}(\omega)+\boldsymbol{\chi}^{(3)}\mathbf{E}(\omega)\nabla\mathbf{E}(\omega)+\cdots . \quad (1)$$

The lowest order term in Eq. (1) describes an electric dipole source. Symmetry considerations show that this contribution is zero in a centrosymmetric medium, thus limiting electric dipole radiation to the interfaces where inversion symmetry is broken. The bulk second harmonic can now be described in terms of the much smaller electric quadrupolelike contributions [second term in Eq. (1)]. However, because of the large volume difference between interface and bulk, this does not necessarily mean that the total bulk second harmonic signal is negligible. Interface sensitivity needs to be verified for any given system. Following the approach of Pan, Wei, and Shen,[2] it is convenient to separate the SH susceptibility into an even (χ^+) and an odd (χ^-) part in the magnetization $\mathbf{M}$. Thus, the induced SH polarization at an interface $\mathbf{P}(2\omega)$ is given by

$$P_i(2\omega)=\chi^+_{ijk}(\mathbf{M})E_jE_k+\chi^-_{ijk}(\mathbf{M})E_jE_k, \quad (2)$$

where $\mathbf{E}$ is the local excitation field at frequency ω at the interface, and we implicity assumed a summation over the repeated indices. The introduced susceptibilities fulfill $\chi^{\pm}_{ijk}(-\mathbf{M})=\pm\chi^{\pm}_{ijk}(\mathbf{M})$. In the following we will drop the ex-

plicit **M** dependence of $\chi^{\pm}_{ijk}$. For a given surface symmetry the χ^{+}_{ijk} and χ^{-}_{ijk} can be easily derived (see Table I). In the longitudinal configuration and for pure p- or s-input polarization we find that all nonzero χ^{+}_{ijk} elements have $i \epsilon \{x,z\}$, giving rise to p-polarized SHG. All nonzero χ^{-}_{ijk} elements have $i=y$, always resulting in s-polarized SHG. From this it follows that the SHG polarization ellipses for $\pm\mathbf{M}$ are each other's mirror image in the plane of incidence, and we can define a nonlinear Kerr angle $\Phi^{(2)}_K$ in correspondence with its linear counterpart $\Phi^{(1)}_K$. Pustogowa and Hübner have shown that for the longitudinal configuration $\Phi^{(2)}_K$ and $\Phi^{(1)}_K$ are given by

$$\tan \Phi^{(2)}_K = i\left[\frac{\chi^{(2),-}}{\chi^{(2),+}} + (h.o.)\right] \tag{3}$$

$$\tan \Phi^{(1)}_K \approx -\frac{\chi^{(1)-}}{\chi^{(1)+}} \frac{\sin\theta_i \cos\theta_i}{\sqrt{\cos^2\theta_i + \chi_0(\omega)}} \tag{4}$$

in which $\chi^{(1),+}$ and $\chi^{(1),-}$ are the nonmagnetic and magnetic contributions to $\chi^{(1)}$. The big difference between the expressions for $\Phi^{(2)}_K$ and $\Phi^{(1)}_K$ is the factor $1/\sqrt{\cos^2\theta_i+\chi_0(\omega)}$ in Eq. (4). This factor causes a small value for $\Phi^{(1)}_K$ but is not present in the nonlinear case. Therefore it is clear that the nonlinear Kerr rotation for all θ_i is always enhanced by a factor $\sqrt{\cos^2\theta_i+\chi_0(\omega)}$. Above this effect, in the nonlinear case one can select large magnetic $\chi^{(2)}$ contributions by a proper choice of input polarization and angle of incidence. This is in contrast with the linear case where one always deals with small off-diagonal magnetic terms $[\chi^{-}(\omega)]$ relative to large diagonal nonmagnetic terms $[\chi^{+}(\omega)]$.

II. EXPERIMENTAL RESULTS AND ANALYSIS

The experiments on the nonlinear Kerr rotation from thin, centrosymmetric magnetic films were stimulated by the prediction of large enhancements of $\Phi^{(2)}_K$ by Pustogowa and Hübner.[12] To enable direct comparison with their theoretical results, experiments were performed on Fe thin films and single crystals. All experiments were done *ex situ* and, therefore, required protective cover layers. The first sample consisted of a thin Fe film (thickness 2 nm), covered with a 2 nm Cr film deposited by rf-diode and dc magnetron sputtering, respectively. As a substrate we used a (100) silicon wafer, with a thermal oxide layer of about 525 nm. The substrate was on a rotating table, which moved with a velocity of 0.96 and 3.97 m/min underneath the Fe and Cr targets, respectively. Both targets were equipped with screens for getting uniformity of the layer thickness better than 1%. The base pressure was 2×10^{-7} Torr and the Ar pressure was 5 mTorr. For the second harmonic experiments we used the 770 nm output of a mode-locked (80 MHz) Ti–sapphire laser. The pulse width was 70 fs and the input power was 100 mW focused on a spot diameter of 100 μm. The experiments were done in the longitudinal configuration, i.e., the magnetization **M** was in the plane of the sample and in the optical plane of incidence (see inset Fig. 1). Figure 1 shows the polarization dependence of the SH signal for an s-polarized input at an angle of incidence of 45° and for **M** along $\hat{x}$ and $-\hat{x}$ respectively. The difference between the two minima of

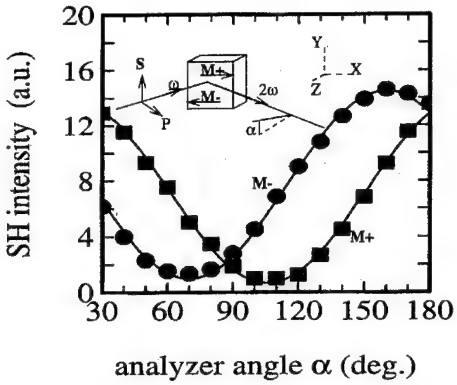

FIG. 1. Output polarization dependence of SHG reflection from an Fe/Cr multilayer, for s-polarized input. Squares: $\mathbf{M}\|\hat{x}$, dots $\mathbf{M}\|-\hat{x}$. The inset shows the experimental configuration.

the curves corresponds to $2\Phi^{(2)}_K \approx 34°$, i.e., a nonlinear Kerr rotation $\Phi^{(2)}_K$ of 17°. In this geometry we measured a linear Kerr angle of 0.03°, using the same Ti–sapphire input beam. These observations correspond to an enhancement of almost *three orders* of magnitude for the nonlinear Kerr rotation! The small linear rotation can be compared with the bulk Fe value of 0.1°.

The nonlinear Kerr angle can be expressed in the s- and p-components of the reflected SH field, denoted by $E_s(2\omega)$ and $E_p(2\omega)$, respectively. The relevant tensor components and their appearance for s- and p-polarized input are shown in Table I. Defining $R \equiv \mathrm{Re}[E_s(2\omega)/E_p(2\omega)]$, $I \equiv \mathrm{Im}[E_s(2\omega)/E_p(2\omega)]$ and $A^2 = R^2 + I^2$ we get

$$\Phi^{(2)}_K = \tfrac{1}{2}\arctan[2R/(1-A^2)] + \phi_0 \tag{5}$$

with $\phi_0=0$ for $A^2 \leqslant 1$, $\phi_0=90°$ for $A^2>1$ and $R \geqslant 0$, and $\phi_0=-90°$ for $A^2>1$ and $R<0$. Equation (5) is completely analogous to expression (3). It is easily verified that in the limit $A \ll 1$ Eq. (5) reduces to $\Phi^{(2)}_K = R$. However, the nonlinear case generally is far from this limit, since $\Phi^{(2)}_K$ can become as large as 90°.

Inspection of Table I shows that the s-input configuration is particularly simple, with only one even, χ^{+}_{zyy}, and one odd, χ^{-}_{yyy}, contributing element per interface. For normal incidence, only the χ^{-}_{yyy} contribution survives. From $E_p(2\omega)=0$ we then find $\Phi^{(2)}_K = \pm 90°$. Moving away from normal incidence, the ratio $|E_s(2\omega)/E_p(2\omega)|$ and, as a consequence, $|\Phi^{(2)}_K|$ decreases so that $\Phi^{(2)}_K$ is tunable over a wide range while scanning the angle of incidence.

A similar argument for a large $\Phi^{(2)}_K$ close to normal incidence is found for a p-polarized input configuration. Table I shows that close to normal incidence, the dominating even tensor components have one z index, and thus vanish at normal incidence, whereas the dominant odd tensor element, χ^{-}_{yxx}, is finite at normal incidence.

Fig. 2 shows the observed nonlinear Kerr rotation for both s- and p-polarized input as a function of the angle of incidence. We observed a small in-plane anisotropy in our experimental results that is possibly induced by the sputtering process. The plotted data in Fig. 2 have been averaged over this azimuthal anisotropy. The solid curves in Fig. 2 are theoretical fits, based on the multiple reflection model, with

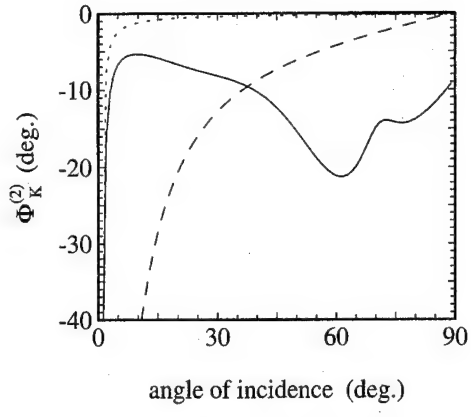

FIG. 3. Nonlinear Kerr rotation $\Phi_K^{(2)}$ for an Fe/Cr multilayer and a bulk Fe surface for s-polarized input as a function of the angle of incidence. The bold solid line is the theoretical fit of Fig. 2. The dashed line is a simulation for $\Phi_K^{(2)}$ of a clean Fe surface, based on the multilayer fit. The dotted line is a simulation for $\Phi_K^{(2)}$ for an Fe/Cr multilayer on a silicon wafer with a 10 nm oxide.

the unknown interface tensor elements of Table I as parameters and the following assumptions. Only the Fe is expected to contribute to the magnetic (odd) nonlinear susceptibility because the Cr film is antiferromagnetic. Furthermore, the top Cr layer will be oxidized, so that the major contribution to the nonmagnetic nonlinear susceptibility is also expected to originate from the Fe film. Therefore we assigned effective SH susceptibilities to the Fe and Cr layer together. We verified that the actual position within the Cr/Fe top layer did not significantly change the results of our fits. In addition to these SH sources at the top layer, we incorporate a nonmagnetic SH source at the Si/oxide interface. The bulk optical constants of the metals and silicon were obtained from Refs. 14 and 15, respectively. Because of the limited number of parameters involved in the s-polarization configuration (χ_{yyy}^{-} and χ_{zyy}^{+} at the top layer, and χ_{zyy}^{+} at the Si/oxide interface) one finds a unique fit to these experimental data points. The fit in Fig. 2 includes a relative maximum of $|\Phi_K^{(2)}|$ near $\Theta_i \approx 65°$, that is due to an enhancement effect through multiple reflections in the thick silicon oxide layer. Similar, but smaller, enhancement factors due to a substrate are also known for the linear Kerr angle.[16]

For the p-polarization, several combinations of tensor elements give satisfying fits. Figure 2 gives one such solution, obtained by choosing fixed values for the relative phase factors and fitting the absolute values of the tensor components. At 45° angle of incidence, we experimentally find for the p input $\Phi_K^{(2)} = 4.9°$.

These results show that for a proper understanding and analysis of the nonlinear response the total electro-magnetic response, linear and nonlinear including multiple reflections, has to be considered. The importance of such substrate effects can be illustrated in the following way. From our thin-film analysis we can simply calculate the response of an Fe surface by letting the thickness of the Fe film go to infinity. Similarly, we can vary the thickness of the silicon oxide layer for the thin-film structure.

Figure 3 shows the results of such simulations. For the thin oxide layer, the enhancement effect around $\theta_i = 60°$ has totally vanished, which demonstrates the importance of the multiple reflections and of the local field effects and thus the role of the substrate.

For the bulk surface, Fig. 3 shows a smooth variation of $\Phi_K^{(2)}$ as a function of the angle of incidence. In accordance with Eq. (5), Fig. 3 shows the $\Phi_K^{(2)}$ can be tuned at will between 0° and 90°, by varying the angle of incidence. This is a direct result of the fact that near normal incidence, the even contribution $\chi_{zyy}^{(2),+}$ vanishes, whereas the odd magnetic term $\chi_{xyy}^{(2),-}$ gives a finite contribution.

The prediction of this large tunable nonlinear Kerr rotation was confirmed by experiments on single crystalline Fe whiskers.[17] The (100) surfaces of the whiskers were capped by molecular beam epitaxy grown Au and Cr layers, while

some experiments were also performed on uncapped, oxidized Fe whiskers. The experiments were done using the 833 nm output of the Ti–sapphire laser. Figure 4 shows the measured angular dependence of the nonlinear Kerr rotation in the longitudinal configuration and s-polarized excitation. In Fig. 4 the experimental results can be seen for an Fe sample with a Cr top layer, an Fe sample with an Au top layer, and for an uncapped oxidized Fe sample. We find a maximum Kerr angle of 80° at an angle of incidence of 6°. This corresponds to an enhancement of more than a factor 10^3, compared with the value for the linear Kerr rotation of 0.03° as obtained in the same experimental setup, using the fundamental incident beam. The solid line in Fig. 4 is a theoretical fit for the Fe/Cr sample based on Eq. (5) and a model for SHG from interfaces.[18] Furthermore, the experimental results are in quite good agreement with the predicted behavior from Fig. 3.

The inset in Fig. 4 shows the experimental results for the longitudinal configuration with p-polarized incident light. In Table I it can be seen that now we are dealing with two odd tensor components, both of which give rise to s-polarized SHG and three even components which produce p-polarized SHG. Therefore it is to be expected that for the same incidence angles the ratio $|E_s(2\omega)/E_p(2\omega)|$ and thus $\Phi_K^{(2)}$ will be smaller compared to the s-input configuration. Near normal incidence the influence of the components χ_{ijk} with a "z" for i, j, or k will again be small. Since all even tensor components have at least one z index the p-polarized SHG will then be small. The s-polarized SHG, which is now dominated by χ^-_{yxx}, is finite. The result is that for small angles of incidence the Kerr rotation will again increase. This is clearly confirmed by our experiments, but seems in contradiction with the theoretical θ_i dependence of Ref. 12. However, there one has only considered the odd component χ^-_{yzz} that also vanishes near normal incidence. At an angle of incidence of 45° the experimental and theoretical configurations should be equivalent. Here we find $\Phi_K^{(2)}=1.2°$ in excellent agreement with the theoretical prediction of 1.4° from Pustogowa and Hübner.[12] In a recent article, the latter authors have included the proper Fresnel dependence in their expression for $\Phi_K^{(2)}$, showing excellent agreement with our experimental findings.[19]

In the longitudinal configuration we also measured the wavelength dependence of both $\Phi_K^{(1)}$ and $\Phi_K^{(2)}$ at an angle of incidence of 45° (see Fig. 5). The average value for $\Phi_K^{(1)}=0.062°$, in excellent agreement with the bulk Fe value of 0.061° of Ref. 20. Figure 5 shows that in the tuning range of the Ti:sapphire laser the Kerr rotations are constant, in agreement with the theoretical prediction of Pustogowa *et al.*[12] From their calculations it follows that for $\Phi_K^{(2)}$ a strong wavelength dependence is expected above 900 nm and below 600 nm. Future experiments in these wavelength ranges are certainly desirable.

In the transversal configuration (**M** along the y axis) for p- or s-input polarization, $\chi_{ijk}=0$ for $i=y$ (see Table I). This means that the SHG signal will always be p polarized. Changing the direction of the magnetization will not affect the plane of polarization but it has an influence on the total SH signal. The magnetic contrast can be defined as

$$\rho(q_{\text{in}}q_{\text{out}})=\frac{I(2\omega,q_{\text{in}}q_{\text{out}},M^+)-I(2\omega,q_{\text{in}}q_{\text{out}},M^-)}{I(2\omega,q_{\text{in}}q_{\text{out}},M^+)+I(2\omega,q_{\text{in}}q_{\text{out}},M^-)}, \tag{6}$$

where $I(2\omega,q_{\text{in}}q_{\text{out}},M^+)$ and $I(2\omega,q_{\text{in}}q_{\text{out}},M^-)$ are the $q_{\text{in}}q_{\text{out}}$ polarized SH intensities for opposite directions of the magnetization. In Fig. 6 our results for ρ_{sp} from the uncapped Fe sample can be seen while the inset in Fig. 6 shows the experimental configuration. Similar results were obtained for the Fe/Au sample. The dependence of the angle of incidence is again easily understood with the help of Table I. For small incident angles the z component of the E vector of the SH signal will be small. This means that the odd tensor component χ^-_{xyy} will dominate, resulting in large magnetic effects. However, in the limit of normal incidence there will only be an odd contribution and no magnetic effects will be seen, as ρ depends on the interference between χ^+ and χ^-. The solid line in Fig. 6 is a theoretical fit of Eq. (6) assuming only the Fe surface to contribute to the SH signal.

III. SUMMARY AND CONCLUSIONS

In this article we have shown how the reflected SHG signal from magnetic surfaces displays nonlinear magneto-optical Kerr effects that are several orders of magnitude larger than their linear equivalents. The reasons for these

enormous enhancements are both the differences in the solutions of the e.m. wave equations as well as the differences in the symmetry properties of the nonlinear and linear optical tensors. The experimental results that have been obtained so far are in excellent agreement with the theoretical predictions (Recently, polar NOMOKE effects have also been measured).[21]

The large, interface sensitive magneto-optical effects offer great possibilities to use this nonlinear technique for studying the magnetic properties of surfaces and interfaces of very thin films and multilayers, an area of intense research nowadays.

Symmetry of the magneto-optic response of the Sagnac interferometer

J. S. Dodge, L. Klein, M. M. Fejer, and A. Kapitulnik
Department of Applied Physics, Stanford University, Stanford, California 94305

We demonstrate the application of the Sagnac interferometer to magneto-optic measurements at an oblique angle of incidence. With an appropriate choice of polarization states for the two counter-propagating beams, a wide variety of magneto-optic effects may be measured, in the absence of an external perturbing field, with a sensitivity of a few hundred nanoradians. Using simple symmetry analysis of the conventional Kerr rotation measurement geometry, we may distinguish contributions to the non-reciprocal phase shift due to the polar, longitudinal and transverse Kerr effects, and consequently completely determine the magnetization vector direction, averaged over the probed region. Magneto-optic hysteresis loops were taken on a permalloy film to demonstrate the effectiveness of the new technique. We discuss the relevance of the Sagnac interferometer to magnetic microscopy and to the study of magnetic anisotropies in thin films.
 [S0021-8979(96)47908-3]

The Sagnac interferometer (SI) has proven to be a useful instrument for sensitive magneto-optic (MO) measurements.[1–3] Very general arguments based on the Helmholtz reciprocity theorem show that the SI can only be sensitive to effects which break time-reversal symmetry, such as the linear magneto-optic effects.[4] The selective sensitivity of the Sagnac to MO effects is its chief advantage over conventional, polarimetric measurement techniques, as it allows one to perform measurements with a sensitivity of 500 nrad/$\sqrt{Hz}$, in the absence of the perturbing magnetic field which is typically used to ensure that the measured effect has a magnetic origin. This advantage is most apparent in applications such as microscopy and magnetic relaxation measurements, which must be performed in constant magnetic field.[3] In near-field scanning optical microscopy especially, depolarizing topographic features can be difficult to distinguish from magnetic features, a difficulty which the SI overcomes by its very nature.[5–8] In previous work, the application of the SI has been limited to normal-incidence Kerr and Faraday rotation measurements. In this work, we demonstrate the more general application of the SI to magneto-optic Kerr measurements at oblique incidence, and show that symmetry arguments allow us to determine all three vector components of the magnetization by appropriate analysis of the MO response.

The SI measures intensity changes due to interference between counter-propagating waves, from which we can infer the relative phase shift between them.[9] By using only one of the polarization eigenmodes of a single-mode, polarization maintaining fiber to guide the light through most of its path in the interferometer, we ensure that the two counter-propagating waves travel along identical paths. One wave can then be thought of as the time-reversed reciprocal of the other, and consequently any phase shift between them must result from an effect which breaks time-reversal symmetry. To measure magneto-optic effects in reflection, we break the fiber loop and insert collimating optics, together with the bulk optics shown in Fig. (1). We use pairs of $\lambda/2$ and $\lambda/4$ retardation plates to transform the polarization states from the linear eigenmode of the fiber to arbitrary polarization states, $\mathbf{P_1}$ and $\mathbf{P_2}$, which we write as Jones vectors in a cartesian basis.[10] The polarizers at both ends of the optics train serve as polarization filters for the reflected beams. The two beams are reflected from a magnetized sample, and the natural coordinate system for describing the magnetization direction, in which we denote each coordinate by the name of its associated magneto-optic effect, is indicated. The only source of non-reciprocal phase shift in the interferometer is the magnetized sample, so we may neglect the rest of the interferometer and calculate only the relative phase shift between the two beams as they traverse the space between two imaginary observation planes $\mathcal{O}_1$ and $\mathcal{O}_2$, indicated in the diagram.

Conceptually, it is helpful to represent the behavior of the single-mode fibers, polarizers and retardation plates by two pairs of idealized optical elements, a polarized planar source and a coherent, polarization sensitive, spatially filtered detector.[11] One of each is located at each of the observation planes, as indicated in Fig. 2. We denote each monochromatic source field at its plane of origin $\mathcal{O}_i$ by $\mathbf{E_i^{src}}(\mathbf{r},t)=\mathbf{E_i^{src}}(\mathbf{r})e^{-i\omega t}$, and the field which the source generates at its plane of detection by $\mathbf{E_i^{src'}}(\mathbf{r},t)=\mathbf{E_i^{src'}}(\mathbf{r})e^{-i\omega t}$. The field which the coherent detector at $\mathcal{O}_i$ accepts will simply be the reciprocal of corresponding source field, $\mathbf{E_i^{det}}(\mathbf{r},t)=\mathbf{E_i^{s*}}(\mathbf{r})e^{-i\omega t}$. Throughout, we will assume that both the incident and reflected field amplitudes are described by a single polarization state over the whole field profile, so that we may write $\mathbf{E_i^{src'}}(\mathbf{r})=\mathrm{E_i^{src'}}(\mathbf{r})\mathbf{P}_1$. This assumption will not generally hold if the sample is inhomogeneous, but the treatment given here may be extended to such cases by following the standard treatment in Fourier optics of coherent imaging.[2,12] In practice, the optics are aligned so that the scalar part of all of the above fields are identical, described approximately by Gaussian functions $E^0(\mathbf{r})$. We may then represent reflection from a material with magnetization vector $\mathbf{M}$ by a reflectivity matrix $R(\mathbf{M})$ which acts only on the polarization state, so that $\mathbf{E_{1,2}^{src'}}(\mathbf{r})=\mathrm{E}^0(\mathbf{r})R(\mathbf{M})\mathbf{P}_{1,2}$. For fixed source fields, the complex amplitude $\alpha(\mathbf{E_i^{src}}(\mathbf{r}),\mathbf{E_j^{src}}(\mathbf{r}),\mathbf{M})$ which the source at $\mathcal{O}_i$ excites in the detector at $\mathcal{O}_j$ will be given by the overlap integral between the two fields:

$$\alpha(\mathbf{E_i^{src}}(\mathbf{r}),\mathbf{E_j^{src}}(\mathbf{r}),\mathbf{M})=\int_{\mathcal{O}_j}\mathbf{E_j^{det*}}(\mathbf{r})\cdot\mathbf{E_i^{src'}}(\mathbf{r})d\mathbf{r}$$

 0021-8979/96/79(8)/6186/3/$10.00

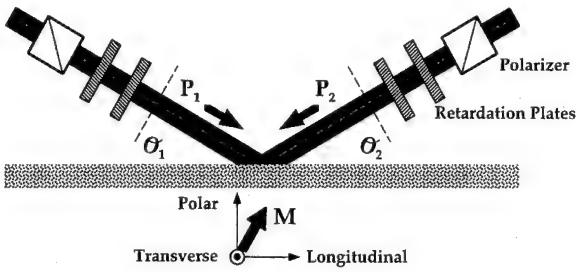

FIG. 1. Bulk optics for measurement at oblique incidence.

$$= \int_{\mathscr{O}_j} \mathbf{E}_\mathbf{j}^{\mathrm{src}}(\mathbf{r}) \cdot \mathbf{E}_\mathbf{i}^{\mathrm{src}'}(\mathbf{r}) d\mathbf{r},$$

$$\propto \mathbf{P_j} \cdot [R(\mathbf{M})\mathbf{P_i}]. \tag{1}$$

The non-reciprocal phase shift between the beams will be

$$\varphi_{\mathrm{nr}}(\mathbf{E}_\mathbf{i}^{\mathrm{src}}(\mathbf{r}),\mathbf{E}_\mathbf{j}^{\mathrm{src}}(\mathbf{r}),\mathbf{M}) = \mathrm{Arg}\left(\frac{\alpha(\mathbf{E}_\mathbf{i}^{\mathrm{src}}(\mathbf{r}),\mathbf{E}_\mathbf{j}^{\mathrm{src}}(\mathbf{r}),\mathbf{M})}{\alpha(\mathbf{E}_\mathbf{j}^{\mathrm{src}}(\mathbf{r}),\mathbf{E}_\mathbf{i}^{\mathrm{src}}(\mathbf{r}),\mathbf{M})}\right). \tag{2}$$

If the sample is nonmagnetic, then by the symmetry of the kinetic coefficients its dielectric tensor ϵ_{ij} must be symmetric,[13] and the Helmholtz reciprocity theorem holds:[4]

$$\int_{\mathscr{O}_1} \mathbf{E}_\mathbf{2}^{\mathrm{src}'}(\mathbf{r}) \cdot \mathbf{E}_\mathbf{1}^{\mathrm{src}}(\mathbf{r}) d\mathbf{r} = \int_{\mathscr{O}_2} \mathbf{E}_\mathbf{1}^{\mathrm{src}'}(\mathbf{r}) \cdot \mathbf{E}_\mathbf{2}^{\mathrm{src}}(\mathbf{r}) d\mathbf{r}. \tag{3}$$

This implies that the phase shift given by Eq. (2) is zero, as expected. If the sample is magnetized, then the dielectric tensor will develop off-diagonal terms, Eq. (3) no longer holds, and we may detect a non-zero φ_{nr}. The SI is dynamically biased to produce a voltage signal which is proportional to the phase shift multiplied by the average optical power at the detector, so the measured signal is roughly proportional to $\varphi_{\mathrm{nr}} \times |\alpha(\mathbf{E}_\mathbf{i}^{\mathrm{src}}(\mathbf{r}),\mathbf{E}_\mathbf{j}^{\mathrm{src}}(\mathbf{r}),\mathbf{M})|^2$. The magnitude of the signal due to this non-reciprocity will depend on the details of the optical constants of the material, the nature of the boundary conditions, the polarization states $\mathbf{P_1}$ and $\mathbf{P_2}$, and the direction of the magnetization. Symmetry considerations will help us choose polarization states which provide useful information about the magnetization state under fairly general circumstances, simplifying our analysis considerably.

We consider the case of an isotropic sample magnetized in an arbitrary direction. Shelankov and Pikus have discussed the constraints which time-reversal symmetry, together with a variety of other crystal symmetries, impose on the reflectivity matrix.[11] Our analysis parallels theirs, and the reader may refer to their work for more details concerning the influence of crystal symmetry and gyrotropy on our results. Neglecting these effects, we can see that there are two transformations which will map the source plane of one beam onto the source plane of the other: (i) C_2, a 180° rotation about the film normal, and (ii), σ_v, a reflection through the plane perpendicular to both the film surface and the plane of incidence. We may choose $\mathbf{P_1}$ and $\mathbf{P_2}$ to satisfy one or both of these symmetries, as shown in Fig. 3. By doing so, we eliminate the contribution of one or more magnetization directions to the magneto-optic response. Consider the case $\mathbf{P_2} = C_2\mathbf{P_1}$. Rotation changes the sign of both the transverse and the longitudinal components of the magnetization, but leaves the polar component unchanged. Thus symmetry requires that a sample magnetized in the polar direction will have the same response to each beam, producing zero relative phase shift between them, while the magnetization along the transverse or longitudinal directions will typically yield a finite shift. In a similar way, by choosing $\mathbf{P_1} = \sigma_v\mathbf{P_2}$ we will observe no longitudinal response. If $\mathbf{P_1}$ and $\mathbf{P_2}$ are linear, p-polarized states, then both symmetries are satisfied and only the transverse component gives a finite response (s-polarized states, due to their symmetry under reflection in the plane of incidence, yield no response whatsoever). Limiting ourselves to the linear response the magnetization, with coupling constants α, we may summarize these statements by the following equations:

$$\varphi_{\mathrm{nr}}^{\bar{p}}(\mathbf{M},\mathbf{E}_\mathbf{1}^{\mathrm{src}}(\mathbf{r})) \equiv \varphi_{\mathrm{nr}}(\mathbf{E}_\mathbf{1}^{\mathrm{src}}(\mathbf{r}),C_2\mathbf{E}_\mathbf{1}^{\mathrm{src}}(\mathbf{r}),\mathbf{M})$$
$$= \alpha_{\bar{p},t} M_t + \alpha_{\bar{p},l} M_l, \tag{4a}$$

$$\varphi_{\mathrm{nr}}^{\bar{l}}(\mathbf{M},\mathbf{E}_\mathbf{1}^{\mathrm{src}}(\mathbf{r})) \equiv \varphi_{\mathrm{nr}}(\mathbf{E}_\mathbf{1}^{\mathrm{src}}(\mathbf{r}),\sigma_v\mathbf{E}_\mathbf{1}^{\mathrm{src}}(\mathbf{r}),\mathbf{M})$$
$$= \alpha_{\bar{l},t} M_t + \alpha_{\bar{l},p} M_p, \tag{4b}$$

$$\varphi_{\mathrm{nr}}^{\overline{pl}}(\mathbf{M}) \equiv \varphi_{\mathrm{nr}}(\mathbf{E_s}(\mathbf{r}),\mathbf{E_s}(\mathbf{r}),\mathbf{M}) = \alpha_{\overline{pl},t} M_t. \tag{4c}$$

A bar above the magnetization direction indicates that this component is forbidden by symmetry from contributing to the signal. These three phase shifts may all be determined simply by changing the orientations of the retardation plates shown in Fig. 1. By determining the five coupling constants,

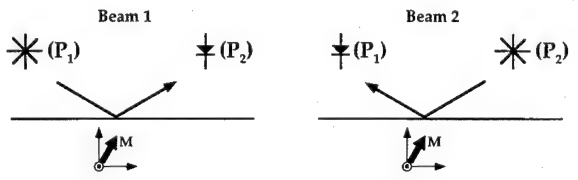

FIG. 2. Idealized schematic of two beams, with planar, monochromatic sources and coherent, polarization sensitive, spatially filtered detectors.

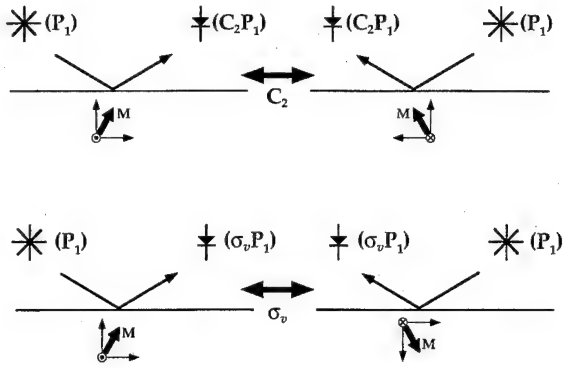

FIG. 3. Symmetries of the experimental apparatus for different choices of the polarization states. When $P_2 = C_2P_1$, the polar effect is not measured. When $P_2 = \sigma_v P_1$, the longitudinal effect is not measured. The operation σ_v transforms the magnetization as shown because it is a pseudovector. P-polarized states satisfy both symmetries and measure only the transverse effect.

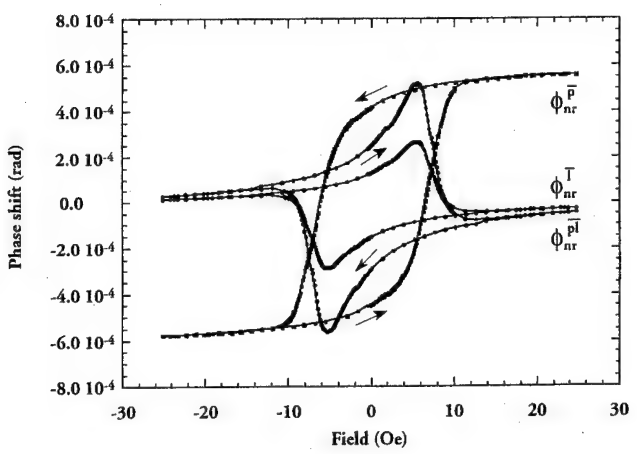

FIG. 4. Raw data from a hysteresis loop in a permalloy film.

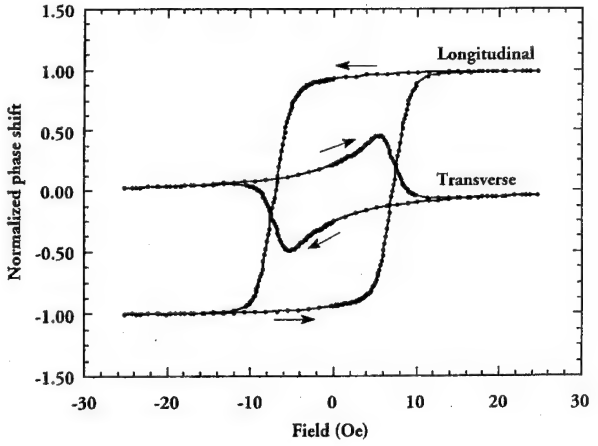

FIG. 5. Normalized magnetization components M_l and M_t calculated from the data in Fig. 4.

we can use Eqs. (4) to calculate the complete magnetization vector from a measurement of the three phase shifts.

To verify this analysis, we have observed hysteresis loops in a permalloy film. Measurements of the three phase shifts described in Eqs. (4) are shown in Fig. 4. In these measurements, the sample was mounted on goniometers for precise alignment to the surrounding optics, and the field was swept with a small horseshoe magnet oriented in the plane of incidence. The field had a small component in the transverse direction, which produced the finite phase shift $\varphi_{nr}^{\bar{pl}}$ seen in the saturated part of the loops. All polarizing optics were carefully aligned to satisfy the required symmetry relations; we estimate the error in this alignment to be less than 1 mrad for any one component. In Eqs. (4), the transverse magnetization contributes to all three phase shifts, and must be subtracted. We obtained $\alpha_{\bar{p},t}$, $\alpha_{\bar{l},t}$ and $\alpha_{\bar{pl},t}$ directly by rotating the magnet to saturate the magnetization in the transverse direction and measuring each of the three phase shifts. We obtained the constant $\alpha_{\bar{p},l}$ in a similar way. We then scaled the hysteresis loop for $\varphi_{nr}^{\bar{pl}}$ accordingly and subtracted it from the other two loops. Demagnetization energy forces the magnetization to lie in the plane of the film, and the curves for $\varphi_{nr}^{\bar{pl}}$ and $\varphi_{nr}^{\bar{p}}$ are in fact proportional. We could not easily saturate the permalloy in the polar direction to measure $\alpha_{\bar{l},t}$, but after subtracting the transverse contribution to $\varphi_{nr}^{\bar{l}}$, the remaining phase shift was zero within the noise of the measurement, so we may safely take $M_p=0$. Fig. 5 shows the normalized magnetization components M_t and M_l which we derive from the data in Fig. 4. The data nicely show the effectively coherent rotation of the magnetization during much of the loop. As the field is increased from -25 Oe, the magnetization rotates toward the transverse direction. Up to about $+5$ Oe, the magnitude of the magnetization $|\mathbf{M}|$ remains constant as M_t increases. Above 5 Oe, we observe a rounding off of the transverse magnetization, while the longitudinal component switches abruptly. The SI measures the average magnetization in the beam area, so the reduction of $|\mathbf{M}|$ in this field range indicates that the switching occurs by domain formation, preventing $\varphi_{nr}^{\bar{pl}}$ from reaching its maximum value. This behavior is similar to that seen in other thin films with uniaxial anisotropy.[14]

We should emphasize that the symmetry properties of the SI allow us to perform these measurements in static or zero applied field as well as for the hysteresis loops shown here. We recently demonstrated the advantage of this capability in normal incidence measurements by correlating the structural domain size in $SrRuO_3$ with the magnetic domain size observed after cooling through the Curie point in zero field.[3] It may be interesting to apply the techniques described here to the study of spin reorientation transitions in epitaxial magnetic films.[15,16] The ability to discriminate clearly between the longitudinal and the polar orientations is an attribute which could be especially useful here. In microscopy with magneto-optic contrast, these capabilities could be useful for characterizing magnetic anisotropy variations in thin films on a microscopic scale.[17] The symmetry considerations are quite general and can be extended to a wide range of experimental geometries.

Second-order magneto-optic effects in anisotropic thin films (abstract)

R. M. Osgood III, B. M. Clemens, and R. L. White
Department of Materials Science and Engineering, Stanford University, Stanford, California 94305-2205

The signal measured in a magneto-optic Kerr effect (MOKE) experiment is normally assumed to be proportional to the component of the magnetization (M) along a certain axis.[1] We have observed significant effects from the M^2 term in the magneto-optic response (i.e., in the rotation and/or ellipticity, which can be thought of as the real and imaginary parts of the same quantity[2]) from films with in-plane magnetization and in-plane magnetic anisotropy. These films were: epitaxial Fe(110)/Mo(110) bilayers and multilayers, thin Fe films with ion-bombardment induced anisotropy, Co(110) thin films, and NiFe films with anisotropy induced with a field during deposition. In all of these films, the in-plane anisotropy created a coherently rotating magnetization (as evidenced by measurement of the component of the magnetization perpendicular to the applied field) that contributed a large M^2 term to the magneto-optic response when an external field was applied close to parallel to the hard axis of the film. The M^2 term in the magneto-optic response changed sign as H was rotated through the hard axis and reached a minimum when H was applied nearly parallel ($\pm 0.5°$) to the hard axis, thus providing a sensitive indication of the location of the sample's hard axis. Spectroscopic Kerr investigations of CoNi/Pt multilayers

W. P. Van Drent and T. Suzuki
Toyota Technological Institute, 2-12-1 Hisakata, Tempaku-ku, Nagoya 468, Japan

Q. Meng, J. C. Lodder, and Th. J. A. Popma
MESA Research Institute, P.O. Box 217, 7500 AE Enschede, The Netherlands

Co_xNi_{1-x}/Pt multilayers with $x=0.4$ and 0.5 were sputtered onto Si substrates. Magnetic and spectroscopic magneto-optic measurements (1.4–5.2 eV) reveal a Kerr rotation up to $-0.48°$ at about 4.5 eV for a sample with rectangular hysteresis loop, about 170 kA/m coercivity, and a Curie temperature of about 300 °C. Pt layers could be made extremely thin (2.9 Å) without loss of perpendicular anisotropy and rectangular hysteresis loop. Simulations show that the Kerr rotation peak shifts back from 4.5 to 3.9 eV with increasing number of bilayers. © *1996 American Institute of Physics.* [S0021-8979(96)13208-6]

I. INTRODUCTION

The interest in Co/Pt based multilayers as magneto-optical recording material is due to several merits: the high magneto-optical (MO) output at short wavelengths,[1] due to the polarized Pt[2] or alloy layers[3] at the interfaces, the high corrosion resistance, and the high perpendicular anisotropy K_{eff} in very thin layers. A disadvantage is the relatively high Curie temperature T_C, which reduces rewritability. By alloying Co with another element, T_C can be lowered, but the favorable properties of Co/Pt should be preserved in the new material. We tried to alloy Co with Ni,[4] as the magnetic phase diagram[5] indicated that T_C decreases significantly with Ni content. Recently, this was confirmed by a study of CoX/Pt multilayers.[6]

II. EXPERIMENT

CoNi/Pt multilayers (ML) were prepared by magnetron sputtering from 2 in. sputter guns in argon pressures $8 \leqslant P_{\text{ar}} \leqslant 48$ μbar. The guns were equipped with shutters and the time between deposition of subsequent layers was about 2 s. The target-substrate distance was fixed at 100 mm, which keeps the substrate relatively plasma free. The samples were prepared on 2 in. Si (111) wafers, which were cleaned in a standard way before insertion. The ML always consisted of a Pt base layer (typically 400 Å) and a stack of 17 or 18 bilayers. Sputter rates were between 1 and 2.5 Å/s. The background pressure before deposition was $<10^{-8}$ mbar. Layer thicknesses were measured by x-ray diffraction (XRD) (low and high angle) and Dektak surface profiler, both on thick layers (of CoNi resp. Pt) and on ML. The bilayer peak was visible up to $P_{\text{ar}}=40$ μbar. Above that the structure is too distorted to observe.

Kerr rotation θ_K and ellipticity ϵ_K of uncoated samples were measured in the range 1.4–5.2 eV by a homemade, automated setup applying the photoelastic modulator principle.[7–9] The accuracy was about 0.001°, and an automatic calibration for *both* θ_K and ϵ_K is performed before each measurement. Details of this calibration will be published elsewhere. A sample heater in the Kerr setup served as the T_C measurement stage.

Magnetic measurements were carried out with a vibrating-sample magnetometer (VSM) ($H_{\max}=3$ T, resolution 5×10^{-9} A m^2) and a homemade torque meter ($H_{\max}=1.8$ T, resolution 3×10^{-9} Nm).

III. RESULTS AND DISCUSSION

Perpendicular ($\perp$) anisotropy was found for both $Co_{40}Ni_{60}$/Pt and $Co_{50}Ni_{50}$/Pt ML in the range $4 \leqslant t_{\text{CoNi}} \leqslant 20$ Å, where $t_{\text{Pt}} \approx 15$ Å. The $\perp$ anisotropy was found for very thin Pt layers: a 17×(5.5 Å $Co_{40}Ni_{60}$/2.8 Å Pt) ML still had $K_{\text{eff}}>0$. K_{eff} can be decomposed in a surface and a volume anisotropy (K_S resp. K_V) by[10]

$$t_{\text{magn}}K_{\text{eff}}=2K_S+t_{\text{magn}}K_V, \tag{1}$$

where t_{magn} is the thickness of the magnetic layer.

For the 50% (40%) Co multilayers $K_S=0.26$ (0.21) mJ/m^2 and $K_V=-257$ (-185) kJ/m^3 were found. These values are in good agreement with others.[11,12] The maximum $\perp$ anisotropy was found for $5 \leqslant t_{\text{CoNi}} \leqslant 8$ Å in both cases.

Figure 1 displays spectroscopic Kerr measurements of a series of 230 Å Pt+17×(*X* Å $Co_{50}Ni_{50}$/14.7 Å Pt). The thinnest magnetic layer (3.8 Å CoNi) gives the lowest θ_K. In this case $M_{\text{S,CoNi}}$ is also very low, which suggests that the magnetic layers are not continuous. θ_K increases gradually with increasing t_{CoNi} to a maximum of about $-0.30°$ at $t_{Co_{50}Ni_{50}}=25$ Å. Thicker CoNi layers did lower θ_K (not drawn). Enhancement due to more CoNi in the skin-depth region is counteracted by the reduction of the amount of polarized Pt in this region, which is dependent on the number of interfaces.

It is clear that θ_K at lower photon energies increases with increasing t_{CoNi} and the features of the Co and Ni spectra (e.g., the peak in θ_K around 1.5 eV) become more pronounced. The same can be seen for ϵ_K, where the spectrum for the sample with 25 Å CoNi layers resembles a mix of the bulk Co and Ni curves. The MO contribution of polarized Pt at high photon energies is found for thin magnetic layers.

The samples with $t_{Co_{50}Ni_{50}}=5.0$, 6.3, and 8.8 Å have $\perp$ anisotropy and unity squareness. Of these, only the first sample has a rectangular hysteresis loop, and therefore $t_{Co_{50}Ni_{50}}=5$ Å was chosen as the starting point for a Pt thickness variation. Figure 2 displays the spectroscopic Kerr measurements for $t_{Co_{50}Ni_{50}}=5$ Å, and $t_{\text{Pt}}=14.7$, 8.4, and 5.9 Å. Even the 5.9 Å sample is perpendicular, in contrast to Co/Pt ML's with similar layer thicknesses. At high photon energies

 0021-8979/96/79(8)/6190/3/$10.00

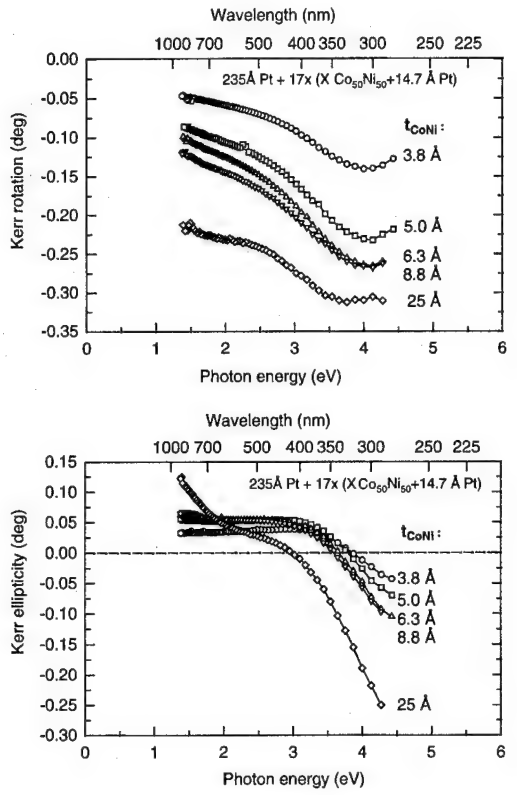

FIG. 1. Spectroscopic Kerr measurements for 230 Å Pt+17 $\times(X$ $Co_{50}Ni_{50}$/14.7 Å Pt). The series ranges from $X=3.8$ to 25 Å.

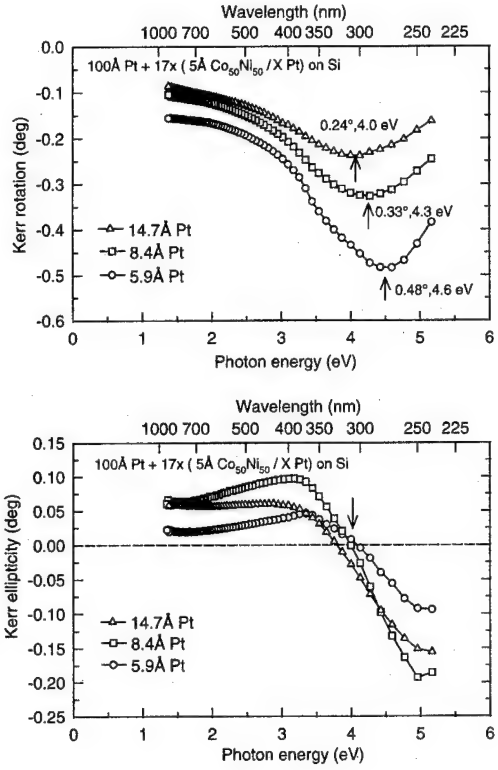

FIG. 2. Spectroscopic Kerr measurements for three samples with decreasing Pt thickness. The samples are 100 Å Pt+17×(5 Å $Co_{50}Ni_{50}$/X Pt) with $X=5.9$, 8.4, and 14.7 Å.

θ_K increases considerably with decreasing t_{Pt}. The maximum value is $\theta_K=-0.48°$ for $t_{Pt}=5.9$ Å, and this is the highest value observed by us for any CoNi/Pt ML. With decreasing t_{Pt} the energy at which the peak occurs shifts up from 4.0 to 4.6 eV. This shift is due to the decreasing total layer thickness, as will be shown by simulations in the next paragraph. Spectroscopic studies of Co/Pt multilayers,[13,14] CoPt alloys,[14,15] and CoNi/Pt multilayers[11] did not reveal such peak shifts, as those results are all taken of ML's that are optically thick.

Figure 3 shows the Kerr hysteresis loop of the sample with a stack of 5 Å CoNi/5.9 Å Pt, taken at 4.13 eV. The loop features unity squareness and high rectangularity. This sample was sputtered at 40 μbar, which results in a high $H_C\approx 170$ kA/m. Although high P_{ar} is a poor way to introduce a morphology that supports a high H_C (due to the increase in media noise), Fig. 3 demonstrates that it is possible to make a CoNi/Pt multilayer with high rectangularity, high H_C, and high θ_K at short wavelengths.

IV. SIMULATION OF KERR EFFECTS

Because the thickness of these ML's is of the order of the skin depth[16] (which is between 10.5 and 13.5 nm for Co,Ni and Pt between 1.5 and 4.0 eV), it is of interest to estimate the Kerr effects for an optical thick ML. Using a simulation based on the mathematical approach of Visnovsky[17] the Kerr effects for arbitrary N were calculated using the measurement results for the thin ML as a starting point. In this way it is possible to estimate the Kerr effect of a thick ML from the measurement of a thin one. The approach was as follows:

(1) Calculate the MO Voigt constants $Q(\lambda)$ of either polarized Pt or CoNiPt alloy layers at the interface by fitting these constants in such a way that the calculation gives the same θ_K and ϵ_K as the measurement.

(2) These $Q(\lambda)$ are used to calculate the θ_K and ϵ_K for a hypothetical N bilayer medium, with arbitrary N.

The layer structure of our "best sample," including the Pt seedlayer and 100 nm of the Si substrate, was used as input for the simulation. Now one can either assume that alloyed layers occur at the interface, or that no alloying occurs, and Pt polarizes at the interfaces. For the alloyed layer, a weighted mix of the optical constants of its constituents was taken. Both schemes were applied with several thicknesses of the polarized resp. the alloyed layer, and negligible

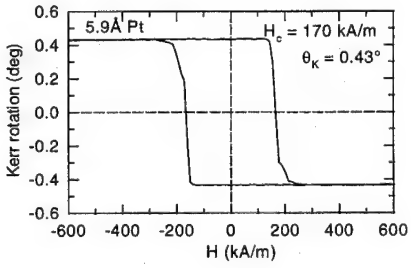

FIG. 3. Kerr hysteresis loop at $E_{photon}=4.13$ eV for 100 Å Pt+17×(5 Å $Co_{50}Ni_{50}$/5.9 Å Pt). The loop has good rectangularity, which is imperative for MO recording.

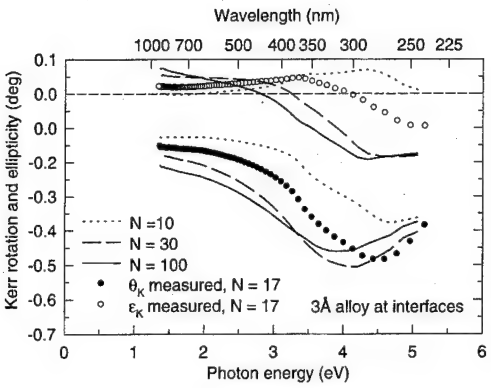

FIG. 4. Simulated Kerr rotation and Kerr ellipticity for several numbers of bilayers N. Measurement of 100 Å Pt+17×(5 Å $Co_{50}Ni_{50}$/5.9 Å Pt) (points) was taken as a starting point for the simulations.

differences between these schemes were found. This corresponds to the expectation that such a thin stack behaves as a single optical layer. For the following a 3 Å alloy layer model was taken. In Fig. 4 measurement and simulations are shown for $N=10$, 30, and 100.

According to the simulations the maximum $\theta_{K,\max}$ should be reached at about 30 bilayers. $\theta_{K,\max}$ calculated by simulations of $N=20$, 25, 40, and 50 (not drawn) was lower than in the $N=30$ case. $\theta_{K,\max}$ for $N=30$ occurs at about 4.1 eV, which is in good agreement with reported results for Co/Pt. θ_K decreases for $N<17$. In the range 1.5–4 eV the simulated optical thick layer has a higher θ_K than the thin one. The UV peak for $N=100$ occurs at a $E_{\text{photon}}\sim 3.9$ eV. This is slightly lower than the 4.2 eV that is expected for the contribution of Pt in Co/Pt ML's and it is certainly lower than the peak position in the measurement. The simulation for the optical thick layer ($N=100$) gives $\theta_{K,\max}=-0.46°$. This is lower than the measurement for $N=17$ ($\theta_K=-0.48°$), but for application purposes it occurs at a much more favorable photon energy.

The simulated ϵ_K decreases faster with increasing photon energy and the overall output is larger (both positive and negative) than in the measurement.

V. CONCLUSIONS

Co_xNi_{1-x}/Pt ML's with $x=0.4$ and 0.5 were prepared by magnetron sputtering. Perpendicular anisotropy was achieved up to $t_{\text{CoNi}}=20$ Å for both compositions. A sample of 17×(5 Å $Co_{40}Ni_{60}$/2.8 Å Pt) was still perpendicular. We attribute this to the lower magnetic moment of CoNi compared to pure Co, which on its turn reduces the demagnetizing field. $\theta_K=-0.48°$ was found for 17×(5 Å $Co_{50}Ni_{50}$/5.9 Å Pt). A large H_C (170 kA/m) and high squareness were other features of this sample.

In situ and *ex situ* optical characterization of electro deposited magneto-optic materials

James N. Hilfiker, Darin W. Glenn, Scott Heckens, and John A. Woollam
Center for Microelectronic and Optical Materials Research, and Department of Electrical Engineering, University of Nebraska, Lincoln, Nebraska 68588

Kurt W. Wierman
Department of Physics, University of Nebraska, Lincoln, Nebraska 68588

Electrodeposition is being investigated as a novel and low-cost method to prepare magneto-optic thin film and nanostructured materials. This deposition method allows precise control over thin-film properties and permits deposition of novel magnetic geometries. Multilayers and alloys can be deposited and controlled by adjusting deposition potentials and ion concentrations in the bath. Nickel/cobalt alloys have been electrodeposited from sulfamate, sulfate, and chloride solutions onto Au substrates. The optical properties were monitored *in situ* with a real-time spectroscopic ellipsometer measuring simultaneously at 44 wavelengths in the 410–750 nm spectral range. *In situ* measurements have the advantage of determining the material microstructural properties (thickness, density, and roughness) before the films are oxidized in the air ambient. *Ex situ* variable angle spectroscopic ellipsometry measurements were taken over the spectral range from 205 to 1000 nm.
 [S0021-8979(96)13308-2]

I. INTRODUCTION

Sputtered Co/Ni and Co/Pt nanometer thick multilayers can exhibit perpendicular magnetization and have previously been investigated as possible recording materials.[1,2] Electrodeposition is investigated as a possible processing technique for similar magneto-optic materials. Alloys can be plated from an electrolyte containing ions of each of the elements to be plated. The ratio of ions in the electrolyte will have a direct effect on the thin-film alloy ratio, and the alloy ratio can be controlled by adjusting the electrolyte constituents. This control is desirable for many magneto-optic materials because of the effects of alloy ratios on Curie temperature, coercivity, optical response, and magneto-optic response. Control of the compensation temperature in TbFeCo is an example.

A full electromagnetic analysis of the multilayer boundary value problem, including dielectric tensor representation for all constituent layers, can provide information about observed optical and magneto-optical phenomena.[3] Predictive modeling with this analysis method allows the optimization of magneto-optic disk performance.[4] Accurate material properties (optical and magneto-optical constants) are necessary to simulate the optical and magneto-optical responses of a disk structure.

In order to accurately model the material thickness and microstructure, *in situ* spectroscopic ellipsometry measurements were taken during the electrodepositions. This allows the materials to be studied before oxidation, and thus the true material optical constants can be used for predictive modeling. The *in situ* measurements also allow diagnostics of time dependent growth effects. Optimization of the thin-film thicknesses and microstructure could be implemented by performing predictive modeling and then controlling the growth.

II. EXPERIMENTAL PROCEDURE

Electrodeposition of cobalt/nickel multilayers and alloys were carried out from the following electrolyte: 90 g/ℓ nickel sulfamate, 30 g/ℓ boric acid, and X g/ℓ of cobalt chloride (where X is varied). Both potentiostatic and galvanostatic depositions were performed using a Princeton Applied Research (PAR) Model 173 potentiostat/galvanostat. A three electrode cell configuration was used in which the working electrode consisted of the substrate to be plated on, the counter electrode was a platinum foil, and the reference electrode was a saturated calomel electrode. A PAR Model 179 coulometer was used to monitor the charge passing through the sample during the deposition.

An electrochemical cell was designed with optical ports to allow ellipsometry measurements through the liquid. An *in situ* spectroscopic ellipsometer (J. A. Woollam Co., Inc.) was used to study the deposition processes. The *in situ* ellipsometer allowed 44 wavelengths to be measured simultaneously over the spectral range from 410 to 750 nm every 40 ms.

A series of cobalt/nickel multilayers and alloys were electrodeposited on optically thick gold films. The gold substrates were prepared by sputter deposition on silicon wafers. A chromium underlayer was first sputter deposited on the silicon substrate to act as an adhesion layer for the gold. X-ray fluorescence measurements were taken on the series of samples to determine the thin-film cobalt-to-nickel alloy ratio.

In situ spectroscopic ellipsometry measurements were also taken on each of these films during deposition. This measurement tool allows the determination of the optical constants and thin-film thicknesses of the deposited layer and their time dependencies. The galvanostatic depositions were modeled with a constant growth rate material model.

 0021-8979/96/79(8)/6193/3/$10.00

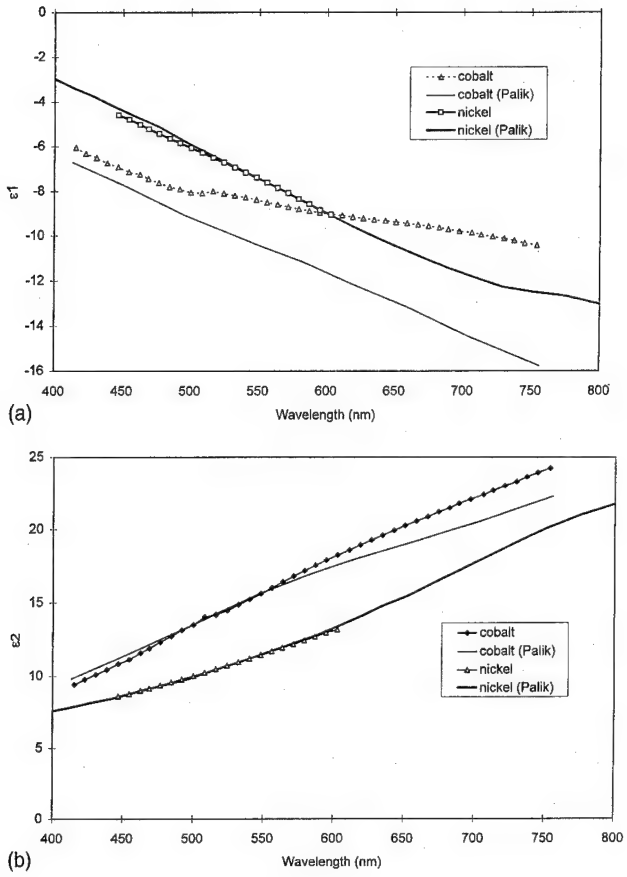

FIG. 1. (a) and (b): Comparison of optical constants determined from *in situ* spectroscopic ellipsometry and those from Palik. (Ref. 5).

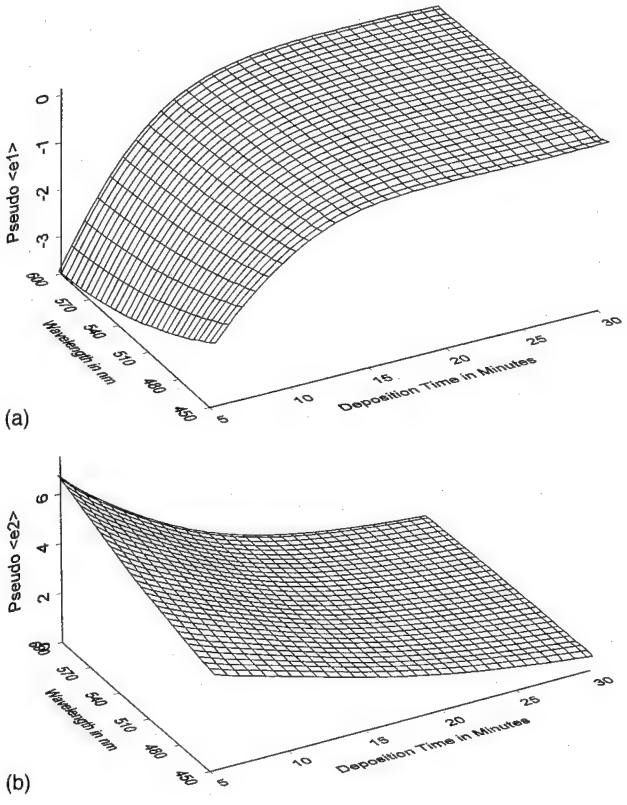

FIG. 2. (a) and (b): Pseudo-dielectric optical constants during the electrodeposition of a cobalt/nickel alloy thin film.

III. RESULTS

The optical constants and growth rates were determined from *in situ* spectroscopic ellipsometry measurements taken during the electrodeposition process. The optical constants for cobalt and nickel were in reasonable agreement with values from the literature, as shown in Fig. 1, with the differences for cobalt probably due to surface roughness.[5] A comparison between growth rates determined by *in situ* ellipsometry and coulometric calculations was also in good agreement.[6]

Ex situ spectroscopic ellipsometry measurements on the optically thick cobalt/nickel alloys showed a basic trend of increasing ϵ_1 and decreasing ϵ_2 as the cobalt ion concentration, X, was increased. The pseudo-dielectric constants from *in situ* ellipsometry for one of the cobalt/nickel alloys are shown in Fig. 2. The film is optically thick after 5 min of deposition (time period shown), yet the dielectric constants continue to change with time. A roughness layer from effective medium theory was able to account for the changes during the early stages of film growth, but failed as the films continued to roughen. The *in situ* evidence that the films were roughening with increasing thickness was confirmed by *ex situ* interference microscope measurements. Alloys of cobalt/nickel deposited to the same final thickness were found to have increasing roughness with increasing cobalt concentration. Therefore, in order to predict the optical response of these electrodeposited materials, care must be given to provide the correct optical model. Further calculations using a model without the inclusion of surface roughness would give incorrect results for magneto-optic constants. If the thickness is to be optimized, the theoretical calculations would have to consider the time dependent change in thin-film optical properties during the growth which would give rise to a different optical and magneto-optic response for different thin-film thicknesses.

Lashmore *et al.*, have investigated electrodeposited copper/nickel multilayers for investigation of giant magne-

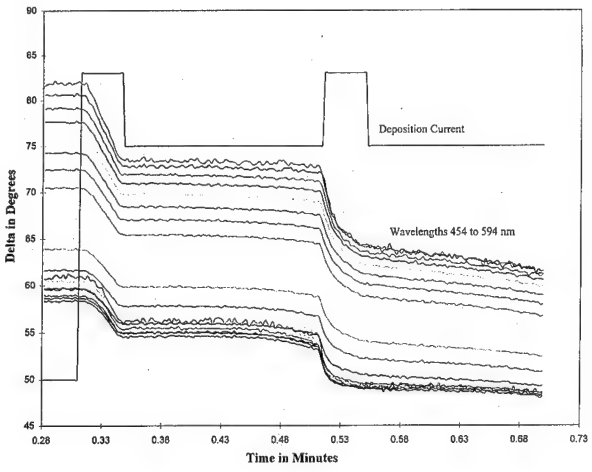

FIG. 3. *In situ* spectroscopic ellipsometry parameter (delta) during a copper/nickel multilayer electrodeposition.

toresistive effects.[7] We have used *in situ* spectroscopic ellipsometry to study the electrodeposition of similar multilayers. For example, the ellipsometric delta parameter during a copper/nickel multilayer deposition is shown in Fig. 3. The multilayers are deposited from the same solution by pulsing to different currents (also shown in Fig. 3).

IV. CONCLUSION

Electrodeposition is an interesting technique which allows the processing of magneto-optic materials. Both alloy and multilayer thin films have been formed with this technique. *In situ* spectroscopic ellipsometry allowed diagnostics of the electrodeposition process. The optical constants from ellipsometry are in good agreement with those from the literature, and will be needed to optimize any magneto-optic device structures.

Theoretical predictions of the polar Kerr effect in Fe and Co

J. M. MacLaren and W. Huang
Department of Physics, Tulane University, New Orleans, Louisiana 70118

We present theoretical calculations of the magneto-optic polar Kerr effect in bcc iron, fcc cobalt, and hcp cobalt. The Kerr angle and ellipticity are derived from the optical conductivity tensor, which is computed using wave functions obtained from full potential local spin-density electronic structure calculations. Predicted Kerr angles and ellipticities are computed as a function of magnetization direction. In the case of iron, the calculated Kerr spectra are found to be in good agreement with experimental results and previous calculations. However, in the case of cobalt, the results of previous theoretical studies differ significantly. Our results are in close agreement with experiment and with one of these previous theoretical studies. © *1996 American Institute of Physics.* [S0021-8979(96)13408-9]

The rotation of plane polarized light upon reflection from a magnetic surface, the magneto-optic Kerr effect, has been studied extensively experimentally because of applications in optical data storage.[1,2] In this technology, a large magneto-optic Kerr effect at short wavelengths is desired in order to achieve projected aerial storage densities. Co/Pt and Co/Pd superlattices have been the focus of much research since these materials exhibit large Kerr rotations and the prerequisite perpendicular magnetic anisotropy.[3] In order for electronic structure calculations to be useful in the design of novel magneto-optic materials, they should demonstrate accuracy in simpler systems such as the $3D$ transition metals. There have been several recent theoretical studies of the Kerr effect in Fe and Co, including one which considered the influence of magnetization direction.[4–6] All of the calculated Kerr spectra for Fe are in good agreement with each other and with experiment. However, in the case of Co, there are significant differences between the various calculations.

The magneto-optic Kerr effect is a consequence of an asymmetry in the refractive indices for left- and right-handed circularly polarized light which results from the combined effects of spin polarization and the spin-orbit interaction. In the technologically important polar Kerr effect, both wave vector and magnetization are perpendicular to the surface. A straightforward analysis starting from the Fresnel relations for reflection from a surface leads to the following expression for the complex Kerr angle:

$$\Theta_k = \frac{-\sigma_{xy}}{\sigma_{xx}\sqrt{1+i(4\pi/\omega)\sigma_{xx}}} \tag{1}$$

in terms of the elements of the optical conductivity tensor ($\sigma_{\alpha\beta}$).

An expression for the optical conductivity tensor at frequency ω in a periodic solid, derived from linear response theory, was given by Wang and Callaway[7]

$$\sigma_{\alpha\beta}(\omega) = \frac{ie^2}{m^2\hbar\Omega}\int d^3k \sum_{\ell\sigma}{}' \sum_{\ell'\sigma'}{}'' \frac{1}{\omega_{\ell'\sigma',\ell\sigma}(\mathbf{k})} \times\left(\frac{\Pi^{\alpha}_{\ell\sigma,\ell'\sigma'}(\mathbf{k})\Pi^{\beta}_{\ell'\sigma',\ell\sigma}(\mathbf{k})}{(\omega-\omega_{\ell'\sigma',\ell\sigma}(\mathbf{k})+i\delta)} + \frac{\Pi^{\beta}_{\ell\sigma,\ell'\sigma'}(\mathbf{k})\Pi^{\alpha}_{\ell'\sigma',\ell\sigma}(\mathbf{k})}{(\omega+\omega_{\ell'\sigma',\ell\sigma}(\mathbf{k})+i\delta)}\right), \tag{2}$$

where e and m are the electronic charge and mass, $\hbar$ Planck's constant, Ω the unit cell volume, and $\delta=1/\tau$, where τ is the relaxation time. The integral is over the Brillouin zone. The primed (double primed) summations are over occupied (unoccupied) electronic states. $\hbar\omega_{\ell'\sigma',\ell\sigma}(\mathbf{k})$ is the energy difference, $E_{\ell'\sigma'}(\mathbf{k}) - E_{\ell\sigma}(\mathbf{k})$, between two eigenstates labeled by band index ℓ and spin σ. The matrix elements of the momentum operator $\Pi^{\alpha}_{\ell\sigma,\ell'\sigma'}(\mathbf{k})$ are given by

$$\Pi^{\alpha}_{\ell\sigma,\ell'\sigma'}(\mathbf{k}) = \int d\mathbf{r}\psi^{*}_{\ell\sigma\mathbf{k}}(\mathbf{r})\left(-i\hbar\frac{\partial}{\partial x_\alpha} + \frac{\hbar}{4mc^2} \times[\sigma\times\nabla V(\mathbf{r})]_\alpha\right)\psi_{\ell'\sigma'\mathbf{k}}(\mathbf{r}). \tag{3}$$

In the calculations presented in this article, the spin-flip term $\hbar/4mc^2[\sigma\times\nabla V(\mathbf{r})]$, given in terms of the Pauli matrices σ and one-electron potential $V(\mathbf{r})$, is neglected. In addition to the interband conductivity, an intraband Drude term is added

$$\sigma_{\alpha\beta}(\omega) = \frac{\sigma_0}{1-i\omega\tau_D}\delta_{\alpha\beta}. \tag{4}$$

The Drude parameters σ_0 and τ_D were taken from the work of Lenham and Treherne.[8] The Drude term is only significant for photon energies less than about 1 eV, and thus has little effect on the Kerr angle in the technologically interesting range of 3–4 eV. In evaluating $\sigma_{\alpha\beta}(\omega)$ using Eq. (2), we have followed the approach suggested by Oppeneer *et al.*, namely to keep a finite value of δ which we choose to be 0.03 Ry. The other common approach is to evaluate in the sharp limit $\delta\to 0$ and use Kramers–Kronig relations to reconstruct the full conductivity tensor.[6]

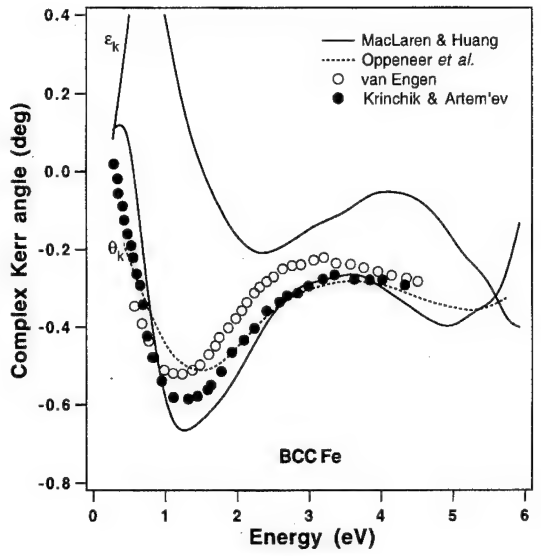

FIG. 1. Kerr angle and ellipticity for bcc Fe. Theoretical data shown are as follows: solid line, this work, dashed line (Refs. 4 and 5). Experimental data shown are open circles (Ref. 15), filled circles (Ref. 14).

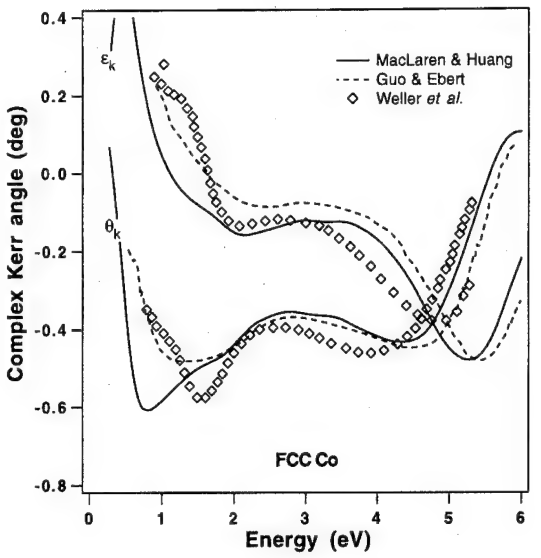

FIG. 2. Kerr angle and ellipticity for fcc Co. Theoretical data shown are as follows: solid line, this work, long dashed line (Ref. 6). Experimental data shown are open diamonds (Ref. 17).

The Bloch states $\psi_{\ell\sigma\mathbf{k}}(\mathbf{r})$ and energy eigenvalues $E_{\ell\sigma}(\mathbf{k})$ are found within the local spin-density approximation using a full potential linearized augmented Slater orbital method (FLASTO). This electronic structure method has been described in detail in other references.[9] Briefly, the method partitions space in muffin-tin spheres and an interstitial region. Within the muffin-tin spheres, the Bloch wave functions are expanded in linear combinations of ϕ and $\dot{\phi}$ (ϕ is a radial solution to the Schrödinger equation at a fixed energy and angular momentum, and $\dot{\phi}$ its energy derivative), while in the interstitial a linear combination of Slater-type orbitals is formed. In our calculations we used 25 Slater-type orbitals per atom. These were chosen to be the $4s$, $3p$, $3d$, $4f$, $4p$, $4d$, and $5s$ functions. This basis has sufficient variational freedom to yield answers in close agreement with the full-potential linearized augmented plane wave method,[10] but with a significantly smaller matrix size. The exponential decay constant were calculated using the formula given by Davenport.[9] A further benefit of this method is that the matrix elements can be evaluated over the unit cell exactly. In calculations which use the muffin-tin or atomic sphere approximations, the contribution to the matrix elements from the interstitial region is difficult to evaluate, and care must be taken in dealing with the integrals over this region. In the FLASTO approach, the wave function in the interstitial is completely described by its Fourier transform. The matrix elements of the gradient operator are easily evaluated between plane wave states for this region. Within the spheres, matrix elements of gradient operator can be derived from the theory of angular momentum.[11] Details about our technique will be the subject of a forthcoming article.[12] Once self-consistent electronic potentials have been obtained, the wave functions and eigenvalues in the presence of the spin-orbit interaction are formed by diagonalizing the Hamiltonian using the spin-orbitless wave functions as basis functions[13] (the so-called second variation method). Since the spin-orbit perturbation is small, the resulting solutions are sufficiently accurate for conductivity calculations. The spin-orbit interaction lowers the symmetry of the crystal, thus all inequivalent wedges of the Brillouin zone must be sampled.

The Kerr angle and ellipticity for bcc Fe is shown in Fig. 1. As can be seen from this figure, the predictions of the FLASTO calculations are in agreement with those of Oppeneer *et al.*[4,5] and with two experimental studies, one by Krinchik and Artem'ev[14] and the other by van Engen.[15] These calculations assumed the magnetization direction to be

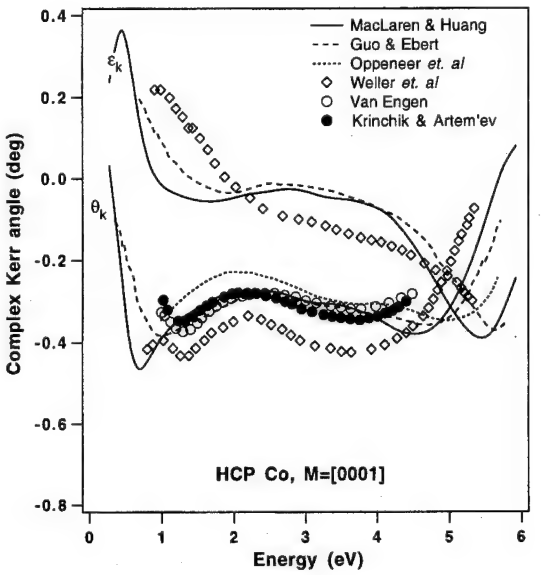

FIG. 3. Kerr angle and ellipticity for hcp Co with the magnetization along the [0001] direction. Theoretical data shown are as follows: solid line, this work, long dashed line (Ref. 6), dashed line *et al.* (Refs. 4 and 5). Experimental data shown are open diamonds (Ref. 17), open circles (Ref. 16), filled circles (Ref. 14).

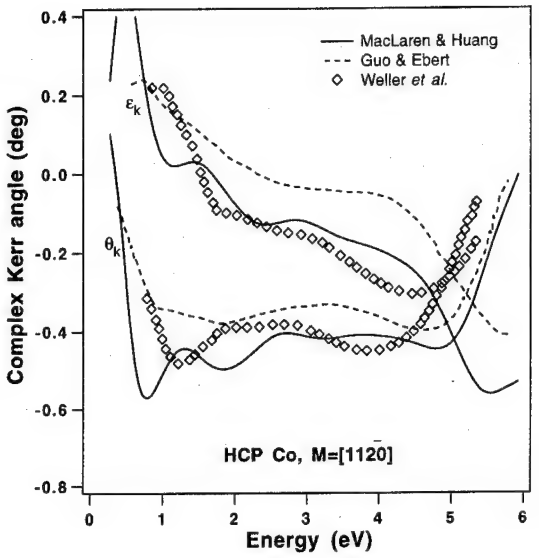

FIG. 4. Kerr angle and ellipticity for hcp Co with the magnetization along the [11$\bar{2}$0] direction. Theoretical data shown are as follows: solid line, this work, long dashed line (Ref. 6). Experimental data shown are open diamonds (Ref. 17).

along the [001] direction. The complex Kerr angle is found to be insensitive to magnetization direction, reflecting the cubic symmetry of the bcc lattice. The anisotropy of the Kerr spectra was discussed by Weller *et al.*[17] These authors concluded that in a cubic lattice the anisotropy in Kerr angle is fourth order in the strength of the spin-orbit coupling, while for an hcp crystal, because of the hexagonal symmetry, the anisotropy should be second order in the spin-orbit coupling strength. Figure 2 shows the Kerr angle and ellipticity for fcc cobalt. Agreement between Guo and Ebert's fully relativistic LMTO calculations,[6] the FLASTO results, and the experimental results for thin-film fcc Co[17] is pretty good. Figures 3 and 4 show the Kerr angle and ellipticity of hcp Co with the magnetization direction along the [0001] and [11$\bar{2}$0] directions, respectively. The anisotropy in the Kerr signal seen experimentally is reproduced in these and Guo and Ebert's calculations.[6] In the case where the magnetization lies along [0001], we see that the FLASTO spectra, and those calculated by Guo and Ebert, agree better with experimental data taken from bulk crystals[14,16] rather than the thin-film data of Weller *et al.*,[17] suggesting that there is some sensitivity to sample preparation. Also, these two calculations are somewhat closer to experiment than either those of Oppeneer *et al.*,[4,5] or those of Gasche.[18] The positions of the minima in the calculated ellipticity and Kerr angle are shifted slightly to higher energy, relecting errors associated with using wave functions obtained from a local spin-density band structure calculation to describe excited states.

In conclusion, we have calculated the Kerr angle and ellipticity for bcc iron, fcc cobalt, and hcp cobalt using the interband conductivity tensor computed from local spin-density band structure calculations. Our approach avoids some of the complications in evaluating matrix elements found in previous studies. The use of calculated ground state wave functions to describe excited states appears to be a good approximation in these metals, at least for energies less than about 6 eV. The level of agreement between theory and experiment is good enough to suggest that this type of calculation is suitable for making predictions of magneto-optical effects in other materials, and work on various Co/Pd and Co/Pt superlattices is in progress.

First principles calculations of the Kerr effect in MnBi, MnSb, and Mn_2BiSb (abstract)

W. Huang and J. M. MacLaren
Department of Physics, Tulane University, New Orleans, Louisiana 70118

R. H. Victora
Eastman Kodak Company, Rochester, New York 14650-2017

First principles electronic structure calculations are used to predict the energy dependence of the polar Kerr effect in MnBi, MnSb, and a Mn_2BiSb alloy. The compounds all have respectable Kerr angles and thus are potential data storage media. The technique used in this work is a full-potential linearized augmented Slater orbital approach. The Kerr angle is obtained from the conductivity tensor that is calculated, within linear response theory, using the Kubo formula. There are several desirable features in this approach. First, unlike methods based upon muffin-tin potentials, open crystal structures present no problems. Second, since the electronic wave functions are defined over the crystal unit cell rather than over space filling overlapping spheres, difficulties in handling the interstitial part of the required matrix elements are avoided. Finally, the small basis set (25 orbitals per atom) leads to reasonable computational times. Results of these calculations show that the Kerr angle in MnBi is above 1° at 1.6 eV and that its variation over 2–4 eV is linear and decreasing. MnSb shows a smaller rotation, about 0.5°, that is almost constant up to 3 eV and then also decreases linearly. The Kerr rotation of Mn_2BiSb is approximately the average of MnBi and MnSb.

Dielectric tensor characterization of $Mn_{0.53}Bi_{0.47}$ and $Mn_{0.52}Bi_{0.44}Sb_{0.04}$ films

Z. Celinski[a] and Zheng Yan
Optical Sciences Center, University of Arizona, Tucson, Arizona 85721

We have grown $Mn_{0.53}Bi_{0.47}$ and $Mn_{0.52}Bi_{0.44}Sb_{0.04}$ alloy films on glass substrates under UHV conditions. These films exhibit good magneto-optical (MO) properties. Unfortunately, the measurements of Kerr rotation and ellipticity cannot by themselves provide reliable evaluation of the MO properties of a layer capped with a dielectric SiO film. The purpose of the present work was to determine the dielectric tensor in the $MnBi_{1-x}Sb_x$ films within a multilayer stack, using a combination of ellipsometric, reflection/transmission, and polar MO Kerr effect measurements in the wavelength range of 360–860 nm. We have evaluated the $Mn_{0.53}Bi_{0.47}$ and $Mn_{0.52}Bi_{0.44}Sb_{0.04}$ films based on the intrinsic MO figure of merit (FOM) defined by $\mathrm{FOM}=|\epsilon_{xy}|/(2\ \mathrm{Im}\ \epsilon_{xx})$, where ϵ_{xy} and ϵ_{xx} are the diagonal and off-diagonal elements of the dielectric tensor of the MO material. For short wavelengths (360–550 nm) the measured FOM in the $Mn_{0.53}Bi_{0.47}$ and $Mn_{0.52}Bi_{0.44}Sb_{0.04}$ films is significantly larger (≥factor of 2) than that commonly observed in TbFeCo films (~0.01).
 [S0021-8979(96)13508-5]

For quite some time, MnBi films have attracted considerable attention as a possible high-density magneto-optical (MO) media.[1] The large Kerr rotation and perpendicular anisotropy have maintained the interest in this material among physicists despite its severe problem, lack of thermodynamical stability. Two phases of MnBi exist, a low-temperature phase (LTP) and high-temperature phase (HTP), which exhibit different MO response. During thermomagnetic writing the HTP phase is quenched and causes a rapid reduction of MO signal. One of the approaches to stabilize the low-temperature phase of MnBi, a phase which exhibits very good MO response, was to substitute a fraction of the Bi atoms with Sb atoms.[2–4]

The aim of the present article is to determine the diagonal and off-diagonal elements of the dielectric tensor for the $Mn_{0.53}Bi_{0.47}$ and $Mn_{0.52}Bi_{0.44}Sb_{0.04}$ films and evaluate the figure of merit (FOM) of these MO layers. To determine the elements of the dielectric tensor of a MO film one must measure thickness and optical constants for all the layers within the structure. To do this, we have performed ellipsometric, reflectance, and polar MO Kerr effect measurements, and analyzed the data using the MULTILAYER computer program. Detailed descriptions of apparatus, measurement procedures, and the computer program can be found in the article by Hong Fu *et al.*[5]

To evaluate the performance of any MO media one should use parameters which do not depend upon the geometry of the studied structures. The intrinsic FOM, introduced for the first time by Mansuripur,[6] provides the best way to compare different media. The FOM, which is solely determined by the dielectric tensor of the MO material, is given by

$$\mathrm{FOM}=\frac{|\epsilon_{xy}|}{2\ \mathrm{Im}\ \epsilon_{xx}}.$$

Frequently, the off-diagonal reflectivity, r_{xy}, has been used in the literature to describe the efficiency of a sample in rotating polarization. The incident, linearly polarized beam has only an x component and the reflected beam has both x and y components. The absolute value of the off-diagonal reflectivity is defined by ratio $|E_y^{\mathrm{ref}}/E_x^{\mathrm{inc}}|$, where E_y^{ref} and E_x^{inc} are the E-field amplitudes of the y component of the reflected light and the x component of the incident light, respectively. The measurements of Kerr rotation Θ_k, ellipticity ϵ_k, and total reflectivity $\mathbf{R}$ can be used to calculate the absolute value of the off-diagonal reflectivity from the following formula:[7]

$$|\mathbf{r}_{xy}|=\sqrt{R(\Theta_k^2+\epsilon_k^2)}.$$

Since values of Θ_k, ϵ_k, and $\mathbf{R}$ strongly depend on the thicknesses of the layers in the studied structure, the value of $|\mathbf{r}_{xy}|$ for the same MO layer may vary significantly. It can be shown,[6] however, that $|\mathbf{r}_{xy}|$ is upper bounded by the FOM. In addition, it is possible to design a structure for which $|\mathbf{r}_{xy}|$ approaches the FOM of the MO material. For these reasons, we will quote both $|\mathbf{r}_{xy}|$ and FOM in our article.

We grew our samples on glass (Corning 7059) substrates under UHV conditions. Sample preparation and systematic studies of the structural, magnetic, and magneto-optical properties of the $MnBi_{1-x}Sb_x$ films have been recently reported elsewhere by Celinski *et al.*[4] The substitution of Bi atoms by Sb does not improve the thermal stability of these MnBi based layers. To avoid ambiguities during analysis of optical measurement data we also grew a single layer of SiO on glass and determined its optical constants independently.

Utilizing a multiwavelength variable-angle ellipsometer we measured the polarization rotation and ellipticity as a function of incident angle Θ_{inc} for linearly polarized light with wavelengths λ within the range 360–860 nm. The measurements of total reflectance R, Θ_k, and ϵ_k at normal incidence were carried out on a MO Kerr spectrometer. All measurements were taken from the film side. The thickness and diagonal elements ϵ_{xx} of the various layers were determined by using the ellipsometric and total reflectance R data. Off-diagonal elements, ϵ_{xy}, were determined by using Kerr effect and ellipsometric data.

Table I shows results of our analysis of the dielectric tensor elements for both MO layers, $Mn_{0.53}Bi_{0.47}$ and $Mn_{0.52}Bi_{0.44}Sb_{0.04}$. We estimated that the error associated with our analysis does not exceed 5%. The quality of our analysis can be assessed by analyzing Fig. 1 which shows a typical set of ellipsometric data. The open and solid symbols represent rotation and ellipticity, respectively, as a function of incident angle for 400 nm wavelength. The solid lines depict the best theoretical fit to this data. In order to obtain such a good fit at short wavelengths values of n and k for the SiO layer had to be slightly modified from those obtained for a SiO layer grown on glass. Table I also contains the n and k values for the SiO layer grown on top of $Mn_{0.53}Bi_{0.47}$ film.

From our measurements we determined that the $Mn_{0.53}Bi_{0.47}$ film was 70 nm thick and the SiO layer was 65 nm thick. These results are in good agreement with values obtained from the thickness monitor during deposition. The Kerr hysteresis loops are fairly squared with a coercive field of 840 Oe (see inset in Fig. 2). Figure 2 shows the wavelength dependence of the Kerr rotation and ellipticity. The observed extrema in Θ_k and ϵ_k, at 600 nm, are related to the interference effect due to the SiO overcoating. As expected, we observed a significant decrease in total reflectivity R at this wavelength. For a wavelength of 400 nm, far from the interference condition, the Kerr rotation and ellipticity still have significantly high values, 0.9° and 0.35°, respectively, indicating good MO response at short wavelength. Figure 3 shows the wavelength dependence of n and k for $Mn_{0.53}Bi_{0.47}$ film. The lines were added to guide the reader's eye. Our values of n and k are comparable with those previously reported in the literature.[5] Figure 4 shows the calculated FOM and off diagonal reflectivity, $\mathbf{r}_{xy}$, as a function of the wavelength for $Mn_{0.53}Bi_{0.47}$ film. Determined values of FOM are smaller than those previously reported.[5] This indicates that measured parameters, such as FOM, are not universal for a given compound but strongly depend on the growth conditions, procedure, and small changes in stoichiometry for the MnBi based compounds.

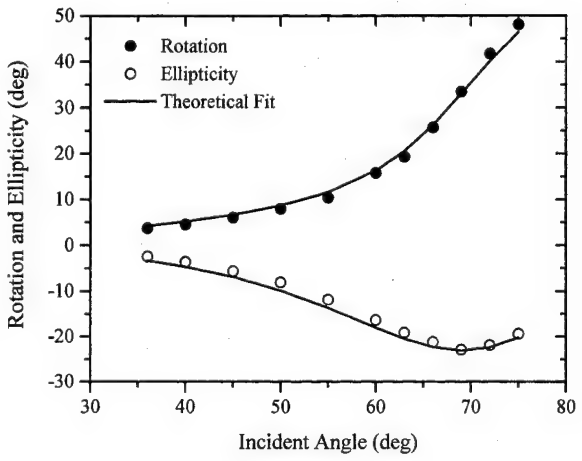

FIG. 1. Measured rotation and ellipticity, open and solid circles, respectively, as a function of incident angle Θ_{inc} at 400 nm wavelength for the $Mn_{0.53}Bi_{0.47}$ sample. The solid lines represent the best fit.

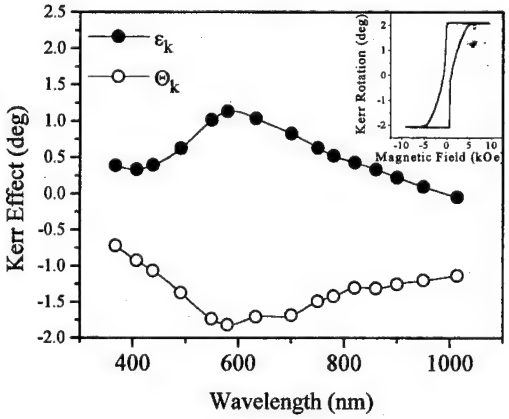

FIG. 2. Measured Kerr rotation Θ_k and ellipticity ϵ_k, open and solid circles, respectively, as a function of wavelength for the $Mn_{0.53}Bi_{0.47}$ sample. The solid lines were added to guide the reader's eye. Measurements were performed from the film side.

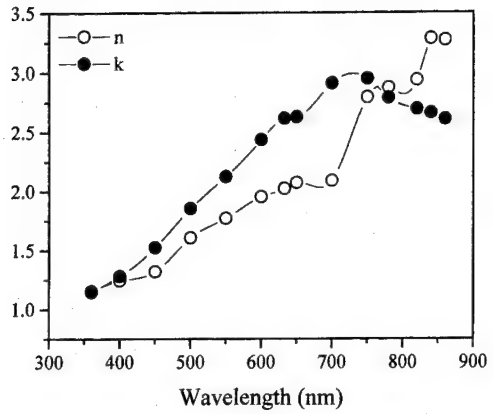

FIG. 3. The best estimate values of n and k as a function of wavelength for the $Mn_{0.53}Bi_{0.47}$ sample.

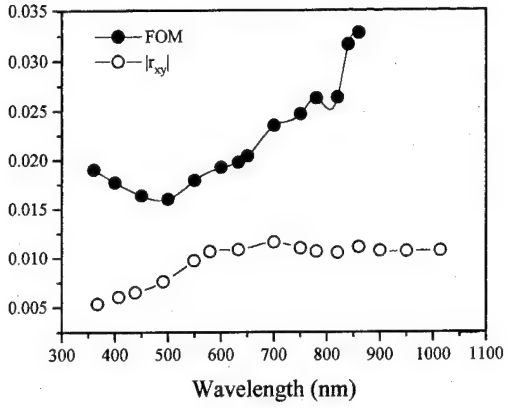

FIG. 4. Measured $|r_{xy}|$ (solid symbols) and the computed FOM (open symbols) for the $Mn_{0.53}Bi_{0.47}$ sample as a function of wavelength.

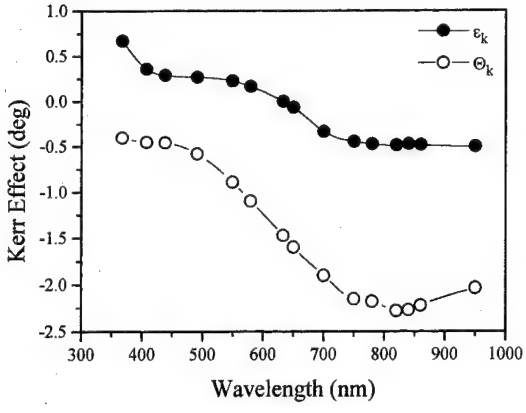

FIG. 5. Measured Kerr rotation Θ_k and ellipticity ϵ_k, open and solid circles, respectively, as a function of wavelength for the $Mn_{0.52}Bi_{0.44}Sb_{0.04}$ sample. The solid lines were added to guide the reader's eye. Measurements were performed from the film side.

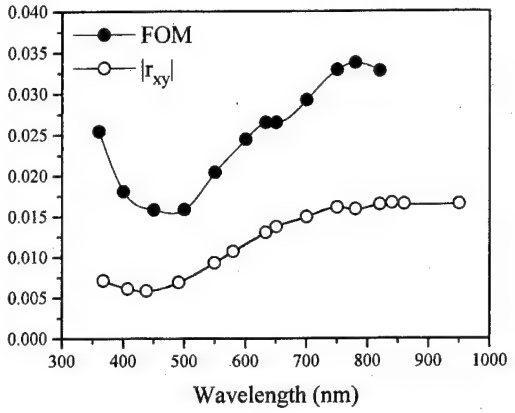

FIG. 6. Measured $|r_{xy}|$ (solid symbols) and the computed FOM (open symbols) for the $Mn_{0.52}Bi_{0.44}Sb_{0.04}$ sample as a function of wavelength.

Our $Mn_{0.52}Bi_{0.44}Sb_{0.04}$ film was also 70 nm thick, capped with a 95 nm SiO layer. The Kerr hysteresis loops are fairly square with a coercive field of 3 kOe. Figure 5 shows the wavelength dependence of Θ_k, and ϵ_k. The observed extreme in Kerr rotation at 800 nm is again related to the interference effect due to SiO overcoating (the total reflectivity also shows a broad minimum at this wavelength). At short wavelengths, the measured values of the Kerr rotation and ellipticity, $-0.4°$ and $0.67°$, respectively, indicate again a good MO response in this material. The determined values of n and k for the $Mn_{0.52}Bi_{0.44}Sb_{0.04}$ film are very similar to that observed for $Mn_{0.53}Bi_{0.47}$ film. This indicates that the presence of Sb atoms does not modify the values of n and k. Figure 6 shows the FOM as a function of wavelength for the $Mn_{0.52}Bi_{0.44}Sb_{0.04}$ film. Only for a narrow range, between 400 to 500 nm, the determined values of FOM are equal to those determined for $Mn_{0.53}Bi_{0.47}$. For all other wavelengths the values of FOM are 25% larger than these determined for $Mn_{0.53}Bi_{0.47}$. At 360 nm, the FOM for $Mn_{0.52}Bi_{0.44}Sb_{0.04}$ is equal to 0.025, more than twice the value observed for TbFeCo, which is currently used for MO recording. This would make our films a good candidate for future MO data storage medium if the thermodynamic stability problem could be solved in MnBi based layers.

Influence of Al capping layers on growth, topography, and magnetic properties on MnBi thin films

U. Rüdiger, P. Fumagalli, P. Dworak, A. Schirmeisen, and G. Güntherodt
Physikalisches Institut, RWTH Aachen, D-52056 Aachen, Germany

Bi/Mn bilayers have been deposited on fused-quartz substrates at room temperature and annealed at elevated temperatures of 300–380 °C. To investigate the influence of capping layers on MnBi crystallite size and magnetic properties, some of the Bi/Mn bilayers were protected by Al and SiO_x layers. The coercive fields of the resulting MnBi films without a protective layer reach values of up to 1.25 T. In case of depositing an Al capping layers prior to annealing, the coercive fields are decreasing strongly showing coercive fields in the range of 0.6 T. In contrast, using SiO_x as a capping layer, the Kerr hysteresis loops show a nonlinearity near the coercive field indicating an inhomogeneous film. The change in the coercive field is explained by the influence of capping layers on the MnBi crystallite size during annealing. © *1996 American Institute of Physics.* [S0021-8979(96)28208-9]

INTRODUCTION

As demonstrated in previous work, the crystallite size of MnBi films depends on film thickness, i.e., the number x of deposited $(Bi/Mn)_x$ bilayers.[1] An increasing number of Bi/Mn sequences is accompanied by an increase in MnBi crystallite size after annealing. The preparation of MnBi films deposited without any protective layer on the Bi/Mn sequences causes smaller particle size as compared to films with an SiO_x capping layer[2,3] since the growth of single MnBi particles is not restricted in the direction perpendicular to the surface. Due to the small crystallite size unusual high coercive fields, H_c, of values up to 1.25 T were measured. In case of single domain particles H_c achieves high values limited only by the intrinsic anisotropy energy.[4] As the number of Bi/Mn bilayers increases from one to three the reflectivity of the resulting MnBi films decreases from 42% down to 5%.[1] In order to reduce the MnBi crystallite size in thicker films, Bi/Mn bilayers were separated by an Al interlayer from each other.[5] Due to the Al interlayer the reflectivity of MnBi films consisting of two Bi/Mn bilayers could be maintained at 38%.[5] By separating two Bi/Mn bilayers with an Al interlayer, polar Kerr hysteresis-loop measurements show a superposition of two hysteresis loops with different coercive fields. The presence of two different coercive fields could be explained by different granularities of the top and the bottom layer.[5] In this work, we study the influence of Al or SiO_x capping layers on growth and magnetic properties of a single Mn/Bi bilayer.

EXPERIMENTAL METHODS

The preparation of MnBi thin films was performed according to the method described elsewhere.[1,5,6] By thermal evaporation of Bi and Mn using Al_2O_3 crucibles Bi/Mn bilayers have been deposited on clean fused-quartz substrates at room temperature. In order to get MnBi films close to the optimum stoichiometry of $Mn_{55}Bi_{45}$ as reported by Di *et al.*,[7] the thickness of the Bi and Mn layer is adjusted to a constant value of 18 nm and 12 nm, respectively. A 2 nm thick Al capping layer is deposited in the same way as the Bi and Mn layers whereas a 50 nm SiO_x capping layer is deposited by electron-beam evaporation of SiO crystals using a Leybold ESV2. The vacuum during deposition varied between 8×10^{-7} mbar and 5×10^{-6} mbar. Film thickness and deposition rate were controlled by an Inficon thickness monitor. In order to obtain c axis oriented MnBi films after annealing, the Bi-deposition rate has to be lower than 0.4 nm/s. In contrast, the Mn-deposition rate is five times larger. The Bi/Mn and Bi/Mn/capping-layer sandwiches were annealed *ex situ* in a quartz tube for 60 min at a temperature of 300 °C and for 30 min at a temperature of 380 °C followed by a 30 min annealing step at lower temperature down to 300 °C, respectively. The films were characterized by x-ray diffraction analysis (XRD), scanning electron microscopy (SEM) and energy-dispersive x-ray analysis (EDX). The coercive field, H_c, was determined by polar Kerr hysteresis-loop measurements at a photon energy of 2.0 eV at room temperature.[1,5]

RESULTS AND DISCUSSION

Preparation and characterization

To control the c-axis orientation of the Bi layer before and the quality of the alloying process of the MnBi films after annealing x-ray measurements have been carried out. Figure 1(a) shows clearly the Bi(000l) peaks, which demonstrate that a Bi layer is highly textured with c axis perpendicular to the film surface, a condition necessary for maintaining the same orientation after annealing.[8] Peaks due to the substrate holder, made of brass, are labeled with an asterisk. Figures 1(b)–1(d) show x-ray pattern after annealing of MnBi films without a protective capping layer, with an Al and a SiO_x capping layer, respectively. The x-ray pattern of MnBi films without and with an Al capping layer are dominated only by the MnBi(000l) peaks [see Figs. 1(b) and 1(c)]. The MnBi films exhibit NiAs-type structure. The formation of an additional MnAl τ phase as reported by Shen can be excluded.[9] In case of depositing a SiO_x protective layer, $Mn_3O_4(h00)$ peaks appear which have intensities of same order of magnitude as the MnBi(000l) peaks [see Fig. 1(d)]. The exclusive presence of $Mn_3O_4(h00)$ peaks indicates an a-axis orientation of the oxide layer. At room temperature Mn_3O_4 exhibits a distorted spinel structure.[10,11]

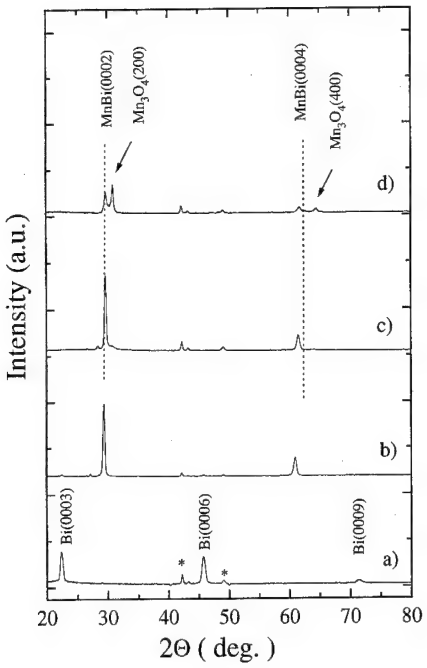

FIG. 1. X-ray analysis of MnBi films (a) before annealing and after annealing, (b) without a capping layer, (c) with an Al capping layer, and (d) with a SiO_x capping layer.

Figures 2(a) and 2(b) show MnBi films after annealing without a protective layer and with an Al capping layer of 2.0 nm thickness, respectively. The topography of the MnBi film with an Al capping layer is smoother than without. The 2.0 nm Al layer covers the MnBi film completely. Nevertheless, it cannot be excluded that a part of the Al diffuse into the bottom MnBi layer during annealing.[5]

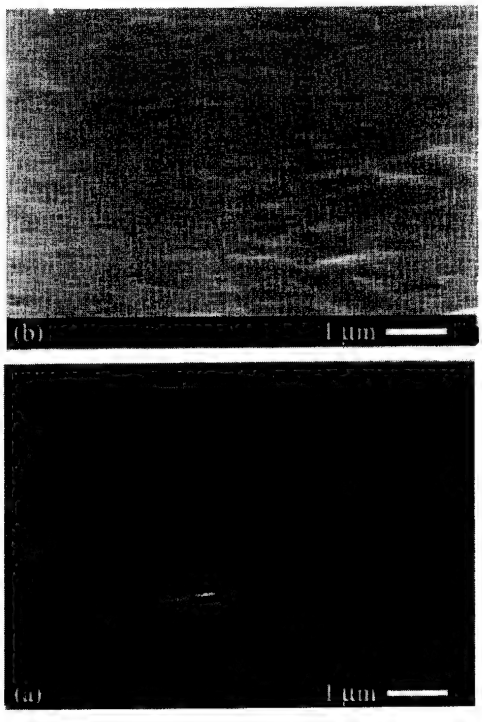

FIG. 2. Topography after annealing of MnBi films (a) without a capping layer, and (b) with an Al capping layer.

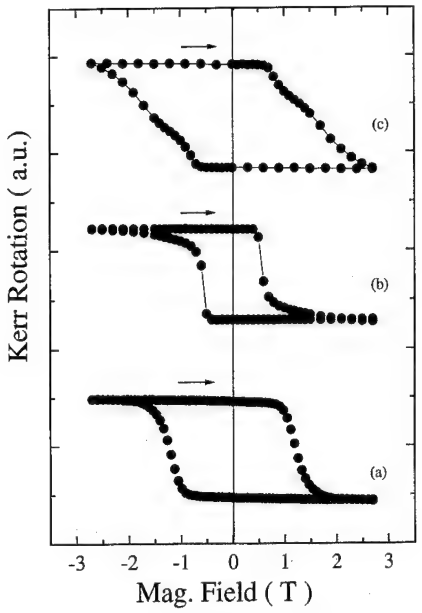

FIG. 3. Polar Kerr hysteresis loops of MnBi films (a) without a capping layer, (b) with an Al capping layer, and (c) with a SiO_x capping layer.

Magnetic properties

For single domain particles, the coercive field, H_c, is limited only by the intrinsic anisotropy energy and decreases linearly as the diameter d of the single domain particles increases.[4] To investigate the influence of different capping layers on crystallite size and hence on the coercive field, polar Kerr hysteresis measurements have been carried out. Hysteresis loops of MnBi films (a) without a capping layer, (b) with an Al capping layer, and (c) with a SiO_x protective layer are plotted in Fig. 3. By covering MnBi films with a 2.0 nm Al capping layer, the coercive field is decreasing from 1.25 T to a value of only 0.6 T. This is in agreement with our previous analysis of Kerr hysteresis loops in MnBi/Al/MnBi multilayers.[5] The preparation of MnBi films with no protective layers on the Bi/Mn sequence causes a smaller particle size since the growth is not restricted in direction perpendicular to the substrate surface which reduces the lateral expansion of the crystallites.[5] In contrast, an Al capping layer reduces the growth perpendicular to the substrate surface which supports the lateral expansion of MnBi crystallites. The influence of an Al capping layer on the MnBi formation process is demonstrated in Figs. 4(a) and 4(b) schematically.

The effect of a SiO_x layer [Fig. 3(c)] is in apparent contradiction with previous literature.[2,3] At a field of 0.7 T, the reversal of magnetization starts but proceeds slowly with increasing field leading to coercive fields of up to 1.5 T. The shape of the hysteresis loop differs from square hysteresis loops of MnBi films without and with an Al capping layer shown in Figs. 3(a) and 3(b), respectively.

An explanation of the unusual hysteresis loops takes into account the close distance (≈20 cm) of the electron beam evaporator to the substrate holder. As a consequence, the

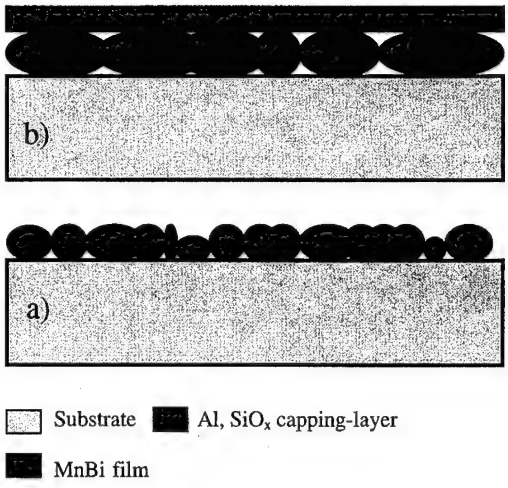

FIG. 4. Model of an annealed MnBi film, originating from a MnBi film (a) without a capping layer, and (b) with an Al or SiO_x capping layer.

SiO_x molecules may impinge onto the substrate at high kinetic energies. This might lead to a very rough Mn/SiO_x interface. After annealing the MnBi crystallite size might be considerably smaller in the interface region due to penetrated SiO_x molecules leading to local regions with increased coercive field.

CONCLUSION

The influence of Al and SiO_x capping layers on the crystallite size and on the coercive field of MnBi thin films has been investigated. An Al overlayer leads to a pronounced decrease in coercivity from 1.25 T down to 0.6 T. This is explained by a restricted perpendicular growth in conjunction with an extended lateral expansion of MnBi crystallites during annealing. Using SiO_x as a protective layer, leads to unusual Kerr hysteresis loops showing a nonlinear magnetization reversal in contrast to literature. This discrepancy is tentatively explained by the close proximity of the SiO target to the substrate holder. The SiO molecules impinge at high kinetic energies onto the substrate, yielding a very rough Mn/SiO interface influencing locally the MnBi formation process. As a result, local regions may form with smaller grain size and, therefore, increased coercivity.

Magnetic and magneto-optical properties of $Mn_xPt_{1-x-y}Zn_y$

Kurt W. Wierman and Roger D. Kirby
Behlen Laboratory of Physics and Center for Materials Research and Analysis, University of Nebraska, Lincoln, Nebraska 68588-0113

In this work we have prepared thin films of the ternary alloy $Mn_xPt_{1-x-y}Zn_y$ by magnetron sputtering onto quartz substrates. We have found a wide range of compositions which are strongly ferromagnetic at room temperature. A transition from a cubic to tetragonal phase with decreasing Pt content is confirmed by x-ray diffraction. X-ray diffraction measurements also show a strong (001) reflection consistent with long range order along the c axis for the tetragonal phase. These films show large complex Kerr rotations (up to 0.7°) in the visible spectrum. This combined with their anisotropic structure suggests that they may be suitable for magneto-optic data storage applications.

INTRODUCTION

The ordered alloys of M_xPt_{1-x} (M=Cr,Mn,Fe,Ni,Co) have received considerable attention because of their interesting magnetic and magneto-optic properties.[1–5] For $x=0.25$ these alloys form the $L1_2$ (Cu_3Au) cubic structure where the magnetic atoms occupy the cube corners and the Pt atoms the face-centered sites. As x increases from 0.25 there is a continuous change in lattice parameters and by $x=0.5$ the alloys develop the $L1_0$ (CuAu) tetragonal structure with alternating layers of M and Pt atoms along the (001) direction. This appears to result from the geometrical requirements of ordered packing of Pt and M atoms of different sizes and not from electron concentration or Brillouin zone effects, as discussed by Brun *et al.* for M=Mn.[2] Mn_xPt_{1-x} alloys are known to undergo a transition from the cubic to a tetragonal structure for $x>0.38$; unfortunately, the increased number of antiferromagnetic Mn-Mn nearest-neighbor interactions induces a complex noncollinear magnetic structure.[6,7] Kato *et al.*[8] initially observed large Kerr rotation and ellipticity in thin films of $MnPt_3$, but hysteresis loops showed an in-plane anisotropy concordant with its cubic structure. Our goal was to substitute a third nonmagnetic element into the Mn-Pt alloy to develop a ferromagnetic tetragonal structure. Thus, in this study ferromagnetic ternary alloys of $Mn_xPt_{1-x-y}Zn_y$ were produced over a wide composition range ($x=0.17$–0.29, $y=0.00$–0.13), and their magnetic and magneto-optic properties were studied.

EXPERIMENT

Mn/(Pt-Zn) multilayers were prepared by dc magnetron sputtering onto room-temperature fused quartz substrates. The base pressure of the sputtering chamber was 4×10^{-7} Torr and the argon sputtering pressure was 2 mTorr. For the series of samples discussed here Pt and Zn were co-sputtered with a layer thickness held constant at 7 Å, while the Mn layer thickness was varied from 3 to 5 Å to obtain the desired $Mn_xPt_{1-x-y}Zn_y$ composition ratios. The compositions of the as-deposited films were measured using x-ray fluorescence and found to be close to the nominal compositions. The total film thickness of each sample was 100 nm and each film was coated with a 100-nm-thick SiO_x protective overcoat. The as-deposited samples were subsequently annealed in vacuum (6×10^{-6} Torr) at 850 °C for 1 h to form the homogeneous crystalline $Mn_xPt_{1-x-y}Zn_y$ alloy.

The saturation magnetization M_s and coercivity H_c of the $Mn_xPt_{1-x-y}Zn_y$ films were measured at 300 K using an alternating gradient force magnetometer. The polar Kerr rotation and ellipticity spectra were measured in a 10 kOe applied field perpendicular to the film plane using a home-built system based on a photoelastic modulator. The Curie temperatures were obtained from Kerr rotation versus temperature measurements in an applied field of 7.1 kOe.

RESULTS AND DISCUSSION

Figure 1 shows the x-ray diffraction results for the annealed films of $Mn_{0.25}Pt_{0.75-y}Zn_y$ for several Zn concentrations. The splitting of the (110), (200), and (220) reflections shown in the $y=0.08$ sample indicates the formation of the tetragonal phase. The presence of the superlattice (001) peak is indicative of substantial long range order along the c axis. Figure 2 shows the a axis and c axis lattice parameters as a function of Pt concentration; for these data, x ranges from 0.17 to 0.29 and y ranges from 0.04 to 0.13. For concentrations greater than 69 at. % Pt the cubic phase with an average a-axis lattice parameter of 3.83 Å is present. This value is

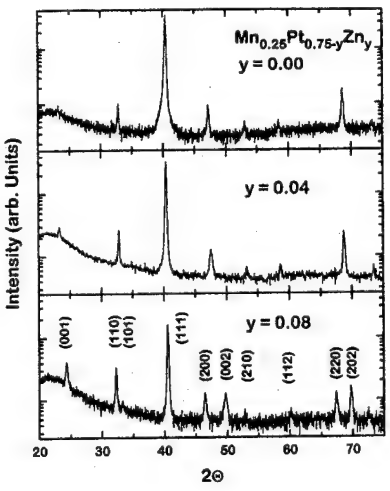

FIG. 1. X-ray diffraction results for $Mn_{0.25}Pt_{0.75-y}Zn_y$ with $y=0.00$, 0.04, and 0.08.

 0021-8979/96/79(8)/6206/3/$10.00

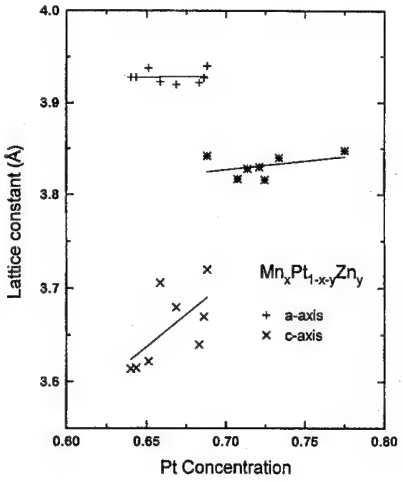

FIG. 2. Lattice parameters for varying Pt concentrations; x ranges from 0.17 to 0.29, y ranges from 0.04 to 0.13. The lines are drawn to aid the eye.

slightly smaller than the reported value of 3.89 Å for bulk $MnPt_3$.[9] Below 69 at. % Pt only the tetragonal phase is present with no indication of the cubic phase. The a-axis lattice parameter is 3.93 Å and is independent of Pt concentration, while the c-axis lattice parameter diminishes from 3.72 to 3.61 Å. At 69 at. % Pt the tetragonal and cubic structural phases co-exist indicating there is a narrow intermediate phase transition region as reported for bulk Mn_xPt_{1-x}.[7]

As Mn-Mn nearest-neighbor interactions are antiferromagnetic the largest possible magnetic moment in the $L1_2$ structure is obtained at Mn concentration of 25%.[7,10,11] For this reason the rest of this discussion will focus on samples with $x=0.25$. Figure 3(a) shows the room temperature in-plane hysteresis loops for $y=0.04$, 0.06, and 0.08. A comparison of the perpendicular (not shown) and in-plane hysteresis loops indicates that the easy axis is not strictly in the plane of the film. Figure 3(b) shows that the saturation magnetization (M_s) decreases with increasing Zn content. Figure 4 shows the Curie temperature (T_c) and coercivity (H_c) as functions of Zn concentration. The initial slope of T_c vs Zn content is nearly the same as the slope found for T_c vs Mn content in Mn_xPt_{1-x}.[10,11] This suggests that the increase of T_c in the two systems has the same origin. It may be due to an increase in macroscopic exchange stiffness between Mn atoms due to a larger number of Mn-Mn nearest-neighbor interactions. Note there is a decrease in the c-axis lattice parameter for higher levels of Zn content which may contrib-

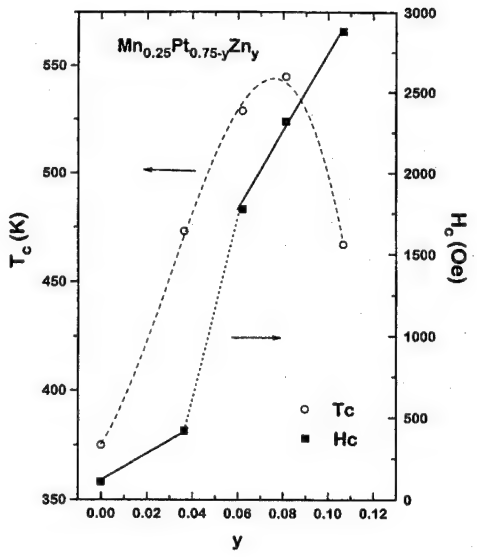

FIG. 4. T_c and H_c vs Zn concentration for $Mn_{0.25}Pt_{0.75-y}Zn_y$. The lines are drawn to aid the eye.

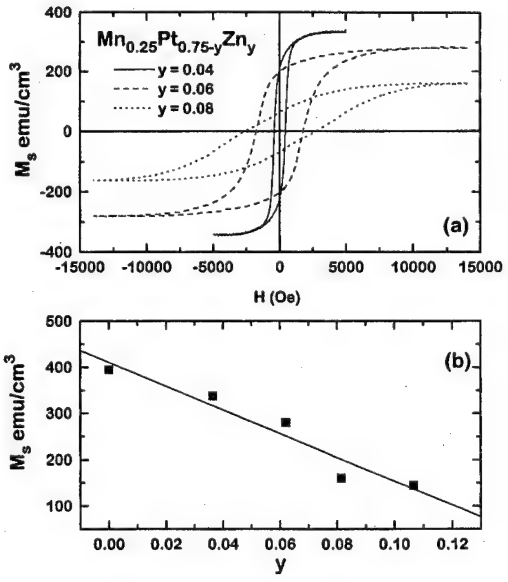

FIG. 3. (a) In-plane hysteresis loops for $Mn_{0.25}Pt_{0.75-y}Zn_y$. (b) M_s vs Zn concentration for $Mn_{0.25}Pt_{0.75-y}Zn_y$. The line is drawn to aid the eye.

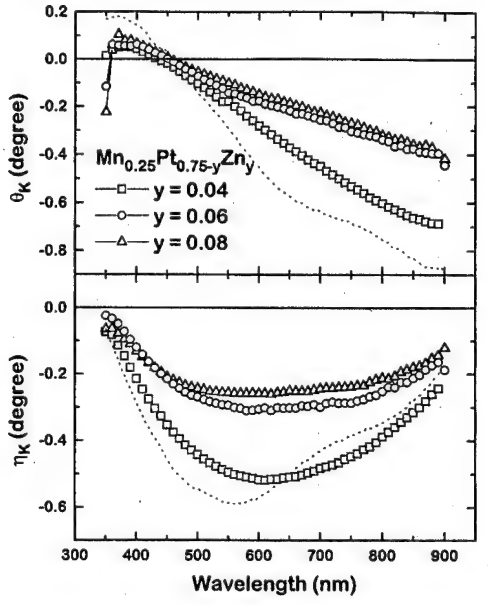

FIG. 5. Kerr rotation and ellipticity wavelength dependence for $Mn_{0.25}Pt_{0.75-y}Zn_y$ measured from the substrate side. Dotted line gives results for $MnPt_3$ measured from substrate side.

ute to the downward trend in T_c. The dramatic increase in coercivity appears to be associated with the structural change from cubic to tetragonal since all samples exhibiting the cubic phase have coercivities ranging from 75 to 660 Oe, while the samples with tetragonal phase have coercivities ranging from 1500 to 2900 Oe.

The room-temperature Kerr rotation (θ_K) and ellipticity (η_K) spectra (measured from the substrate side) for $Mn_{0.25}Pt_{0.75-y}Zn_y$, $y=0.04$, 0.06, 0.08, are shown in Fig. 5. The present spectra are similar to those of pure $MnPt_3$ (shown as dotted line) and the overall decreases in magnitude of θ_K and η_K correlate well with the decrease in M_s.

CONCLUSION

The magnetic and magneto-optical properties of $Mn_xPt_{1-x-y}Zn_y$ alloy films have been investigated. We found that the formation of the tetragonal phase primarily depends on the Pt content, but the addition of Zn influences the formation of a ferromagnetic tetragonal phase with a fairly large saturation magnetization. The crystallographic sites of the Zn atoms have not been determined, but diffraction suggests a preferential layering of the Pt atoms to form alternating (Mn-Zn-Pt)/Pt layers along the (001) direction. No (100) diffraction peak was observed in the tetragonal phases. This together with the rapid decrease in M_s with Zn content seem to indicate a large degree of disorder in the (Mn-Zn-Pt) layer. Such disorder would lead to an increase in the number of Mn-Mn antiferromagnetic exchange interactions.

The mechanism of magnetostriction in transition metal bulk (fcc Co) and thin films [Co/Pd(001) and Co/Cu(001)] is investigated using the *ab initio* full potential linearized augmented plane wave method. With the aid of the state tracking and torque approaches the magnetocrystalline anisotropy energy, the essential ingredient of the magnetostriction, is found to be a linear function of the interlayer distances. The calculated magnetostrictive coefficients and magnetoelastic coupling constants for bulk fcc Co agree very well with experiment. The calculated λ_{001} at the Co/Pd(001) interface is much larger in magnitude ($+2.3\times10^{-4}$) and differs in sign compared to that for Co/Cu(001)(-5.7×10^{-5}). In these thin films, the hybridization between the Co- $d_{xz,yz}$ and the underlying substrate d states is found to play the key role. © *1996 American Institute of Physics.* [S0021-8979(96)77808-8]

I. INTRODUCTION

It has been observed that the magnetostriction in transition metal systems is very sensitive to change of environment and can be strongly enhanced in thin film geometries such as at the Co surface[1,2] and at Co/Pd,[3] Co/Cu,[4] and Ni/Ag (Ref. 5) interfaces and multilayers. Due to its intrinsic complexities and difficulties, however, the mechanism of the magnetostriction in these materials still remains as a major challenge today.[6] It is known that the anisotropic magnetostriction (as distinguished from the small volume magnetostriction) is determined by the two key ingredients, namely, the elastic constants and the strain-dependence of magnetocrystalline anisotropy (MCA) energy (so-called magnetoelastic coupling). For a magnetostrictive transition metal thin film, its thickness (l) should change when the magnetization turns from the perpendicular direction ($l_\perp$) to the in-plane direction ($l_\parallel$). Since the lattice constant in the lateral plane is fixed by the nonmagnetic substrate, the magnetostrictive coefficient can be determined as

$$\lambda=\frac{4}{3}\frac{l_\perp-l_\parallel}{l_\perp+l_\parallel}. \tag{1}$$

If we focus on the contribution from the interfacial layers, we can interpret l as the equilibrium overlayer/substrate distance. For real transition metal overlayer systems, the difference between $l_\perp$ and $l_\parallel$ is very small so that

$$\lambda=\frac{2}{3}\frac{l_\perp-l_\parallel}{l_0}, \tag{2}$$

where l_0 is the equilibrium overlayer/substrate distance for any direction of magnetization and can be obtained by fitting the calculated total energy as a quadratic function of l ($l_0=-b/2a$) as $E=al^2+bl+c$. If we assume that the MCA energy is a linear function of l as $E_{\mathrm{MCA}}=k_1l+k_2$, then we have $l_\perp-l_\parallel=k_1/2a$ and

$$\lambda=-2k_1/3b. \tag{3}$$

Obviously, while the value of b can be easily calculated, the bottleneck for determination of λ is the value of k_1, i.e., the strain dependence of the MCA energy.

In the present paper, we review our recent developments on the state tracking[7] and torque[8] approaches which enable us to obtain highly stable MCA energies for transition metal thin films, and allow us to report, for the first time, calculated magnetostriction coefficients of transition metals in thin film [Co/Cu(001) and Co/Pd(001)] and bulk (fcc Co) forms. We found that the MCA energy clearly exhibits a good linear relationship with respect to the lattice distortion for each system investigated; this demonstrates the possibility of determining magnetostriction coefficients using modern energy band approaches.

II. METHODOLOGY

A. Model

The single particle Kohn–Sham equation is solved self-consistently using the full potential linearized augmented plane-wave (FLAPW) method, which makes no shape approximation for the potential, charge, and wave functions[9] and provides highly precise total energies. For the Co/Cu(001) and Co/Pd(001) thin films, we used a slab model consisting of five Pd (Cu) substrate layers and a pseudomorphic Co overlayers on each side. The ideal fcc structure with a lattice constant of 7.35 a.u. (6.83 a.u.) is assumed for the Pd (Cu) substrate layers while the vertical Co–Pd(Cu) interlayer distance varies as a parameter. When self-consistency for the semirelativistic calculations is achieved, i.e., when

 0021-8979/96/79(8)/6209/4/$10.00

$\sqrt{\overline{\Delta\rho_c^2}}$ and $\sqrt{\overline{\Delta\rho_s^2}}$ are less than 2.0×10^{-4} e/(a.u.)^3 (here ρ_c and ρ_s stand for charge and spin densities, respectively), the spin–orbit coupling (SOC) Hamiltonian is invoked as a perturbation in a second variational way.

B. MCA by state tracking and torque approaches

As is known, the strength of SOC in $3d$ transition metal systems is very weak (30–50 meV, or 100 times smaller than that of the crystalline field) and thus can be well treated using a perturbative framework. As stated in the often-used MCA force theorem,[10,11] the MCA energy can be approximately taken as the band energy

$$E_{\mathrm{MCA}}=E(\rightarrow)-E(\uparrow)$$
$$=\sum_{\mathrm{occ}'}\epsilon_i(\rightarrow)-\sum_{\mathrm{occ}''}\epsilon_i(\uparrow)+O(\delta\rho^n). \tag{4}$$

Very recently, we proved that the order of n goes up to 4 for thin film systems[11] and thus the force theorem should be able to provide sufficient accuracy for MCA energy determinations. However, several numerical uncertainties have been inherent in most previous *ab initio* MCA calculations[12–14] because the sets of occupation, i.e., {occ′} and {occ″}, were determined through the Fermi filling scheme which relies on the very limited information from the eigenvalues, ϵ_i.

Recently, we proposed the state tracking approach[7] in which the {occ′} and {occ″} are determined according to their projections back to the occupied set of the unperturbed states. Since this procedure ensures minimum change in the charge and spin densities as required by the force theorem and excludes the possible randomness in the Brillioun zone (tracking at a given k point),[7] very stable MCA results have been obtained for magnetic thin films such as Fe, Co, and Ni monolayers in free standing case as well as on various substrates (Cu and Pd, etc.) with relatively small number of k points.[15–17] Perhaps more importantly, the behavior of MCA for transition metal thin films can now be related to more fundamental properties such as band structures and wave functions.[17] This enables us to explore the underlying physics and, furthermore, to figure out a way to tune the MCA for transition metal systems: The strong in-plane MCA of a free standing Co monolayer is found to originate from the coupling between the occupied $d_{xz,yz}$ and unoccupied d_{z^2} and $d_{x^2-y^2}$ states at the $\bar{M}$ point.[17] When adsorbed onto the Cu substrate, for example, the $d_{xz,yz}$ state is lowered in energy due to the interfacial hybridization and thus the MCA energy becomes less negative in Co/Cu overlayer systems and even positive in Co/Cu sandwiches.

More recently, we proposed a torque[8] method which can further depress the remaining uncertainties resulting from the SOC interaction between near-degenerate states around the Fermi level (so-called surface pair coupling). To demonstrate the idea of the torque method, recall that the total energy of an uniaxial system can be well approximated in the form of

$$E=E_0+K_2\sin^2\theta+K_4\sin^4\theta, \tag{5}$$

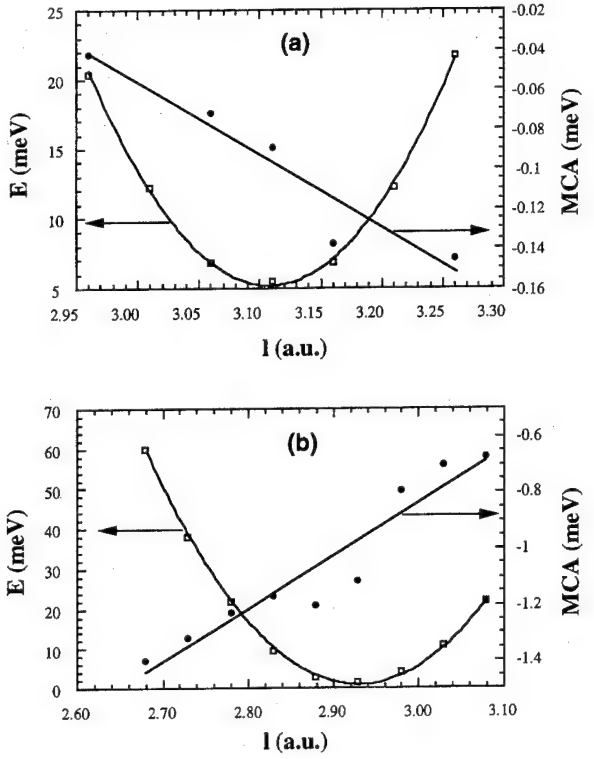

FIG. 1. The calculated change in total energy (left scale) and MCA energy (right scale) as a function of the overlayer/substrate interlayer distance for (a) Co/Cu(001) and (b) Co/Pd(001).

where θ is the angle between the normal axis and the direction of magnetization. It is easy to find that the MCA energy is equal to the angular derivative of the total energy (torque) at a "magic angle" of $\theta=45°$ as

$$E_{\mathrm{MCA}}\equiv E(\theta=90°)-E(\theta=0°)$$
$$=K_2+K_4=dE/d\theta|_{\theta=45°}. \tag{6}$$

If we apply the Feynman–Hellman theorem, E_{MCA} finally can be evaluated as (note only $H^{\mathrm{soc}}=\xi\mathbf{s}\cdot\mathbf{L}$ depends on θ in the Hamiltonian)

$$E_{\mathrm{MCA}}=\sum_{\mathrm{occ}}\left\langle\Psi_i'\left|\frac{dH}{d\theta}\right|\Psi_i'\right\rangle\Bigg|_{\theta=45°}$$
$$=\sum_{\mathrm{occ}}\left\langle\Psi_i'\left|\frac{\partial H^{\mathrm{soc}}}{\partial\theta}\right|\Psi_i'\right\rangle\Bigg|_{\theta=45°}, \tag{7}$$

where Ψ_i' is the ith perturbed wave function.

The advantage of the torque method is obvious since in this approach we only have to deal with one particular magnetic orientation and thus only one Fermi surface is required for the k integration. In addition, the MCA energy is expressed as the expectation value of the angular derivative of H^{soc} and thus it is much more insensitive to the surface pair coupling. With the aid of the state tracking and torque methods, very stable results have been obtained for various transition metal systems and thus we are able to attack the long standing problem of magnetostriction in transition metals.

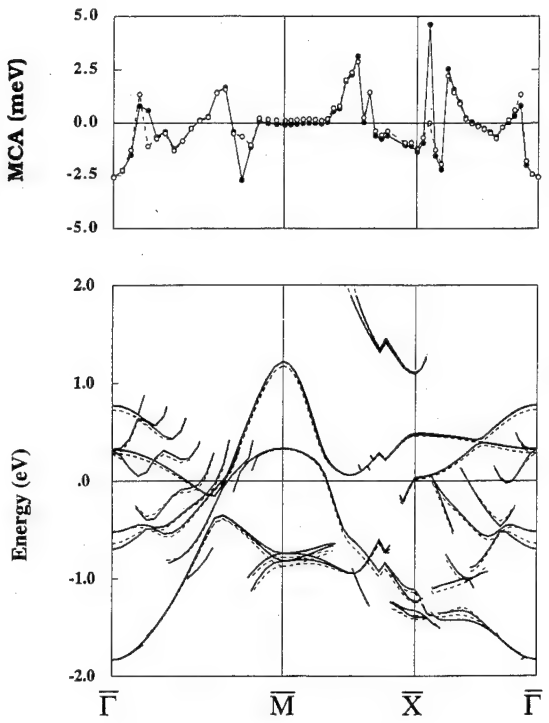

FIG. 2. The calculated band structures (bottom panel) and the distributions of the MCA energies (top panel) along high symmetry directions in the BZ of Co/Cu(001) in the equilibrium (solid lines, l=3.11 a.u.) and a reduced geometry (dashed lines, l=2.96 a.u.).

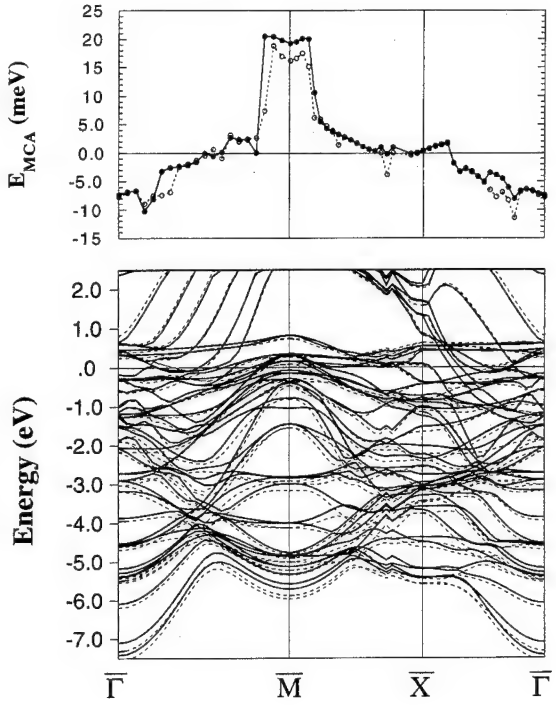

FIG. 3. Same as Fig. 2 but for Co/Pd(001) in equilibrium (solid lines, l=2.96 a.u.) and in a reduced geometry (dashed lines, l=2.76 a.u.).

III. RESULTS

To determine values of k_1 and b in Eq. (3), we calculated E and E_{MCA} for Co/Cu(001) and Co/Pd(001) as functions of their overlayer/substrate interlayer distances, l. For each system, as shown in Fig. 1, while the total energy curve can be well fitted by a parabola, the MCA energy exhibits a fairly good linearity—indicating the precision of the present calculations and also justifying the huge range of strain ($\Delta l/l \sim 15\%$) used in calculations relative to saturation magnetostrictive strains ($\Delta l/l \sim 10^{-5}$). We found for Co/Cu(001) that b and k_1 are equal to -4390 and -0.376 meV/a.u., respectively; thus, the calculated λ_{100} is -5.7×10^{-5}.[18] The negative sign means that the Co–Cu interlayer distance contracts when the direction of magnetization changes from in-plane to normal to the surface. Dramatically, we found that the MCA energy for Co/Pd(001) becomes more *negative* when the Co–Pd distance shrinks and thus λ_{001} becomes *positive*, $+2.3\times10^{-4}$, just opposite to those for Co/Cu(001). This result is in reasonable agreement with experiment data currently available.[3]

To reveal the physical background for magnetostriction in transition metal thin films, we need to explain why the MCA energy becomes less (more) negative when the Co–Cu (Co–Pd) distance decreases. As discussed above, the MCA energy can be altered if one increases the energy separation between the $d_{xy}-d_{xz,yz}$ and $d_{z^2}-d_{xz,yz}$ states around the $\bar{M}$ point.[17] Of key importance, we can see from the band structure in the bottom panel of Fig. 2, where only states with weight larger than 50% in the Co muffin-tin (MT) spheres are given, that the Co-$d_{xz,yz}$ states hybridize with the underlying Cu d states and split into a few states (each branch shown in Fig. 2 has only a 54% weight in the Co MT sphere) and thus their energy positions are lowered. As a result, the MCA energy in the top panel of Fig. 2 becomes almost zero around the $\bar{M}$ point and, subsequently, the MCA energy of Co/Cu(001) is only -0.1 eV/adatom at the equilibrium geometry. When the Co–Cu interlayer distance is shortened further to 2.96 a.u., as shown by the dashed lines in Fig. 2, the energy position of the Co-$d_{xz,yz}$ states appears very sensitive to the Co–Cu distance and is lowered further by 0.05 eV. As expected, the MCA energy shifts up to be slightly positive around the $\bar{M}$ point. Thus the hybridization between Co-$d_{xz,yz}$ and Cu states is the main driving force for the magnetostriction for Co/Cu(001).

The band structures of Co/Pd(001) are plotted in the bottom panel of Fig. 3, where the solid lines indicate the bands for the equilibrium geometry (l=2.96 a.u.) and the dashed lines are for a further contracted case (l=2.76 a.u.). Due to the strong Co–Pd interfacial hybridization in both the occupied and unoccupied parts, almost all of the Co states lose their localizations in the Co MT sphere (most of them have less than 40% weighting). Most strikingly, the Co-$d_{xz,yz}$ states are split even into the unoccupied region around the $\bar{M}$ point and, correspondingly, a *positive* contribution to the MCA energy in the $\bar{M}$ neighborhood is found as shown in the top panel in Fig. 3. When the Co–Pd interlayer distance is shortened further to 2.76 a.u., as shown by the dashed lines in Fig. 3, the band broadening enlarges the energy separation between the occupied and unoccupied Co-$d_{xz,yz}$ states and thus their *positive* contributions to the MCA energy is reduced. Again, the most pronounced features happen around the $\bar{M}$ point whereas the contributions from other k points

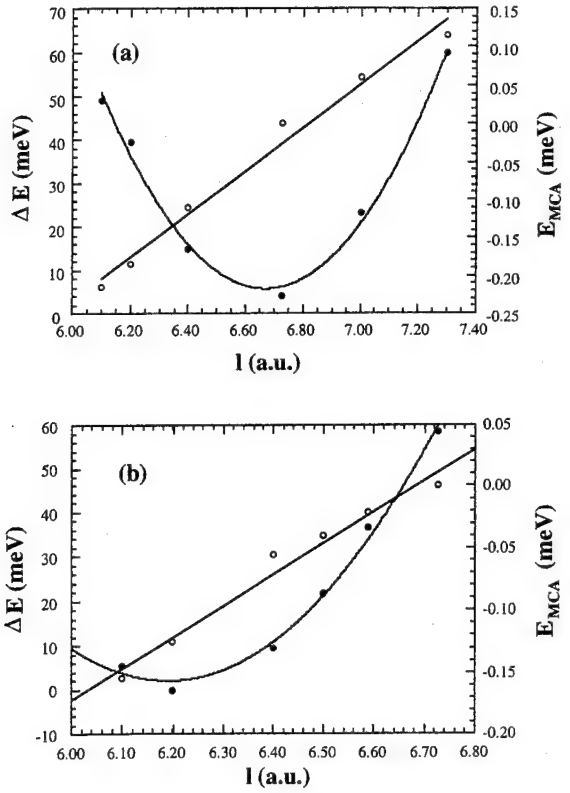

FIG. 4. The calculated change in total energy (left scale) and MCA energy (right scale) as a function of the length of the c axis for fcc Co bulk with distortions that preserve (a) a constant volume and (b) a constant area in the lateral plane.

appear not to be very sensitive to the change of Co/Pd distance.

As a further step, we investigated the magnetostriction for a bulk cubic transition metal. In Fig. 4, the calculated change in total energy (left scale) and MCA energy (right scale) per Co atom for bulk fcc Co with respect to the length of the c axis are given for distortion modes with (a) a constant volume and (b) a constant area in the lateral plane. The linear relationship between E_{MCA} and l is obvious for both cases—indicating a possibility to determine the magnetostriction even for a cubic transition metal bulk. Quantitatively, for cases (a) and (b) respectively, the calculated λ_{001} are 10.2×10^{-5} and 6.8×10^{-5}, while the magnetoelastic coupling constants,[19] namely B_1, are -1.6×10^{8} erg/cm^3 and -2.4×10^{8} erg/cm^3. The results for the case with a constant volume are surprisingly close to the measured λ_{001} [1.3×10^{-4} (Ref. 20)] and B_1 [-1.6×10^{8} erg/cm^3 (Ref. 21)], and appear to validate the present approach for determining magnetostriction in transition metal systems.

IV. CONCLUSION

In conclusion, with the aid of the state tracking and torque techniques for calculating the MCA energy, the precision of modern first principles approaches appears to be sufficient for the determination of the magnitude, sign and mechanism of the tiny magnetostriction values observed in transition metal thin films. This new capability for making theoretical predictions and, perhaps more importantly, providing meaningful physical insights, appears possible to help guide the search for the right elements and compositions to synthesize thin films with desired magnetostrictive properties.

[18] A 5%–10% uncertainty may be involved since the MCA energy for l=3.16 is away from the trend due to the effects of the surface pair coupling (SPC), i.e., the MCA energy changes from −0.14 meV/adatom to −0.09 meV/adatom when the SPC is dropped. Although these effects also appear to be not negligible for some k-points in Fig. 2, we found that the elimination of SPC affects the MCA energies only very slightly (<0.01 eV/adatom) for other geometries for Co/Cu(001).

Materials with a large capacity to dissipate mechanical energy are of interest for passive vibration damping. We have measured the zero-field damping capacity of the giant magnetostrictive terbium–dysprosium–iron compounds by quasistatic stress–strain hysteresis loops. The magnetization and strain of the samples were measured for increasing and decreasing compressive stresses, up to 50 MPa. The zero-field, room temperature damping capacity ($\Delta W/W$) was calculated from the stress–strain loops and is plotted against maximum stress. The damping capacity maximum for the alloy with the nominal Terfenol-D composition occurs at 4.1 MPa with the value 1.75 which corresponds to $Q^{-1}=0.28$. The damping is almost independent of stress in a multi-phase sample, $(Tb_{0.6}Dy_{0.4})Fe_{1.4}$, which contains both Laves phase and elemental rare earth. © *1996 American Institute of Physics.* [S0021-8979(96)77908-4]

I. INTRODUCTION

Magnetomechanical damping of vibrations has been known for many years,[1] but has not been exploited in modern applications of passive damping materials. Magnetic alloys with large magnetomechanical coupling factors, k, such as Terfenol-D ($Tb_{0.3}D_{0.7}Fe_2$) with $k=0.7$, transform elastic energy into magnetic energy in each vibration cycle according to the ratio $k^2/(1-k^2)$. If the magnetic system has a high loss factor, less energy is returned to the elastic system and the vibration is damped. In previous work,[2] we extracted the magnetomechanical damping capacity of Terfenol-D from transducer stress–strain hysteresis curves measured with magnetic field at different stresses. The stress–strain hysteresis was related to a Stoner–Wolfarth type magnetic hysteresis caused by magnetic domain jumping between different easy axis directions. Both the data and model indicate that damping should be a maximum for zero field bias conditions.

In this paper we measure the quasistatic stress–strain hysteresis curves for zero field bias for both polycrystalline Terfenol-D rods, as well as for a rare earth rich $(Tb_xD_{1-x})Fe_y$ sample. In the Terfenol sample the maximum damping capacity exceeds unity, suggesting a great potential for this material for high stress applications.

II. EXPERIMENT AND RESULT

The samples consisted of high purity rare earths and iron melted by rf heating and subsequently poured into a cylindrical mold. The Terfenol-D sample had a nominal composition of $Tb_{0.3}D_{0.7}Fe_2$, a diameter of 1.5 cm, and exhibited a simple polycrystalline morphology with grain size ranging between 0.025 and 0.05 cm. The high rare earth concentration eutectic sample had a nominal composition of $(Tb_{0.6}Dy_{0.4})Fe_{1.4}$, a diameter of 0.9 cm, and exhibited a complex polycrystalline morphology with no feature larger than 0.01 cm.

The samples were placed in an apparatus that could apply incremental quasistatic uniaxial pressure up to 100 MPa and a saturating magnetic field of 2500 Oe. The apparatus was instrumented with an analog pressure gage and a calibrated NIST traceable load cell. Each sample was instrumented with two commercial foil strain gages and a 50 turn pick-up coil. Each stress–strain data acquisition sequence started with the application of a saturating magnetic field being directed along the stress axis. This was done to establish an initial strain state equivalent to the remanent state that would be produced by a saturating tensile stress. Since Terfenol is a brittle intermetallic which is fragile under tensile stress, only the compressive portions of the stress–strain hysteresis loops were obtained by direct application of stress.

In order to determine the damping characteristics of highly magnetostrictive materials, a series of strain data as a function of positive stress was taken, each series started at zero stress and a reproducible initial-state strain, went up to a predetermined maximum stress (σ_m) and, returned to zero stress. The results of this procedure for the polycrystalline Terfenol-D sample is shown in Fig. 1. The inset details the maximum stress applied for each individual data set. Similar curves were obtained for the sample containing the eutectic. However, for this sample, the enclosed stress–strain area which corresponds to the losses, are smaller.

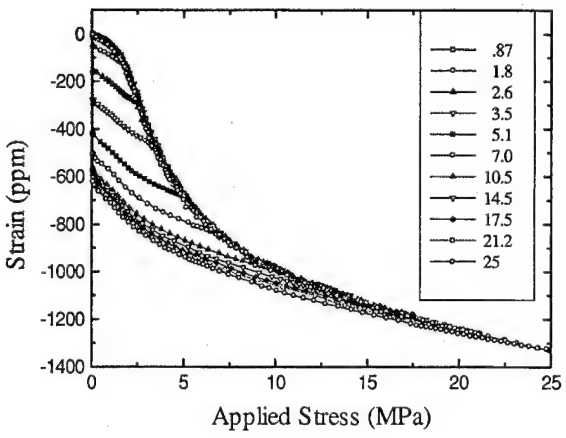

FIG. 1. Stress–strain half loops taken at room temperature on polycrystalline Terfenol-D. The inset shows the maximum applied stress (σ_m) for each half loop.

 0021-8979/96/79(8)/6213/3/$10.00

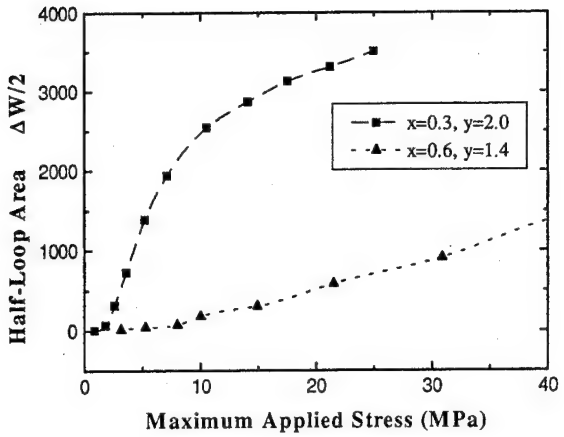

FIG. 2. The half loop enclosed area for polycrystalline Terfenol-D (■) and the high eutectic sample (▲) as a function of maximum applied stress (σ_m).

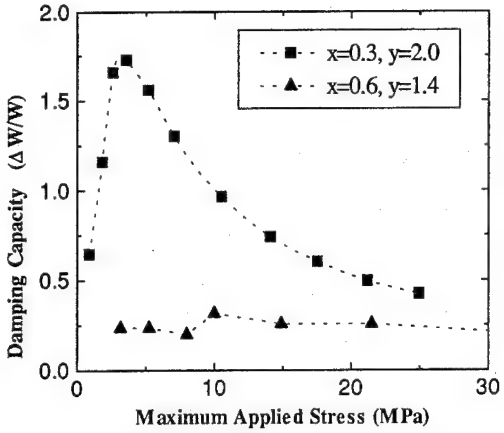

FIG. 3. The damping coefficient $\Delta W/W$ for polycrystalline Terfenol-D (■) and the high eutectic sample (▲) as a function of maximum applied stress (σ_m).

The damping capacity was calculated from these data sets by integrating the half loop area and applying the formula: $\Delta W/W=(2*\text{half loop area})/[1/2(\sigma_m*\epsilon_m)]$. Here ϵ_m is the strain corresponding to the maximum stress, σ_m. The areas for both samples are plotted vs σ_m in Fig. 2. The corresponding values of $\Delta W/W$ are plotted in Fig. 3.

Application of a bias magnetic field, ($0<H<500$ Oe), during the damping data acquisition leads to a reduction in the damping coefficient with increasing applied field.

III. DISCUSSION

In order to understand and tailor magnetomechanical damping we need to relate it to the independently measurable materials parameters: magnetization, M, magnetocrystalline anisotropy, K, magnetostriction, λ, and elastic modulus, Y. Stress–strain hysteresis due to magnetoelastic coupling derives from some of the same loss mechanisms that contribute to magnetic hysteresis. However, since the tensor symmetries of a magnetic field and an applied stress are different, their effect on domain wall motion and magnetic domain rotation will be different, depending on the crystal symmetry of the material.[2] Stress cannot discriminate between 180 deg domains and therefore will not produce hysteresis in materials with uniaxial symmetry. In a cubic material such as Terfenol, an applied stress will change the relative energies of the initially equivalent easy axis domain orientations. At some critical stress the magnetization will jump between the now inequivalent directions, and the strain which is coupled magnetoelastically to the magnetization will also change discontinuously. We define the critical stress to be that stress for which the barrier between the energy minima disappears. Steady state oscillations will drive the system cyclically between two different magnetization/strain states. A derivation of stress–strain hysteresis for a stress applied along [001] to a cubic crystal with {100} easy axes ($K>0$) was presented in the appendix of Ref. 2. Critical stresses are found to be proportional to K/λ and the peak damping capacity is proportional to $Y\lambda^2K$. Calculations for a Terfenol single crystal with {111} easy axes ($K<0$) proceeds in the same way by finding the minima of the generalized free energy for the single crystal with an externally applied stress, σ

$$E=K(\alpha_i^2\alpha_j^2+\cdots)-\tfrac{3}{2}\lambda_{100}(c_{11}-c_{12})(\epsilon_{ii}\alpha_i^2+\cdots)$$
$$-3\lambda_{111}c_{44}(\epsilon_{ij}\alpha_i\alpha_j+\cdots)+\tfrac{1}{2}c_{11}(\epsilon_{ii}^2+\cdots)$$
$$+c_{12}(\epsilon_{ii}\epsilon_{jj}+\cdots)+\tfrac{1}{2}c_{44}(\epsilon_{ij}^2+\cdots)-\sigma\cdot\epsilon,$$

where the α_i are the vector components of the magnetization, the ϵ_{ij}'s are the Cartesian strains, and λ_{100} and λ_{111} are the lowest order cubic magnetostriction constants. For Terfenol, λ_{100} is about zero to a good approximation and may be neglected. The ϵ_{ij}'s are eliminated by imposing the equilibrium conditions $\partial E/\partial\epsilon_{ij}=0$, and the equilibrium value of α can then be determined from the condition of zero torque $\boldsymbol{\alpha}(\partial E/\partial\boldsymbol{\alpha})=0$. Solutions of the torque equations, obtained numerically, yield magnetization-stress hysteresis loops. Magnetoelastic strain loops are calculated from them using $\epsilon=3\lambda_{111}(\alpha_i\alpha_j\beta_i\beta_j+\cdots)$, where β defines the stress–strain axis.

A series of stress–strain hysteresis loops for stress applied in the $(1\bar{1}0)$ plane at an angle θ from the [110] direction is shown in Fig. 4. We can approximate the stress–strain hysteresis for a Terfenol polycrystal by an appropriately weighted sum of the hysteresis curves for individual crystallites randomly oriented with respect to the stress axis.

A. Stress along [111]

Here the two easy axes collinear with the stress ([111] and $[\bar{1}\,\bar{1}\,\bar{1}]$) are inequivalent to the other six easy directions, which are all equivalent to each other. The stress-collinear pair remains stationary but the other six easy directions rotate with applied stress and the magnetization jumps between them and the two stationary easy directions at the critical stresses $\sigma=-0.15K/\lambda_{111}$ and $\sigma=0.44K/\lambda_{111}$ [see Fig. 4(b)].

B. Stress along [112]

For stresses applied along lower symmetry directions such as [112], all of the easy axes rotate with applied stress. The moment jumps between the easy axis pair nearest to the stress direction ([111] and $[\bar{1}\,\bar{1}\,\bar{1}]$) and the pair ($[11\bar{1}]$ and $[\bar{1}\,\bar{1}1]$) in the same $(1\bar{1}0)$ plane at the critical stresses $\sigma=-0.17\ K/\lambda_{111}$ and $\sigma=0.25\ K/\lambda_{111}$ [see Fig. 4(c)]. The re-

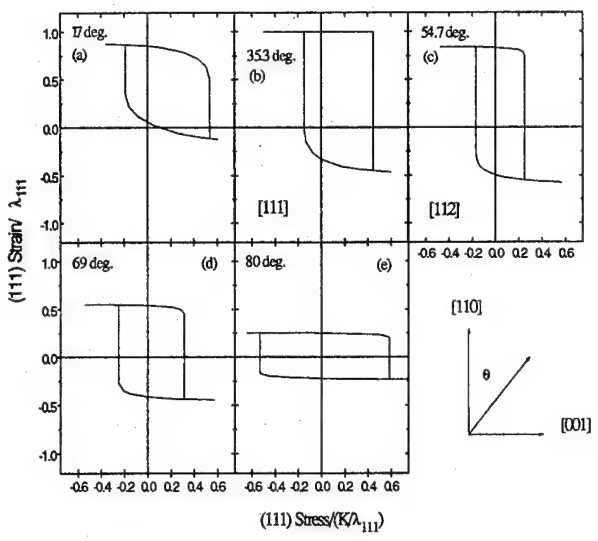

FIG. 4. Calculated stress-strain hysteresis loops for [111] easy material and for stress applied in the $(1\bar{1}0)$ plane at increasing angle, θ, from [110]. Stress in units of K/λ_{111}, positive values indicate compressive stress. Strain in units of λ_{111}, negative values indicate compressive strain. Jumps are indicated by vertical lines.

maining four easy axis directions not in the $(1\bar{1}0)$ plane are less strongly affected by the applied stress. The barriers preventing out-of-plane jumping do not disappear until jumping has already occurred in-plane thus out of plane jumping may be neglected to lowest order.

C. Stress along [001]

In this case all of the easy directions remain equivalent and no jumping occurs. At angles of applied stress close to this hard axis [Fig. 4(e)], the critical stress for jumping approaches infinity and the magnitude of the jumps approaches zero. A similar thing happens for stress applied along or close to [110] [Fig. 4(a)], except that in this case only the four in-plane axes remain equivalent and out-of-plane jumping should be included.

By inspection we see that the maximum hysteresis occurs for crystallites oriented with an easy axis close to the applied stress direction. For Terfenol ($\lambda = 1600E\text{-}6$, $K = 8E4$ J/m^3) the maximum damping capacity is predicted for a stress applied along [111] with a peak value of about 5 at 15 MPa stress [see Fig. 4(b) for the stress–strain curve that yields this result). Averaging over crystallites will reduce the hysteresis by a factor of 2–3 depending on the texturing of the sample. This estimate is consistent with the maximum damping capacity as measured in Terfenol and shown in Fig. 3 above. The data for the eutectic sample illustrates both a reduction of damping capacity due to a smaller proportion of magnetostrictive material and the extreme broadening of the damping peak due to the spread of stresses experienced by material in a composite. The measured damping capacity of 0.2, however is still quite large when compared to conventional damping materials.

The temperature dependence of Young's modulus has been measured for a series of $Tb_{1-x}Dy_xZn$ pseudobinary compounds with x ranging from 0 to 1. From the sharp dips in the modulus vs temperature data, the reorientation transition temperatures have been determined, and the magnetic phase diagram deduced. Magnetization measurements taken on the same samples show less pronounced features at the corresponding temperatures. © *1996 American Institute of Physics.* [S0021-8979(96)78008-3]

INTRODUCTION

The series of pseudobinary compounds $Tb_{1-x}Dy_xZn$ have several characteristics which make them attractive for scientific and technological reasons. They have simple atomic structures (CsCl), are all ferromagnets with only one magnetic species whose magnetic polarization arises almost exclusively from the localized $4f$ electrons.[1] Easy axis reorientations observed for $x \leq 0.6$ (Refs. 2 and 3) mean low anisotropies at temperatures near the transition points. This, combined with large magnetostrictions leads to strong magnetomechanical coupling, depending on x, from 63 K at $x=0$ to 4.2 K near $x=0.6$. The use of fourth- and sixth-order anisotropy constants to describe the magnetic energy has not been adequate for describing related pseudobinary rare earth compounds. In fact, for the low-T portion of the $T-x$ phase diagram there are phases in which the magnetization is directed along nonprincipal axes.[4] One requires at a minimum, eighth-order anisotropy terms to reproduce these phases.[5] The higher-order terms can arise from crystalline electric field contributions to the $4f$-electron wave functions[6] and from local fluctuations in magnetization direction caused by competing terbium and dysprosium anisotropies.[7] The former mechanism is in principle present even in the binary compounds while the latter is expected to vary as $x(1-x)$.

In the past, these magnetic phase diagrams were determined by torque magnetometry on single crystal specimens of $Tb_{1-x}Ho_xFe_2$,[8] and Mössbauer measurements[4] on polycrystalline Laves phase pseudobinaries. At present, only polycrystalline specimens of the $Tb_{1-x}Dy_xZn$ are available. The special feature of the Laves phase, which allowed use of Mössbauer spectra to determine the easy directions, is missing in the CsCl structure. It is still possible, however, to determine the phase boundaries, if not the nature of the phases themselves by measuring the elastic modulus vs temperature. Intuitively, minima or sharp features of some kind would be expected at a magnetization reorientation temperature. We report measurements of Young's modulus as a function of temperature for a series of polycrystalline $Tb_{1-x}Dy_xZn$. Broad minima were found in all the samples. For $x \lesssim 0.5$ sharp dips were seen as well. For $x=0.125$, two such dips were seen. The dips are interpreted as marking second-order transitions between different easy magnetization directions. From these and prior[3] data, a magnetic phase diagram is constructed which predicts the existence of a phase with $[u,v,0]$ easy axis from $x \approx 0.1$ to $x \lesssim 0.5$. Some idea of the x dependence of the ratios of the fourth- and sixth-order anisotropy constants was obtained using this phase diagram. The origin of the broad temperature minima observed in all samples is discussed in terms of a model of competing crystalline and dipolar anisotropies.

EXPERIMENT

Polycrystalline alloys of $Tb_{1-x}Dy_xZn$ with $0<x<1$ were prepared at Ames Laboratory from stoichiometric proportions of 99.99% pure Tb, Dy, and Zn.[9] Small disks (~100 mg) for magnetization measurements and small transducer rings (~6 mm i.d.×~8.8 mm o.d.×~0.8 mm thick) for magnetoelastic measurements were cut from each alloy composition. To improve sample homogeneity, the samples were then annealed in an inert atmosphere for a period of 18 h up to 1 week at ~900 C. Magnetization as a function of temperature and magnetic field was measured for each disk sample in a vibrating sample magnetometer. The magnetoelastic properties were measured using the ring samples toroidally wound with three coils: (1) a dc bias coil, (2) an ac excitation coil, and (3) an ac pickup coil. The dc bias coil was used to magnetize the samples before each measurement. The complex impedance as a function of frequency was measured to determine resonant frequencies as a function of temperature. The former are related to Young's modulus, E, as

$$E=\omega_r^2 \rho a^2, \tag{1}$$

where a is the ring radius [$a=1/4$(o.d.+i.d.)], ρ is the density, and ω_r is the resonant frequency. Errors in the temperature measurement were on the order of ±1.5%. Further experimental details can be found in Ref. 3.

RESULTS

Figure 1 shows the modulus vs temperature for samples with $x=0$ and $x=0.075$. The sharp dip in the $x=0$ (TbZn) modulus at $T=63$ K coincides with the reorientation temperature measured in single crystals by magnetization vs temperature curves.[3] Besides the sharp dip in modulus at 53 K in the $x=0.075$ sample, note the drop in modulus at temperatures below 20 K. At larger x, the sharp dip is found at lower temperatures, while a second dip at around 13 K is

 0021-8979/96/79(8)/6216/3/$10.00

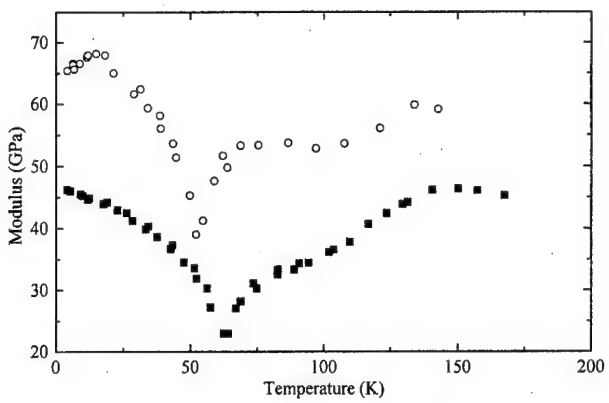

FIG. 1. Young's modulus vs temperature for TbZn (■) and $Tb_{0.925}Dy_{0.075}Zn$ (○).

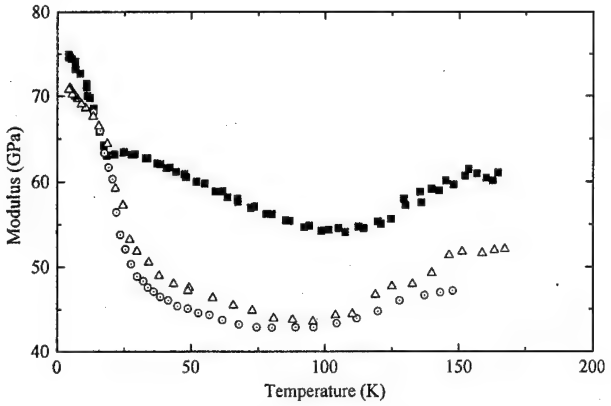

FIG. 3. Young's modulus vs temperature for $Tb_{0.6}Dy_{0.4}Zn$ (■), $Tb_{0.5}Dy_{0.5}Zn$ (△), and $Tb_{0.4}Dy_{0.6}Zn$ (⊙).

apparent in the 0.125 sample (see Fig. 2). Note also that the dip in the 0.150 sample is broader, and is largest at yet a lower temperature than those with smaller x. As x is increased beyond 0.15, the dip becomes narrower and moves to lower temperature. By $x=0.4$, the dip, while still clearly visible, represents a relatively small decrease in modulus on a background that is rapidly increasing with decreasing temperature. At $x=0.5$, the dip was seen in some runs and not in others. It is not visible in the data presented in Fig. 3. There is, however, a slight rise in the magnetization between 15 and 5 K. The $x=0.6$ sample does not show any dip in modulus for temperatures down to 4.2 K, although the magnetization does show a small increase around 10 K.

Assuming that the temperatures at which the cusplike dips appear in the moduli mark the boundary between different easy axis magnetization directions, we have constructed the magnetic phase diagram for $Tb_{1-x}Dy_xZn$ depicted in Fig. 4. The facts that the magnetization of TbZn reorients directly from [100] to [110],[2] that there are two cusplike dips in the modulus of the $x=0.075$ sample, and that the modulus dip of the $x=0.15$ sample is relatively broad (which means that this sample is near a phase boundary over a wide temperature range), support the indicated assignments of phases on the $T-x$ diagram.

The magnetization measurements also show a significant coercivity at low temperatures for $x\geq 0.6$ which increases to about 1 kOe for $x=1.0$ and $T\leq 20$ K. Coercive fields of that order of magnitude below 25 K have been reported previously for DyZn.[10]

As we mentioned at the outset, at least three anisotropy constants are required to describe a phase diagram such as that of Fig. 4, in which there exist regions in which the magnetization lies in nonprincipal directions. Writing the anisotropy energy of a particular crystallite in terms of α_i, the direction cosines of the magnetization,

$$E=K_4\sum_{i>j}\alpha_i^2\alpha_j^2+K_6\alpha_x^2\alpha_y^2\alpha_z^2+K_8\sum_{i>j}\alpha_i^4\alpha_j^4, \tag{2}$$

it was shown in Ref. 5 that the $[u,v,0]$ phase is stable for $0\geq K_4/K_6\geq -0.5$, $K_6/K_8>2$. Since the portion of the phase diagram near $x=0$ shows no such phase, it must be that $K_8=0$ for $x=0$. On the other hand, for $x\geq 0.1$, the $[u,v,0]$ phase is stable for all $T<35$ K, so K_8 must increase rapidly

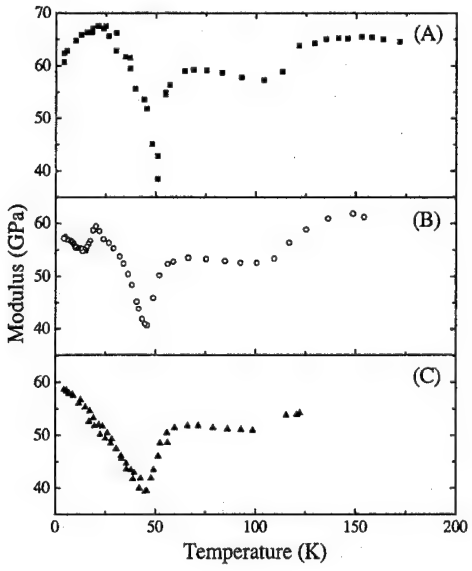

FIG. 2. Young's modulus vs temperature for (A) $Tb_{0.9}Dy_{0.1}Zn$, (B) $Tb_{0.875}Dy_{0.125}Zn$, and (C) $Tb_{0.85}Dy_{0.15}Zn$.

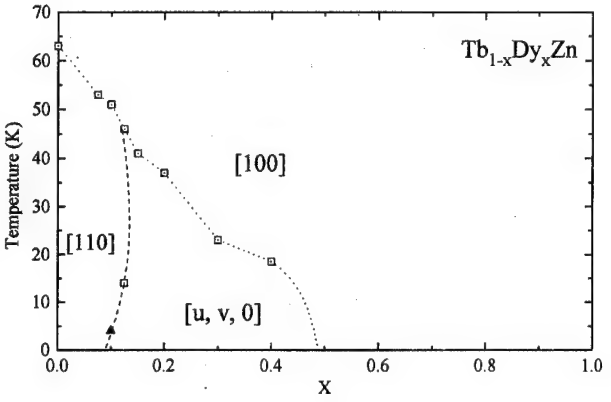

FIG. 4. Easy magnetization phase diagram for $Tb_{1-x}Dy_xZn$. The dashed lines are guides to the eye. The solid triangle is estimated from the drop in the $x=0.1$ modulus as $T\to 0$. The open squares represent the lowest points of the sharp dips in modulus vs temperature.

with x, and remain nonzero at least as far as $x=0.6$. These circumstances lead us to conclude that most of the contribution to K_8 comes from the Tb–Dy competing anisotropy effect. If this is so, we expect that the $[u,v,0]$ phase is nonuniform; only the direction of the net magnetization is actually along $[u,v,0]$; the local magnetization varies spatially within each domain.

MAGNETOELASTIC MODULUS SOFTENING

For all the samples, we find a softening of the modulus below the Curie temperature, T_C. In contrast to the cusplike features which mark the magnetization reorientations, this softening takes place over a wide temperature range, from just below T_C to as low as 25 K for the $x \geqslant 0.4$ samples. Similar softening has been observed in the shear moduli of RCo_2 compounds[11] and in $Tb_{0.3}Dy_{0.7}Fe_2$.[12] The origin of these reductions in the moduli is undoubtedly the magnetoelastic coupling, traceable to the anisotropic rare earth atoms. Schematically, we have the change in modulus as

$$\Delta E \approx -B^2/K_{\text{eff}}, \tag{3}$$

where B is some magnetoelastic coupling coefficient and K_{eff} is an effective anisotropy. For cubic polycrystals, K_{eff} is determined by a competition between fourth (K_4) and higher-order anisotropy coefficients, which tend to pull the magnetization along easy crystalline axes, and the dipole forces which tend to align the magnetization along the circumferential direction, in the case of our ring-shaped samples. The latter we model as a uniaxial (K_2) anisotropy, going as M^2. Just below the Curie temperature, the uniaxial anisotropy dominates; $\Delta E \sim -B^2/K_2$. Well below this temperature regime, $\Delta E \sim -B^2/K_4$. In between these extremes, the two anisotropies compete, causing a series of reorientations over a broad range of temperatures at which K_{eff} is much smaller than either K_4 or K_2. The result is a broad minimum in ΔE plotted vs K_2/K_4. When mapped onto the temperature axis, using for example M^4 for the temperature dependence of the crystalline anisotropy, the result is a broad dip in the modulus vs temperature, as observed. Details of the modelling and more precise comparisons with the data will be published separately.

SUMMARY

Young's modulus as a function of temperature has been measured for a series of $Tb_{1-x}Dy_xZn$ pseudobinary compounds with x ranging from 0 to 1. From the sharp dips in the modulus vs temperature data, the reorientation transition temperatures have been determined, and the magnetic phase diagram deduced. Magnetization measurements taken on the same samples show less pronounced features at the corresponding temperatures. We note that the model discussed in the previous section, with suitable allowance for different sample shapes and measurement frequencies, should describe the temperature softening of the Young's or shear modulus in any magnetoelastic polycrystal.

Enhancement of piezomagnetic response of highly magnetostrictive rare earth-iron alloys at kHz frequencies

P. P. Pulvirenti and D. C. Jiles
Ames Laboratory, Iowa State University, Ames, Iowa 50011

R. D. Greenough and I. M. Reed
Department of Applied Physics, University of Hull, Hull, United Kingdom

The effects of Al and Si additions on the frequency response of highly magnetostrictive Tb–Dy–Fe alloys have been studied. These elements reduced the electrical conductivity of the material, thereby increasing the depth of penetration of ac magnetic fields and extending the operational frequency range. Complex permeability measurements were made on doped and undoped polycrystalline samples with the objective of studying the improvement in energy conversion efficiency at kilohertz frequencies as a result of the alloying additions. The resulting complex permeability was compared with the values for single crystal specimens of $Tb_{0.3}Dy_{0.7}Fe_{1.92}$ at a range of frequencies from 10 Hz to 50 kHz. © *1996 American Institute of Physics.* [S0021-8979(96)78108-X]

INTRODUCTION

The room temperature magnetostriction of rare earth-iron alloys, such as Terfenol-D has a magnitude of typically 1600 ppm.[1] This has stimulated research into their use in sensor and transducer applications. For instance, micropositioning and adaptive vibration control applications require an appropriate high frequency response. Undoped Terfenol-D has a conductivity of 60×10^{-8} Ω m which significantly reduces the magnetic field penetration. For example, the skin depth is typically 1.5 mm in Terfenol-D at 50 kHz. This limits the diameter of a Terfenol-D rod that can usefully be employed and consequently restricts the load bearing capability of an actuator. Doping Terfenol-D with light elements such as aluminum, silicon, or boron could offer a route whereby the electrical resistivity can be increased by providing scattering sites for the conduction electrons, thereby reducing eddy current effects without having a large adverse effect on the magnetoelastic properties.

EXPERIMENTAL TECHNIQUES

Measurements of complex permeability were taken as a function of frequency for both doped and undoped polycrystalline samples and for twinned single crystal samples of Terfenol-D. Each specimen was approximately 50 mm long and 9 mm in diameter. The voltage signal from an encircling flux coil on the specimen was analyzed using a lock-in amplifier. The lock-in amplifier provided the reference signal driving the solenoid which generated the applied magnetic field. An ac magnetic field amplitude of 240 A/m was applied at frequencies in the range 10 Hz–50 kHz. The variation of complex permeability with frequency is shown in Fig. 1 for single crystal Terfenol and three specimens of polycrystalline Terfenol. Resonance–antiresonance data obtained from the rate of change of magnetic induction are shown in Fig. 2.

The performance of the materials was quantified in terms of the two piezomagnetic coefficients, $d=(d\lambda/dH)_B$ and $g=-(d\lambda/dB)_\sigma$ and the magnetomechanical coupling coefficient k. Real and imaginary components of the piezomagnetic strain coefficient g, elastic compliance s, and complex permeability μ were determined for the polycrystalline samples.

The magnetomechanical coupling coefficient k is often calculated from resonance-antiresonance data using

$$k^2=\frac{\pi^2}{8}\left[1-\left(\frac{f_r}{f_a}\right)^2\right], \tag{1}$$

where f_r is resonant frequency and f_a is the antiresonant frequency. Another method for calculating k is using the piezomagnetic coefficient g, permeability at constant stress μ_s and compliance at constant induction s_B. This is the so-called *three parameter* method. The value of k is obtained from

$$k^2=g^2\frac{\mu_s}{s_B}. \tag{2}$$

Both of these methods for determining k have limitations, however. The resonance method takes no account of the behavior of the material other than the locations of the

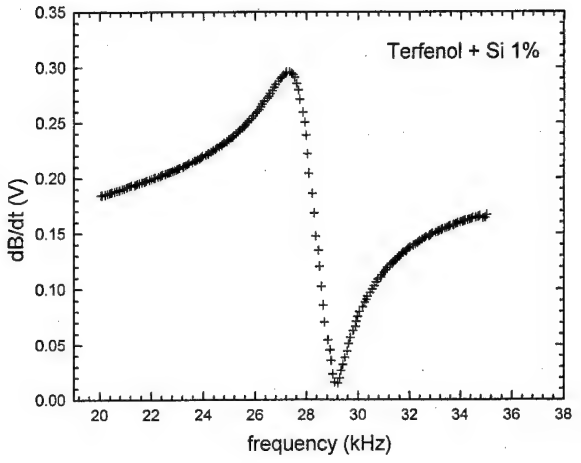

FIG. 2. Resonance–antiresonance peaks for polycrystalline Terfenol +1% Si.

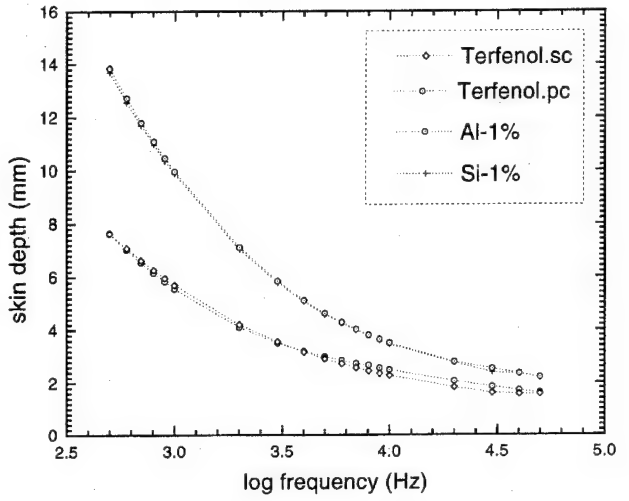

FIG. 3. Calculated skin depth of Terfenol samples as a function of frequency of applied field.

resonance and antiresonance frequencies, and therefore is highly susceptible to slight shifts, or even inaccuracies in the determination of these frequencies.

On the other hand, the analysis leading up to the derivation of Eq. (2) for the three parameter method is flawed because it rests on the assumption of small amplitude, linear and reversible displacements, all three of which are disputable in the case of a ferromagnetic material.

Recently an improved method has been developed for the determination of the coupling coefficient k using plane wave modeling techniques.[2] This allows the shape of the entire frequency response curve of Fig. 2 to be used to determine k. Such a calculation is both more robust and more appropriate than the conventional methods used to date.

The coupling factor, k was obtained from the magnetomechanical resonance in rods of different compositions, each approximately 50 mm long and 9 mm in diameter. With no applied prestress, a longitudinal dc bias field of 52 kA/m was sufficient to obtain maximum coupling. The frequency of an oscillatory excitation field of amplitude 80 A/m was swept through a range of frequencies including the resonance and antiresonance. The amplitude and phase of the emf induced in a flux coil wound around the sample were recorded continuously through the whole resonance region. The calculated values of coefficients, g, μ_s, and s_B were corrected for the effects of specimen shape and resonant frequency using the plane wave model.[2]

A comparison was made of the measured response with that predicted from a model based on plane acoustic wave propagation in a magnetoelastic medium.[3,4] Values for the piezomagnetic strain coefficient g, permeability at constant strain μ, and the elastic compliance at constant induction s_B, enabled the magnetomechanical coupling coefficient k to be calculated. The resistivities of the specimens were measured using a standard four probe method.

RESULTS AND DISCUSSION

Nominal skin depth δ was calculated for all samples using

$$\delta = \sqrt{\rho/\nu\pi\mu}, \tag{3}$$

where ρ is the resistivity, ν is the frequency, and μ is the permeability. Skin depth variation for the different samples as a function of frequency is shown in Fig. 3. The skin depths for the doped specimens were calculated using Eq. (3) together with the measured values of the resistivity ρ. The resistivities of the doped samples are an average of 125% greater than the pure Terfenol samples. The skin depths at 1 kHz were found to be 80% greater in the doped specimens than in both the pure polycrystalline Terfenol and the pure single crystal Terfenol.

The polycrystalline unalloyed Tb–Dy–Fe material had $d=1.37\times10^{-9}$ m/A, $g=0.756\times10^{-3}$ A s^2/kg, and $k=0.23$. An addition of 1% Al increased d to 1.89×10^{-3} m/A and increased k to 0.287. An addition of 1% Si increased d to 1.92×10^{-9} m/A and increased k to 0.290. These results showed that alloying additions of either 1% Al or Si led to an increase of typically 55% in energy conversion efficiency in the material (see Table I). This improvement arises primarily because of the improved depth of penetration of the magnetic field in the material as shown in Fig. 3.

CONCLUSION

There is a need to extend the useful operating range of magnetostrictive materials such as Terfenol-D. Presently, material performance is limited by skin depth, which depends on conductivity of the material, and decreases with frequency. The most obvious means to achieve improved performance at high frequency is to limit or reduce the con-

TABLE I. Magnetomechanical coupling coefficients and energy conversion efficiency for various samples.

Sample	k	$(\Delta k)^2$
Polycrystalline Terfenol	0.232	...
Terfenol +1% Al	0.287	53%
Terfenol +1% Si	0.290	56%

ductivity. In this work we have alloyed 1% Al or Si with Terfenol to decrease the conductivity. A concomitant reduction in permeability occurs on the addition of Al or Si to Terfenol. This is due to pinning of domain walls by the impurity atoms. Results show that the addition of 1% Al or Si increased the resistivity thus leading to an improvement of field penetration at kHz frequencies and to a 53% or 56% improvement in energy conversion efficiency. However, the addition of higher concentrations of Al or Si resulted in specimens which were extremely brittle and this was recognized as disadvantageous. An alternate method of improving the performance would be through the fabrication of layered specimens consisting of alternate layers of Terfenol and a material of lower conductivity such as silicon.

Texture in magnetic annealed Terfenol-D films

M. Loveless and S. Guruswamy
Department of Metallurgical Engineering, University of Utah, Salt Lake City, Utah 84112

The paper will present an approach to obtaining (111) textured Terfenol-D films suitable for use in magnetostrictive devices. Amorphous thin films of Terfenol-D were rf magnetron sputter deposited on (100) silicon single crystal substrates. A composite target was used to obtain the Terfenol-D films. Samples were subsequently annealed in the range of 300 to 600 °C in the presence of a 2000 Oe magnetic field for times of 15 min to 1 h. X-ray diffraction studies were performed using a Siemens D5000 diffractometer to examine the changes in the preferred crystalline orientation in films with changes in annealing time, annealing temperature, and field orientation. The magnetic properties were examined using a Micromag 2900 alternating gradient magnetometer. Magnetic annealing at 450 °C showed the best combination of magnetic properties. The films exhibited in-plane H_c values in the range of near zero to 350 Oe and M_s values in the range of 200 to 550 emu/cc. © *1996 American Institute of Physics.* [S0021-8979(96)78208-6]

INTRODUCTION

Large magnetostrictive strains, of the order of 0.1%, make $(Dy_{0.3}Tb_{0.7})Fe_2$ (Terfenol-D) intermetallic bulk alloys and thin films very attractive for use as magnetostrictive sensors and actuators.[1,2] While these alloys have been used in bulk form in a number of commercial and military applications, their use in microactuation and sensing is beginning to be explored. Amorphous and crystalline films of Terfenol alloys have been prepared by several investigators[2–5] and the influence of annealing, composition variations, and sputtering conditions on the magnetostrictive behavior of these films have been examined. Amorphous films deposited without rf bias tend to show perpendicular anisotropy while films deposited with an rf bias have shown in-plane anisotropy.[4] Stresses in the as deposited film also influence the magnetic anisotropy of the film with tensile stresses promoting in-plane easy magnetization. Thermal annealing of amorphous Terfenol films with no applied magnetic field has shown that crystallization was achieved at 450 °C and the magnetic properties and magnetostrictive behavior was inferior to amorphous as deposited films.[4] Magnetic annealing treatments have been shown to modify the magnetostrictive behavior and the magnetic anisotropy in bulk magnetic Terfenol alloys.[6–8] The influence of magnetic annealing has been shown to depend on the stresses present in the film during annealing.[7]

This paper examines the possibility of applying an external magnetic field during annealing of amorphous Terfenol-D films to promote the nucleation of grains with [111] crystallographic axis in the film plane and in the direction of the applied field. The intent of this work is to examine the magnetic properties and the change in crystallographic orientation of magnetically annealed thin films as function of annealing time and temperature.

EXPERIMENTAL PROCEDURE

A film of Terfenol-D was deposited by rf magnetron sputtering from a mosaic target. The sputtering power was 150 W and the atmosphere was ultrahigh purity argon at a pressure of 5 mTorr. The target itself consists of a 2 in. diameter disk 100 μm thick of pure iron with pie shaped spokes of pure terbium and dysprosium spot welded to the surface. The nominal composition of a film produced from this target is $Tb_{0.30}Dy_{0.70}Fe_{2.00}$. The substrates used in these experiments were a 2 in. diam (100) silicon wafer and a 10 μm thick, 2 in. diameter (100) silicon membrane. This film was found to contain more iron than expected so another film was produced which contains less iron. The first film mentioned above will be referred to as the iron rich film and the second will be referred to as the iron deficient film.

Electron probe microanalysis was used to determine the composition of the deposited films.

The substrates were subsequently fractured into strips parallel to the primary flat. Small samples were taken and given magnetic annealing treatments in a high vacuum flash furnace. Annealing temperatures were 300 °C, 450 °C, and 600 °C. Annealing times were 15, 30, and 60 min. Table I shows the conditions for all of the annealing treatments.

Magnetic properties were measured parallel and perpendicular to the film plane of all samples using a vibrating sample magnetometer.

X-ray diffraction experiments were carried out on annealed samples and on the as deposited films.

RESULTS AND DISCUSSION

Total thickness of the iron rich film was around 2 μm as measured by an oscillating quartz crystal thickness monitor.

TABLE I. Summary of annealing treatments.

Sample	Annealing temp.	Annealing time	Field
Iron deficient	450 °C	30 min	no field
Iron deficient	450 °C	30 min	in-plane
Iron rich	300 °C	15 min	in-plane
Iron rich	300 °C	30 min	in-plane

 0021-8979/96/79(8)/6222/3/$10.00

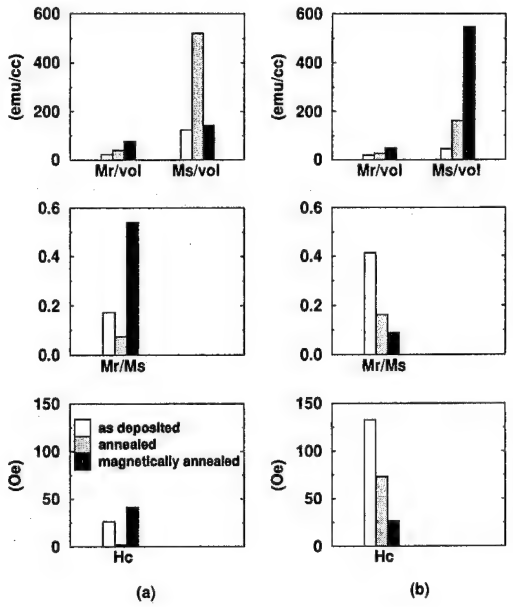

FIG. 1. Comparison of magnetic properties in the as deposited, annealed (450 °C, 30 min) and magnetically annealed (450 °C, 30 min) states of the iron deficient (a) and iron rich (b) films.

Sputtering was stopped when visual inspection of the substrate revealed that it had bulged up in the center. Examination of the target after sputtering showed that the rare earth portions of the target had worn completely through in some areas. The average surface stoichiometry of the film as determined by electron probe microanalysis is $Tb_{0.30}Dy_{0.70}Fe_{2.90}$. The excess iron content is due to the increased surface area of pure iron exposed on the target after the rare earth patches had worn through. After the original film was found to be off composition, a new film was deposited from a new target on a thick silicon wafer as well as the 10 μm silicon substrate. This new target was found to be intact after sputtering. Compositional analysis of the new film showed it to be $Tb_{0.34}Dy_{0.66}Fe_{1.64}$. Experiments at 450 °C were repeated on this film.

The curvature of both films in the as deposited state was toward the substrate, indicating compressive stresses in the films. Samples magnetically annealed at 300 °C retained this curvature while samples magnetically annealed at 450 °C and 600 °C changed their curvatures to indicate tensile stresses in the film. The sample annealed at 450 °C with no applied field also changed curvature. This result is independent of annealing time. The sample annealed at 600 °C for 60 min developed a rust colored oxide on the surface making the data obtained from this sample suspect.

Magnetic properties are affected profoundly by the presence of a magnetic field during annealing. Figure 1 shows a comparison of magnetic properties measured parallel to the film plane for as deposited, annealed, and magnetically annealed samples of both films. For the iron rich film, a clear trend is visible in the magnetic properties as a result of annealing treatment. The desirable properties of low coercivity (H_c), low M_r/M_s, and high saturation magnetization (M_s) are best achieved by the magnetically annealed sample.

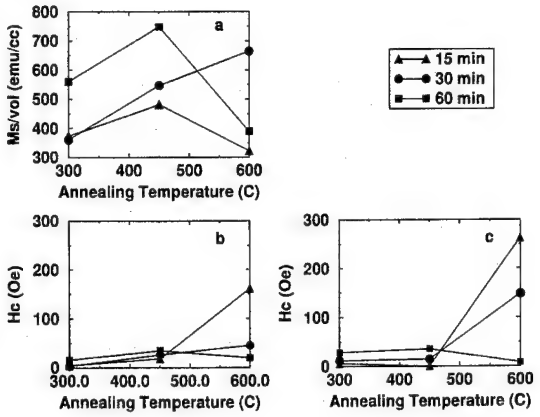

FIG. 2. Temperature dependence of M_s(a), and H_c measured parallel (b), and perpendicular (c) to magnetically annealed samples of the iron rich film.

Since strain in Terfenol-D alloys is more closely related to the magnetization than the applied field, the ratio M_r/M_s gives a good indication of the hysteresis that is expected in the magnetostriction. A lower value is desirable because that would indicate less hysteresis. The iron deficient film shows optimum properties in the no field annealed state.

Samples of the iron rich film tend to display maximum M_s when magnetically annealed at 450 °C. Samples magnetically annealed at 600 °C tend to have the largest H_c. The only exception to this is the 60 min sample magnetically annealed at 600 °C. This sample developed a rust colored oxide on the surface which possibly affects the coercivity. The coercivity measured parallel and perpendicular to the film plane tend to follow similar trends. Figure 2 shows these

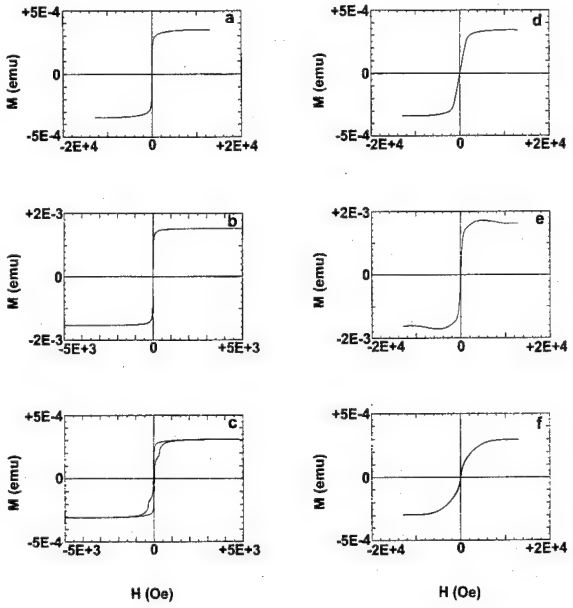

FIG. 3. Hysteresis loops of the iron deficient film measured in-plane for the as deposited (a), annealed (450 °C, 30 min) (b), magnetically annealed (450 °C, 30 min) (c) samples, and perpendicular to the film plane for the as deposited (d), annealed (450 °C, 30 min) (e), and magnetically annealed (450 °C, 30 min) (f) samples. The data shown is not normalized by sample volume.

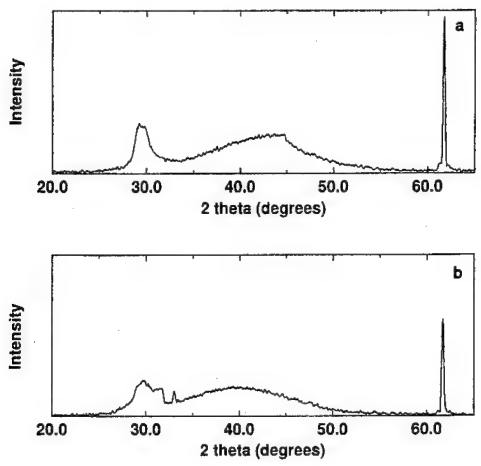

FIG. 4. X-ray spectrum of iron deficient film annealed at 450 °C for 30 min with no magnetic field (a) and with a magnetic field (b) present during annealing.

trends.

Figure 3 shows hysteresis loops of the iron deficient film measured in-plane and perpendicular to the film. Included in the figure are loops from the as deposited, annealed (450 °C, 30 min), and magnetically annealed (450 °C, 30 min) samples. As expected, saturation is achieved at lower fields when measured in-plane.

The properties of the iron deficient film were measured in two in plane directions to look for anisotropy resulting from the magnetic field during annealing. The properties measured parallel and perpendicular to the annealing field were found to be identical. This indicates that there is no in plane anisotropy of the magnetic properties.

X-ray diffraction showed the as deposited iron deficient film to be amorphous. The as deposited iron rich film spectrum has one small peak indicating the presence of some crystalline material. All samples of the iron deficient film showed strong peaks after annealing that could correspond to Fe_2(Tb,Dy). There were additional peaks in the magnetically annealed sample spectrum to those in the no field annealed spectrum. Other than the magnetic field present during annealing, these samples were processed identically. This indicates that the magnetic field causes some change in the crystalline nature of the film during annealing. Further investigation is necessary to determine the identity of all phases present. Possibilities include Fe_2(Tb,Dy), rare earth oxide, iron oxide, and pure dysprosium. All of these phases have peak positions in common with those found in the experimental diffraction patterns of the iron deficient film annealed at 450 °C for 30 min. Figure 4 shows the diffraction patterns of the iron deficient film annealed with and without a magnetic field at 450 °C for 30 min. Note the extra peaks in the spectrum of the magnetically annealed sample.

CONCLUSIONS

No preferred in-plane texture was observed as a result of the magnetic field during annealing. One possible explanation for this is the effect of the stresses found to be present in the film. Even though no strong evidence for texture was found, the presence of a magnetic field during annealing of Fe–Tb–Dy thin films does affect the crystal structure and magnetic properties. In the iron rich film, the magnetic field causes lower H_c and higher M_s values than annealing in the absence of a field. For the iron deficient film, the magnetic field causes higher H_c and lower M_s values.

Stress dependence of magnetostrictions and strains in ⟨111⟩-oriented single crystals of Terfenol-D

Xuegen Zhao, Guangheng Wu, Jinghua Wang, Kechang Jia, and Wenshan Zhan
State Key Laboratory for Magnetism, Institute of Physics, CAS, P.O. Box 603, Beijing 100080, People's Republic of China

Single crystals of $Tb_{0.27}Dy_{0.73}Fe_2$ were prepared successfully by the Czochralski (CZ) method using a magnetic levitation cold crucible first in this laboratory. The Laue x-ray technique and metallography verified its twin-free single crystalline perfection. Weidmanstatten precipitation (WSP) slightly exists in these specimens with WSP platelets parallel to the {111} planes of Terfenol-D. Saturation magnetostriction were measured along three principal crystallographic axes [111], [11 $\bar{2}$] and [1 $\bar{1}$0] of single crystal $Tb_{0.27}Dy_{0.73}Fe_2$ with magnetic field parallel and then perpendicular to the measuring direction, which gives an intrinsic magnetostriction $\lambda_{111}=1640\times10^{-6}$ for ⟨111⟩ easy axis. Stress dependence of magnetostrictions and strains measured along three mutually perpendicular axes, [111], [11 $\bar{2}$], and, [1 $\bar{1}$0] on ⟨111⟩-oriented single crystalline rods of Terfenol-D indicates that apparent magnetostriction for ⟨111⟩ direction increases with increasing applied compressive stress along the rod axis, and reaches 2375×10^{-6} under a stress of 24 MPa and a magnetic field of 20 kOe. Maximum d_{33} decreases with the increment of applied stresses and the amount of WSP, and ranges from 1×10^{-6}/Oe to 6×10^{-6}/Oe at about 500 Oe. Less hysteresis appears. Magnetizing processes are calculated and compared with the measured changes of magnetostriction. The authors conclude that ⟨111⟩-oriented single crystal of Terfenol-D is suitable for precise displacement actuators although it would be much better to eliminate the WSP precipitation. © *1996 American Institute of Physics.* [S0021-8979(96)78308-2]

INTRODUCTION

⟨111⟩-oriented single crystals of intermetallic compounds $Tb_xDy_{1-x}Fe_2$ with $x=0.27$ to 0.3, known as Terfenol-D, have been dreamed for more than ten years since Clark and co-workers[1] established that Terfenol-D exhibits very large anisotropic magnetostriction, $\lambda_{111}\gg\lambda_{100}$, and rather low magnetocrystalline anisotropy. It is expected that single crystal rods with a ⟨111⟩ axial orientation and a low defect density posses optimum magnetostrictive properties and find broad applications in vibration emitters such as sonar transducers. Unfortunately, it was only possible to grow crystals along ⟨112⟩ direction and usually occupied by lamellar twins with the plated face parallel to the (111) plane. Much work[2] has been done on such twinned single crystals and it has been found[3,4] such crystals exhibit excellent magnetostrictive properties under compressive stress but twin interfaces, rare earth inclusion and Weidmanstatten precipitates (WSP) and defects inhibit magnetic domain movements by pinning mechanisms. Recently, twin-free ⟨111⟩-oriented single crystals of Terfenol-D have been grown[5] successfully in this laboratory with a cold crucible. The stress dependence of magnetostrictions and elastic strains of single crystals has been investigated.

EXPERIMENTAL METHODS

Single crystals of $Tb_{0.27}Dy_{0.73}Fe_2$ were grown by using the Czochroaski method with an induction heating magnetic levitation cold crucible. Starting materials of composition $Tb_{0.27}Dy_{0.73}Fe_y$, with $y=1.60$–1.80, were prepared from metals of the purity of 99.95%. The metals were alloyed by means of a rf induction heating cold crucible growth system for about 1 h before growth. ⟨111⟩ oriented single crystal bars with dimensions of about $2\times2\times10$ mm^3 were used as seeds. X-ray diffraction, Laue back-reflection and metallographical examinations were employed to determine if the samples were single crystals and determine the crystallographic directions. Crystal rods as grown with diameters of 6–12 mm and maximum length of about 80 mm were cut into bars of $5\times5\times15$ mm^3 with [111], [11 $\bar{2}$] and [1 $\bar{1}$0] crystal axes perpendicular to their surfaces respectively. Compressive stresses up to 24 MPa were applied along the ⟨111⟩ axial direction by a screw-driven aluminum device fixed between the poles of an electromagnet. The electromagnet with a fixed pole gap of 5 cm can produce a magnetic field up to 20 kOe. Magnetostrictions and strains were measured by strain gauge method.

RESULTS AND DISCUSSION

X-ray diffraction showed the characteristic diffraction peaks of (111), (222), (333) solely on the transverse sections of the specimens. Laue back-reflection photography confirmed them to be single crystalline with the growth direction along ⟨111⟩ axis. No other phases can be distinguished. However metallographical microscopy shows the existence of slight Weidmanstatten precipitates parallel to {111} planes. WSP can be used as the macro-scale trace of twin interfaces because it always appears parallel to {111}. However WSP traces show no existence of twins in these samples. Zones that are not rare earth rich and without WSP can be found along the rod sometimes. It suggests critical conditions be necessary for growing WSP-and-inclusion-free single crystals of Terfenol-D.

Magnetostrictions were measured at room temperature along three perpendicular crystallographic axes, [111], [11 $\bar{2}$] and [1 $\bar{1}$0].

 0021-8979/96/79(8)/6225/3/$10.00

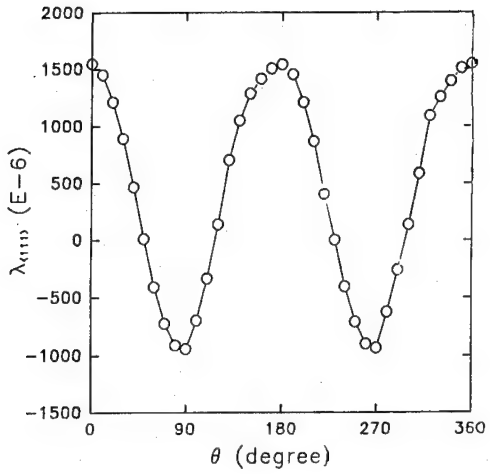

FIG. 1. Magnetostriction vs the relative angles between the [111] measuring direction and applied (1 $\bar{1}$0) magnetic field.

The saturation magnetostrictions measured with applied magnetic field of 20 kOe rotating in (11 $\bar{2}$) and (1 $\bar{1}$0) planes were used to calculate the intrinsic magnetostriction λ_{111} by means of the well-known equation

$$\lambda=(3/2)\lambda_{100}(\alpha_1^2\beta_1^2+\alpha_2^2\beta_2^2+\alpha_3^2\beta_3^2)+3\lambda_{111}\times(\alpha_1\alpha_2\beta_1\beta_2+\alpha_2\alpha_3\beta_2\beta_3+\alpha_3\alpha_1\beta_3\beta_1). \quad (1)$$

In which α_i and β_i are the direction cosines of magnetization and measuring direction relative to principal ⟨100⟩ crystallographic axes. This method eliminates the influence of prealignments of magnetic domains caused by residual stress or magnetizing history. One of the experimental results is shown in Fig. 1. An intrinsic magnetostriction $\lambda_{111}=1640\times10^{-6}$ for ⟨111⟩ easy axis has been obtained, which is consistent with the previous result.[1]

The magnetostrictions measured with the magnetic field and compressive stress applied in the axial direction of [111] are shown in Fig. 2. The magnetostriction in the axial direction at 3 kOe increases with increasing applied compressive stress until it reaches a maximum of 2200×10^{-6} under 12 MPa, then decreases slightly. The relative change d_{33} of magnetostriction with magnetic field almost be unchanged until 6 MPa, then it becomes smaller with increasing applied compressive stress. d_{33} can range from 1×10^{-6}/Oe to 6×10^{-6}/Oe at about 500 Oe when the sample is located in a magnetically close circuit. Less hysteresis appears. However the saturation field shifts higher when compressive stress increases, which is true for the stress dependence of magnetostrictions along the [11 $\bar{2}$] and [1 $\bar{1}$0] directions.

It should be noticed that the magnetostrictive behavior under 18 MPa is very different from others. Another magnetization process can be seen clearly in the region of 2.0–2.5 kOe. The [111] magnetostriction changes with a unique slope and the [11 $\bar{2}$] one begins to decrease with increasing magnetic field. This phenomenon also appears in the sample with much fewer defects even under a rather low stress of 3 MPa, as illustrated in Fig. 3.

The elastic strains ϵ of specimens under different stress and 0, 20 kOe magnetic field were measured and shown in Fig. 4. The strains measured in a magnetic field of 20 kOe which is large enough to saturate the specimens, are much smaller than that at 0 kOe due to the large magnetostriction. The change rate of these two strains relative to applied stresses decreases with increasing stresses.

The maximum magnetostrictive strain measured along [111] direction was also shown in Fig. 4. It increases faster under the lower stresses of 0–9 MPa. It is regarded that the

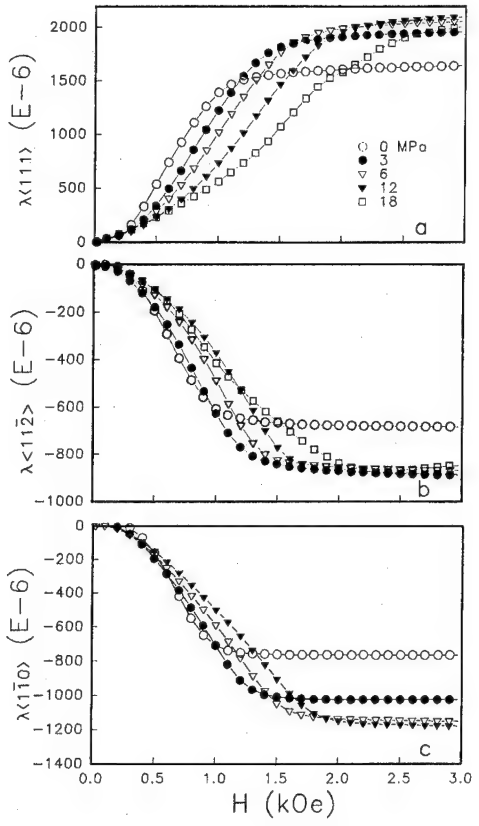

FIG. 2. Magnetostriction curves vs applied magnetic field under different compressive stresses, measured in the direction of (a) [111], (b) [11 $\bar{2}$], and (c) [1 $\bar{1}$0].

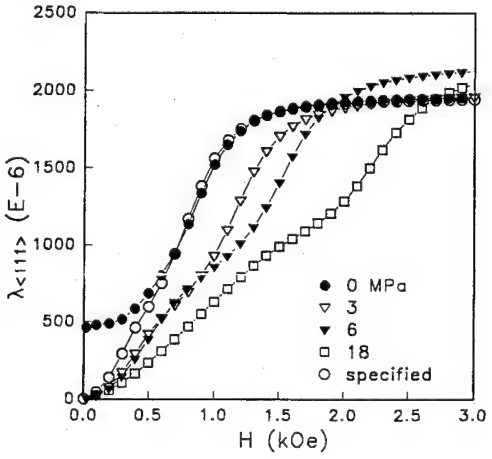

FIG. 3. Magnetostriction curves vs applied magnetic field under different compressive stresses, measured in the direction of [111].

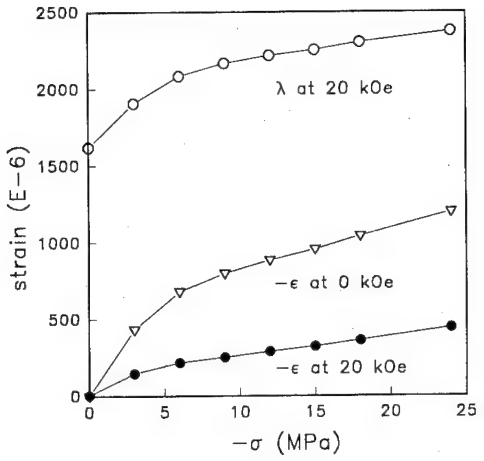

FIG. 4. Magnetostriction λ and elastic strains ϵ vs applied compressive stress, measured in the direction of [111].

magnetic domains rotate their directions from the axial [111] toward other ⟨111⟩ easy axes under certain stress, which increases the volume of non-180° magnetic domain movements that contribute to magnetostrictive strain. This rotation process seems easy because it proceeds between easy directions. Using Eq. (1) and the magnetostrictions measured in three directions mentioned above, we have calculated the possible arrangement of magnetic domains. We found that when the ⟨111⟩ magnetostriction reaches about 2200×10^{-6} in which the magnetic domains could be assumed to arrange completely along the ⟨111⟩ axes other than the [111] axis at the beginning, the distributions of magnetic domains in other ⟨111⟩ axes are not equal. It might results from the deviation of the applied stress from the axial ⟨111⟩ direction. Under higher stress, the magnetic domains rotate from the ⟨111⟩ easy directions toward ⟨112⟩ directions which are perpendicular to the axial [111] direction. The larger stress is needed to overcome the higher magnetocrystalline anisotropy in the ⟨112⟩ directions. Inclusions and defects hinder all of these rotations.

We can expect that the maximum magnetostrictive strain of 2460×10^{-6} calculated from the measured ⟨111⟩ magnetostriction should be attained when all magnetic moments be forced perpendicular to the axial ⟨111⟩ direction at the beginning. But it is not the case even when the applied stress reaches 24 MPa, a stress enough to overcome the magnetocrystalline anisotropy energy in ⟨112⟩ directions. We can only obtain a maximum magnetostriction of 2375×10^{-6}. The mechanical interactions of inclusions and defects with magnetic domains or of magnetic domains with each other may be the reason. It is known that a magnetic heat treatment will improve dramatically the magnetostrictive properties of twinned single crystals with an axial ⟨112⟩ direction and cause a large magnetostrictive jump at low magnetic field. The treatment makes magnetic domains arrange along the same direction just like a single domain and makes the inherent rotation of magnetic domains possible. It also diminishes the mechanical interactions in the sample and reduces the compressive prestress necessary to obtain maximum strain. It would be better if ⟨111⟩-oriented single crystal be annealed in a magnetic field large enough to make all magnetic domains arranged parallel one ⟨112⟩ axis and perpendicular to ⟨111⟩ axial direction, or just only parallel to one ⟨111⟩ axis that is far from the axial ⟨111⟩. Certainly, growth condition should be delicately controlled in order to prevent the formation of rare earth inclusion or WSP.

CONCLUSION

Twin free ⟨111⟩ oriented single crystals of Terfenol-D, $Tb_{0.27}Dy_{0.73}Fe_2$, have been grown by means of CZ method with an induction heating magnetic levitation cold crucible. The magnetostriction measurements along [111], [11 $\bar{2}$] and [1 $\bar{1}$0] directions with applied magnetic field of 20 kOe rotating in (11 $\bar{2}$) and (1 $\bar{1}$0) planes have confirmed the intrinsic ⟨111⟩ magnetostriction $\lambda_{111}=1640\times10^{-6}$, and $\lambda_{111}\gg\lambda_{100}$. With stress and magnetic field applied in the axial ⟨111⟩ direction, the saturation magnetostriction in this direction and at the field of 20 kOe increases with increasing applied stress, so does the saturation magnetic field. However maximum d_{33} does not change until 6 MPa but decreases with further increase of the applied stresses, and ranges from 1×10^{-6}/Oe to 6×10^{-6}/Oe. Two magnetizing stages can be observed in these samples under certain stresses, which demonstrates two different inherent magnetic domain movements. The maximum magnetostriction available in ⟨111⟩ direction is 2375×10^{-6}, not the calculated value of 2460×10^{-6}. The interaction of defects and magnetic domains should be taken into account. No hysteresis can be seen apparently. The authors think that these materials are suitable for vibrating emitters and displacement actuators where the stress can change not too much. Defect-free single crystals would show better magnetostrictive properties.

Effects of surface topology and texture on exchange anisotropy in NiFe/Cu/NiFe/FeMn spin valves

C.-M. Park, K.-I. Min, and K. H. Shin
Division of Metals, Korea Institute of Science and Technology, P.O. Box 131, Cheongryang, Seoul 130-650, Korea

We have investigated the effects of texture and interfacial roughness on the exchange anisotropy in NiFe/Cu/NiFe/FeMn spin valves with different buffer layers (no buffer, Cu, or FeMn) on Si(100) or Si(111) substrates by magnetron sputtering. The crystalline structure, surface topology, and exchange anisotropy field (H_{ex}) were characterized. The exchange anisotropy was established all in (111), (200), and (220) textured samples and there was no systematic relationship between the type of texture and H_{ex}. However, it was found that H_{ex} increased as the surface roughness decreased. The results lead us to believe that interfacial roughness rather than crystallographic texture controls the development of the exchange anisotropy. © *1996 American Institute of Physics.* [S0021-8979(96)55308-0]

I. INTRODUCTION

Giant magnetoresistance of exchange-biased spin valve multilayers of the NiFe/Cu/NiFe/FeMn type has received much attention. The magnetotransport behavior is dependent on unidirectional exchange anisotropy at the interface between the ferromagnetic layer and the antiferromagnetic layer. There has been great interest in the factors that influence the exchange anisotropy.[1,2]

Many reports state that crystalline orientation conditions are important for the establishment of the exchange anisotropy. It has been reported,[1] for example, that the exchange anisotropy field is large when the (111) diffracted intensity of spin valve sandwich is high. Jungblut *et al.*[2] reported that the exchange anisotropy field in NiFe/FeMn couple strongly depends on the crystal orientation. Jungblut *et al.* also tried to account for the orientational dependence of exchange anisotropy field by crystallographic condition, i.e., the compensated or uncompensated nature of ideal NiFe/FeMn interface, but no obvious relation between experimental result and theoretical expectation was observed.

The shortcoming of the interfacial crystallographic condition for exchange anisotropy is that it ignores topological roughness of the ferromagnetic/antiferromagnetic interface. Real interfaces have some roughness and the exchange interaction at the interface is likely to be far more complicated than in the ideal planar case. So far there has been little study on the effects of the interfacial topology on the exchange anisotropy.

The purpose of this study is to examine the effects of preferred orientation and interfacial topology on the exchange anisotropy of spin valves.

II. EXPERIMENT

Exchange-biased spin valve samples consisting of Si/buffer layer 50 Å/NiFe 80 Å/Cu 28 Å/NiFe 40 Å/FeMn 150 Å/Cu 50 Å were fabricated by three-gun magnetron sputtering with 5×10^{-3} Torr argon pressure during deposition. Ferromagnetic NiFe layers were deposited by rf magnetron sputtering and the other layers (Cu and FeMn) were deposited by dc magnetron sputtering. The base pressure was below 5×10^{-7} Torr. Films of 1×1 cm^2 were deposited at room temperature in a uniform magnetic field of 300 Oe which determines the direction of exchange anisotropy.

For texture control, FeMn and Cu buffer layers were used with Si(100) or Si(111) substrates, which were precleaned with dilute HF. For Si(111) substrates, the Si[111] axis was off orientation by 4° from the surface normal toward a Si[110] axis. Samples without a buffer layer were also fabricated.

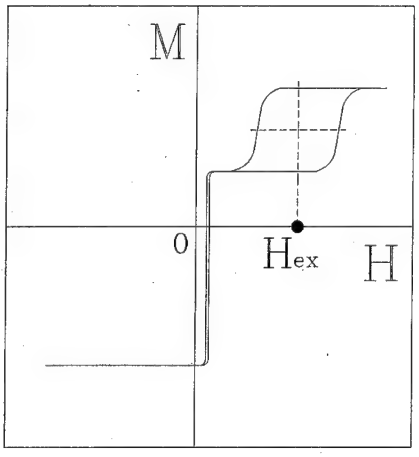

FIG. 1. Typical hysteresis loop of exchange-biased spin valve. The exchange anisotropy field H_{ex} is defined as the horizontal shift of the center of the hysteresis loop of the exchange-biased ferromagnetic layer.

 0021-8979/96/79(8)/6228/3/$10.00

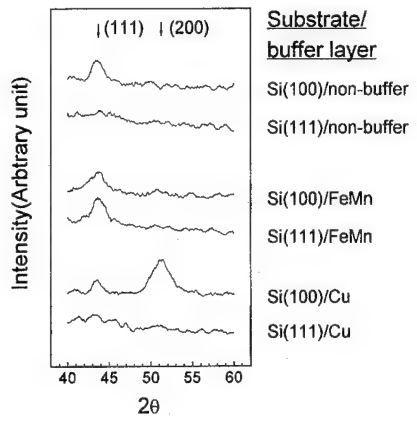

FIG. 2. X-ray diffraction patterns of Si(111 or 100)/NiFe 80 Å/Cu 28 Å/NiFe 40 Å/FeMn 150 Å/Cu 50 Å and Si/(Cu or FeMn 50 Å)/NiFe 80 Å/Cu 28 Å/NiFe 40 Å/FeMn 150 Å/Cu 50 Å.

Crystallographic texture of the samples was assessed by x-ray diffraction. Transmission electron microscopy (TEM) analysis was also performed on selected samples. The exchange anisotropy fields were characterized by a vibrating sample magnetometer (VSM). H_{ex} corresponds to the horizontal shift of the center of the hysteresis loop from the center of whole plot due to the exchange anisotropy of the NiFe/FeMn couple. Figure 1 shows how H_{ex} is determined from an M-H curve.

In order to characterize the interfacial topology, surface topology analyses were performed by using PSI AP-200 AutoProbe LS atomic force microscope (AFM). Because multilayers often grow coherently up to considerable thickness when deposited by sputtering, it is reasonable to think that the surface topology is related to the interface topology, if the interface is not too far from the top surface. In our case, they are separated by 200 Å.

III. RESULTS AND DISCUSSION

X-ray diffraction patterns of six spin valve samples with different buffer layers grown on Si(100) or Si(111) substrates are shown in Fig. 2. For samples with an FeMn buffer layer on Si(100) or Si(111) substrate, a (111) peak is observed. The sample without a buffer layer on Si(100) shows a (111) peak. No sign of peak is seen in the unbuffered sample grown on Si(111). A (200) peak with a weak trace of (111) peak is detected in a sample with a Cu buffer layer on Si(100). The predominant (200) texturing is consistent with previous reports.[3,4] For the sample with a Cu buffer layer on Si(111), no peak is observed. TEM analysis, however, suggested a pseudoepitaxial (220) growth, similar to that reported[5] in NiFe/Cu multilayers with a Cu buffer layer on misoriented Si(111) substrates. No sign of (220) peak was observed near the expected position ($2\theta \sim 75°$), which is not shown in Fig. 2. More detailed description of the TEM analysis will be published elsewhere.

The exchange anisotropy field H_{ex} determined from an M-H curve is shown, together with the textures developed, in Table I. The samples with an FeMn buffer layer have larger H_{ex} values by about a factor of 2 than those without a buffer layer. The samples with a Cu buffer layer have intermediate H_{ex} values. It seems from Table I that H_{ex} does not depend on the substrate, whether it be Si(100) or Si(111).

TABLE I. Textures and exchange anisotropy field (H_{ex}) values of the samples shown in Fig. 2.

Substrate and buffer layer	Texture	H_{ex} (Oe)
Si(100)/nonbuffer	(111)	80
Si(111)/nonbuffer	untextured	80
Si(100)/FeMn	(111)	180
Si(111)/FeMn	(111)	190
Si(100)/Cu	(200)+weaker (111)	130
Si(111)/Cu	(220)[a]	140

[a](220) texture is identified from TEM diffraction pattern analysis, not from XRD spectrum.

A prominent feature of the results is that a considerable exchange anisotropy field of about 130 Oe is established for the samples that have the preferred orientations (200) and (220). Also noticeable is the fact that H_{ex}'s of 80 Oe at the least are observed for all samples including the untextured one. Nakatani *et al.*[1] have reported that the FeMn layer becomes antiferromagnetic and applies an exchange bias field to the NiFe layer when a sample has a high (111) diffracted intensity. From our study, however, it is found that there is

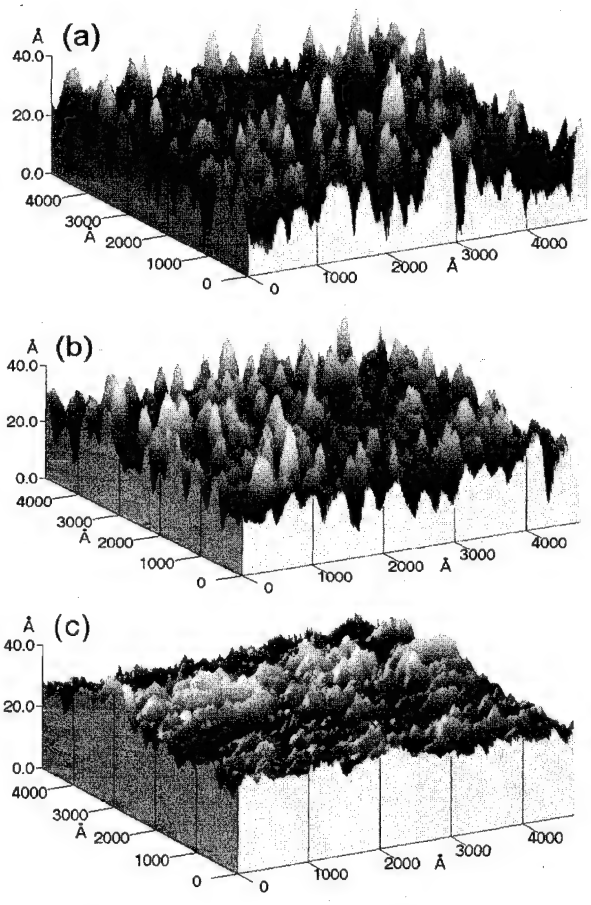

FIG. 3. AFM surface topographs of (a) nonbuffered, (b) Cu buffered, and (c) FeMn buffered NiFe/Cu/NiFe/FeMn/Cu films on Si(111) substrates.

no proportional dependence of H_{ex} on (111) diffracted intensity. Jungblut *et al.*[2] have investigated a dependence of H_{ex} of molecular-beam-epitaxy-grown Cu/NiFe/FeMn samples on the growth orientation and found that there is no obvious relation between the H_{ex} and the compensated or uncompensated nature of the NiFe/FeMn interface. Our results based on texture are consistent with this finding of Jungblut *et al.* Both results suggest that a specific texture is not necessarily a critical factor for establishing an exchange anisotropy, and that preferred orientation alone cannot explain this phenomenon satisfactorily.

No current theoretical model can account for the experimental results of the largest exchange anisotropy field with (111) texturing in FeMn. The discrepancy between expectation and experimental result can be attributed to the assumption that NiFe/FeMn couple has an ideal interface.

The idealized interface does not exist in reality as in the case of multilayers deposited by sputtering. In this case, interfacial roughness can have a great influence on the exchange interaction at the interface by changing the local spin arrangement and the number of antiparallel moments at the interfacial plane. In the naive picture of the uncompensated ideal interface, for example, roughness will cause compensation and thus reduction of H_{ex}. The interface topology, therefore, must be examined in addition to the texture.

Surface topographs of films grown on Si(111) substrates taken by AFM are shown in Fig. 3. These figures show peaks and valleys. Valleys are several hundred angstroms apart on the average. This is roughly of the size of the grains, suggesting that this surface topology may be closely related to the nucleation and growth of the initial film layer. It can be seen from Fig. 3 that the surface becomes flatter when a Cu buffer layer is introduced and even flatter in the case of an FeMn buffer layer. In Table II, roughness parameters (median height, mean height, R_{rms}, and R_{ave}) are given, together with their definitions. It is obvious from this table that roughness decreases in the sequence of nonbuffer, Cu, and FeMn, and H_{ex} increases in this sequence. Therefore, a systematic relationship is found between the surface roughness and H_{ex};

TABLE II. Surface roughness for AFM height profiles shown in Fig. 3, estimated by the parameters defined as follows: $\bar{z}$=mean height $=\frac{1}{N}\sum_{n=1}^{N} z_n$, $R_{rms}=\sqrt{\sum_{n=1}^{N}(z_n-\bar{z})^2/(N-1)}$, $R_{ave}=\sum_{n=1}^{N}|z_n-\bar{z}|/(N)$, where N is the number of data points and z is the height of each data point within the height profile. Median height is the height value which divides the height histogram into two equal areas.

Si(111)/ buffer layer	Median height (Å)	Mean height (Å)	R_{rms} (Å)	R_{ave} (Å)	H_{ex} (Oe)
Nonbuffer	25	23	6.9	5.5	80
Cu	20	18	5.6	4.4	140
FeMn	12	12	3.2	2.4	190

namely samples with flatter surfaces have larger exchange anisotropy. Summarizing our results, it seems that the exchange anisotropy is more sensitive to surface roughness than to the specific texture of the sputter-deposited film. Our results suggest that the dependence of exchange anisotropy on texture reported in previous works[1,2] might result from changes in NiFe/FeMn interface topology rather than in texture. More sophisticated experiments are required to examine the connection of crystallography with the interfacial exchange interaction.

IV. CONCLUSION

For exchange-biased spin valves with (111), (200), or (220) textures, no systematic relation between the texture and exchange anisotropy was observed. It was found that the exchange anisotropy increased as the surface roughness decreased. These results lead us to emphasize the role of interfacial roughness rather than texture in the establishment of exchange anisotropy.

High sensitivity in magnetoresistance of epitaxial NiFe/Cu/Co (/Cu) (100) superlattices

Y. Kawawake, H. Sakakima, Y. Irie, and M. Satomi
Central Research Labs., Matsushita Electric Industrial Co., Ltd. 3-4, Hikaridai, Seika-cho, Souraku-gun, Kyoto-fu, 619-02, Japan

Noncoupled-type [NiFe/Cu/Co(/Cu)] single-crystal-like superlattices were prepared on Si/Cu(100) substrates using ultrahigh vacuum evaporation. Si/Cu (5 nm)/[Co (3 nm)/Cu (6 nm)/NiFe (3 nm)/Cu (6 nm)]×10 multilayers showed 6.1% magnetoresistance (MR) change with 2 kA/m of applied field, which is much higher sensitivity than those of poly-crystalline films. Furthermore, placing a thin Ag layer (0.2 nm) at the midpoint of a Cu layer improved the MR sensitivity of the epitaxial film. Sandwich-type Si/Cu (5 nm)/NiFe (10 nm)/Cu (2.4 nm)/Ag (0.2 nm)/Cu (2.4 nm)/Co (10 nm) superlattice showed sharp switching characteristics of the MR curve between lower and 4.3% higher resistivity. These epitaxial films showed biaxial anisotropy in the film plane with easy axes of [011] and [0$\bar{1}$1] directions. The higher MR sensitivity in the epitaxial films may originate in the square-shaped magnetization curves along the easy axes [011] and [0$\bar{1}$1] of the Co layers. Flatness of interface was also effective to improve the MR sensitivity of the films. [S0021-8979(96)55408-7]

I. INTRODUCTION

Among a number of systems showing a giant magnetoresistance (MR) behavior, noncoupled-type [NiFe/Cu/Co/Cu] multilayers have been intensively studied because of their low-field operation.[1] In the above system, antiparallel alignment of magnetizations was realized by using the difference of the coercivities of two ferromagnetic layers. Shinjo and Yamamoto reported that glass/[Co (3 nm)/Cu (5 nm)/NiFe (3 nm)/Cu (5 nm)]×15 multilayers showed a resistivity change of 7% in 100 Oe (≅8 kA/m).[1] This sensitivity is lower than that of FeMn/NiFe/Cu/NiFe spin-valve multilayers.[2] In this study, we have tried to improve the sensitivity of NiFe/Cu/Co/Cu multilayers by improving the soft magnetic properties of NiFe layers by reducing the couplings between ferromagnetic layers.

Epitaxial NiFe/Cu/Co(/Cu) superlattices were prepared on Si/Cu (100) substrates to control the crystalline anisotropy of NiFe and Co magnetizations. In the epitaxial [NiFe/Cu] multilayers[3] and Co/Cu/Co sandwich films,[4] the exchange couplings between ferromagnetic layers with the (100) orientation were smaller than those with the (111) orientation.[3,4] Therefore (100) orientation could be thought preferable orientation to improve MR sensitivity in noncoupled type NiFe/Cu/Co(/Cu) films than (111) orientation.

II. EXPERIMENT

HF etched Si(100) single-crystal substrate was placed in an ultrahigh vacuum chamber. A 5–50 nm thick Cu buffer layer was deposited on Si(100) substrate at room temperature (RT) and NiFe/Cu/Co(/Cu) film was prepared on the Cu buffer layer at RT. Crystal growth was *in situ* monitored by reflection high-energy electron diffraction (RHEED). MR was measured by four-point probe method and magnetization was measured by a vibrating sample magnetometer (VSM). Magnetic field was applied both in [011] and in [001] directions in the film plane. Electric current was along the [001] direction of the film in the film plane. All measurements were performed at RT.

III. RESULTS AND DISCUSSION

After the deposition of 50-nm-thick Cu buffer layer on Si(100) substrate, a strain-free flat surface of Cu(100) was realized.[3] Figure 1(a) shows RHEED pattern after the deposition of Si/Cu (5 nm)/[Co (3 nm)/Cu (5 nm)/NiFe (3 nm)/Cu (5 nm)]×10 multilayers. Streak pattern of RHEED was maintained during the deposition of the [Co/Cu/NiFe/Cu] multilayers. The orientational relationships of the sample are Si(100)//Cu(100)//Co(100)//NiFe(100) in the stacking direction and Si[011]//Cu[001]//Co[001]//NiFe[001] in the film plane.

Figure 2 shows Cu layer thickness t dependence of MR curve of Si/Cu (5 nm)/[Co (3 nm)/Cu (t nm)/NiFe (3 nm)/Cu (t nm)]×10 multilayers. The MR ratio of the sample with $t=6$ changes from 0.4% to 6.5% in the field range from 0 to 2 kA/m in [011] direction (solid line) while smaller change in MR ratio could be observed in [001] direction (dashed line). These films showed biaxial anisotropy with easy axes of [001] and [0$\bar{1}$1] directions in the film plane. As t increases, the MR ratio decreases owing to shunting effect ($t \geqslant 6$), however, in the $t=10$ sample clear switching characteristics between high and low resistivity could be observed due to free and independent rotations of Co and NiFe magnetizations. Couplings between Co and NiFe layers exist to some extent even in the sample with $t=6$.

To reduce the couplings between ferromagnetic layers, we interposed thin Ag layer at the midpoint of a Cu layer. Figure 3 shows MR curves of Si/Cu (5 nm)/[Co (3 nm)/Cu ($2.5-x/2$ nm)/Ag (x nm)/Cu ($2.5-x/2$ nm)/NiFe (3 nm)/Cu ($2.5-x/2$ nm)/Ag (x nm)/Cu ($2.5-x/2$ nm)]×10 multilayers. The samples with $x=0.1$ and 0.2 show higher sensitivities than the sample without Ag layer ($x=0$). The MR ratio of the sample with $x=0.4$ is lower than those of $x \leqslant 0.2$ and the MR curves of the sample has negligible angular dependence,

 0021-8979/96/79(8)/6231/3/$10.00

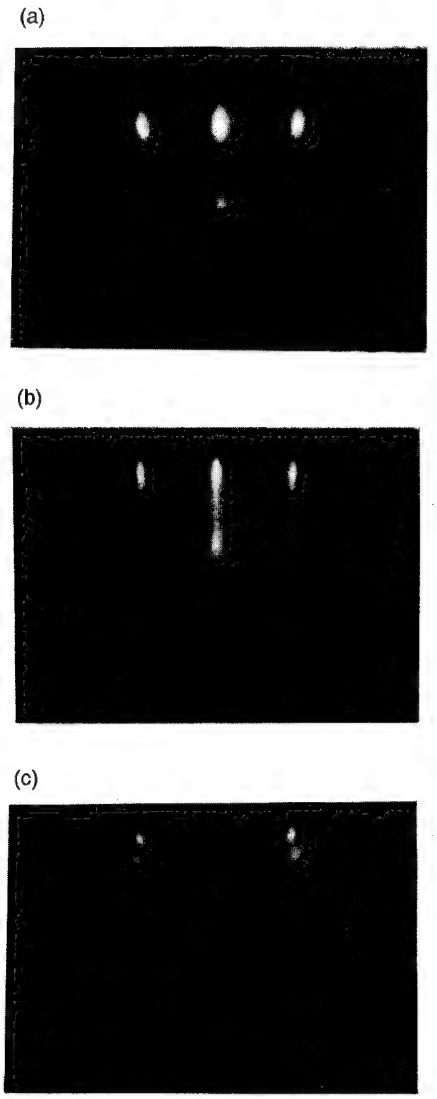

FIG. 1. RHEED patterns of Si/Cu (50 nm)/[Co (3 nm)/Cu (2.5−x/2 nm)/Ag (x nm)/Cu (2.5−x/2 nm)/NiFe (3 nm)/Cu (2.5−x/2 nm)/Ag (x nm)/Cu (2.5 −x/2 nm)]×10 multilayers. (a) x=0, (b) x=0.2, and (c) x=0.4.

which is characteristic of poly-crystalline film. RHEED patterns after deposition of the samples with x=0, 0.2 and 0.4 are shown in Fig. 1. Figure 1(b) (x=0.2) shows a more streaky pattern, which is indicating a flatter surface of the film, than Fig. 1(c) (x=0). This result possibly indicates that the interposition of thin Ag layers improves the flatness of the interface between ferromagnetic and nonmagnetic layers.

We have also investigated electric and magnetic properties of sandwich-type NiFe/Cu(/Ag/Cu)/Co films in Si/Cu substrates. In this case, samples were prepared on a thinner buffer layer to increase resistance. Therefore more distortion was induced in these samples, however, they were epitaxially grown on Si/Cu with the same orientational relationships as those of the samples on 50-nm-thick Cu buffer layer. Figure 4 shows (a) MR and (b) magnetization curves of Si/Cu (5 nm)/NiFe (10 nm)/Cu (2.4 nm)/Ag (0.2 nm)/Cu (2.4 nm)/Co (10 nm) film. Figure 4(a) shows clear switching characteristics of resistivity along the [011] direction in the film plane. The MR ratios of the samples are 4.3% and 3.4% in [011]

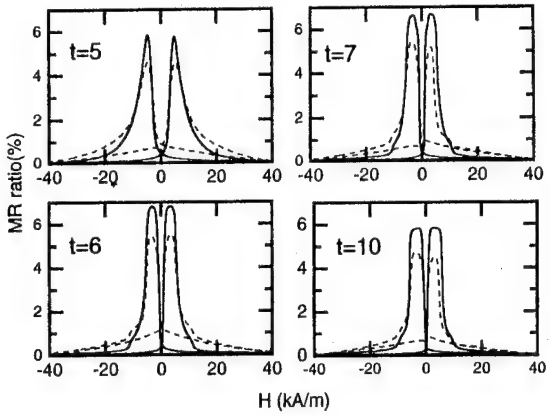

FIG. 2. Room-temperature MR curves for Si/Cu (50 nm)/[Co 3 nm)/Cu (t nm)/NiFe (3 nm)/Cu (t nm)]×10 multilayers with Cu thickness t of 5, 6, 7, and 10 nm. Magnetic field was applied both in the [011] direction (solid line) and in the [001] direction (dashed line).

and [001] directions, respectively. The difference in MR curves between [011] and [001] should come from the difference between magnetization curves of both directions. In Fig. 4(b), the soft layer (NiFe layer) rotates at about 1 kA/m in the same way in both directions, however, only about 70% of the magnetization of the hard layer (Co layer) rotates at about 3.5 kA/m in the [001] direction, while the nearly whole magnetization of the Co layer rotates at the same field in the [011] direction.

In a cubic crystal, magnetocrystalline anisotropy E_a is generally expressed by

$$E_a = K_1(\alpha_1^2\alpha_2^2 + \alpha_2^2\alpha_3^2 + \alpha_3^2\alpha_1^2) + K_2\alpha_1^2\alpha_2^2\alpha_3^2 + \cdots, \quad (1)$$

where α_1, α_2, and α_3 are direction cosines of magnetization from the crystallographic axes and K_1 and K_2 are cubic anisotropy constants.[5] When the magnetization rotates in the (100) plane, the second term of Eq. (1) is zero and it is expressed as

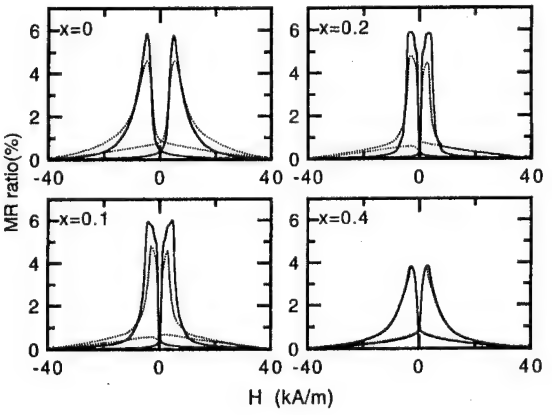

FIG. 3. MR curves of Si/Cu (50 nm)/[Co (3 nm)/Cu (2.5−x/2 nm)/Ag (x nm)/Cu (2.5−x/2 nm)/NiFe (3 nm)/Cu (2.5−x/2 nm)/Ag (x nm)/Cu (2.5 −x/2 nm)]×10 multilayers with Ag thickness x of 0, 0.1, 0.2, and 0.4 nm. Magnetic field was applied both in the [011] direction (solid line) and in the [001] direction (dashed line).

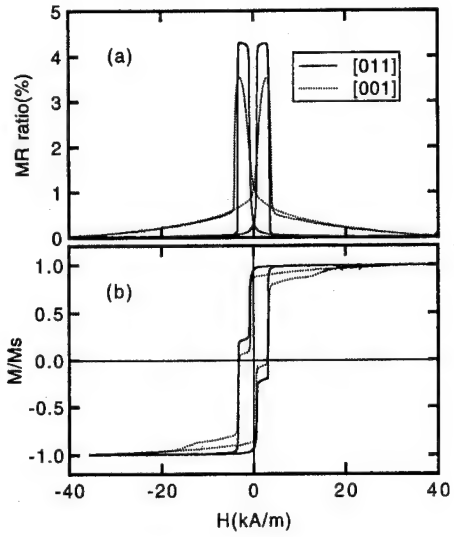

FIG. 4. MR and magnetization curves of Si/Cu (5 nm)/NiFe (10 nm)/Cu (2.4 nm)/Ag (0.2 nm)/Cu (2.4 nm)/Co (10 nm) film with the applied field in the [011] direction (solid line) and in the [001] direction (dashed line).

$$E_a=\frac{K_1}{8}(1-\cos 4\theta)+\cdots, \tag{2}$$

where θ is an angle between magnetization and [010] axis. In fcc Co, the sign of K_1 is minus.[6] Therefore Eq. (2) means biaxial anisotropy with the easy axes of [011] and [$0\bar{1}1$] in the plane. This qualitatively agrees with the results on the epitaxial NiFe/Cu/Co(/Cu) films. The origin of biaxial anisotropy of the films comes from crystalline anisotropy of fcc Co.

Minor MR loop was also measured on the sample along the [011] direction as shown in Fig. 5. In Fig. 5, Co magnetization is fixed to one direction and NiFe magnetization rotates from parallel state to antiparallel state to Co magnetization at H_2, and from antiparallel to parallel at H_1. Therefore the switching fields, H_1 and H_2 can be written as follows:

$$H_1=H_{\text{coupling}}-H_{c\text{NiFe}}, \quad H_2=H_{\text{coupling}}+H_{c\text{NiFe}}, \tag{3}$$

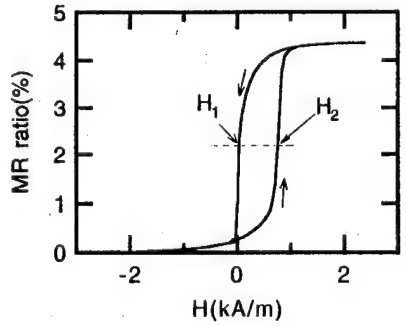

FIG. 5. MR minor loop of Si/Cu (5 nm)/NiFe (10 nm)/Cu (2.4 nm)/Ag (0.2 nm)/Cu (2.4 nm)/Co (10 nm) film with the applied field in the [011] direction.

while H_{coupling} is the coupling field between Co and NiFe layer and $H_{c\text{NiFe}}$ is the coercivity of NiFe layer.[7] Equations (3) mean $H_{\text{coupling}}=(H_1+H_2)/2$ and $H_{c\text{NiFe}}=(H_2-H_1)/2$. From Fig. 5, the calculated values of H_{coupling} and $H_{c\text{NiFe}}$ are 0.44 and 0.4 kA/m, respectively. The exchange field of poly-crystalline [Cu (5.5 nm)/Co (2.5 nm)/Cu (5.5 nm)/NiFe (2.5 nm)] multilayers were estimated to be 7 Oe (0.56 kA/m) by Shinjo *et al.*[8] by measuring angular dependence of resistivity in small field. The value of the epitaxial film is roughly the same as that of the poly-crystalline film. Therefore sharp switching characteristics of MR in the epitaxial film are not caused by the reduction of exchange couplings of the film.

Interface roughness should have an effect on exchange couplings between ferromagnetic layers. In [NiFe(Co)/Cu] multilayers, no evidence of a giant MR or antiferromagnetic couplings could be observed in the poly-crystalline films. Oscillations of MR ratio were observed, however, in epitaxial films in which flatter interfaces were observed than in poly-crystalline films.[3] These results suggested that flatter interfaces formed by epitaxial growth promoted the antiferromagnetic couplings between ferromagnetic layers. In the epitaxial [NiFe/Cu/Co/Cu] multilayers, the interposition of thin Ag layer decreased roughness of the interface and improved the MR sensitivity. Interface roughness might generate pinholes and ferromagnetic coupling between ferromagnetic layers. In poly-crystalline [NiFe/Cu/Co/Cu] multilayers, Cr underlayer improve interface flatness and MR sensitivity of the film.[9] Our results on epitaxial films suggests that in noncoupled-type [NiFe/Cu/Co/Cu] multilayers, interface flatness improves MR sensitivity.

IV. CONCLUSION

In the epitaxial [Co/Cu/NiFe(/Cu)] films on Si(100)/Cu substrates, high MR sensitivity along the [011] and [$0\bar{1}1$] directions in the film plane was realized. Furthermore, interposition of thin Ag layer in a Cu layer improved MR sensitivity of the film. The higher MR sensitivity in the epitaxial films may originate in the square-shaped magnetization curves along the easy axes [011] and [$0\bar{1}1$] of the Co layers. Flatness of interface was also effective to improve the MR sensitivity in the films.

Naval Research Laboratory, Washington, DC 20375-5640

We have made spin-valve structures of Permalloy/Cu/Co by sputtering or electron-beam deposition onto the antiferromagnetic oxide NiO. The oxides were made either by deposition of the metals and subsequent oxidation or by growing them *in situ* using reactive sputtering. The magnetic properties of the giant magnetoresistance structures were studied by magnetoresistance, vibrating sample magnetometry, and ferromagnetic resonance methods. The oxides were characterized by x-ray diffraction and atomic force microscopy. We studied surface roughness and structure as functions of thickness and oxidation temperature and correlated the oxide properties with the magnetic performance. We found that the metal layer roughened during the postdeposition oxidation process and that the resulting oxide layers were very effective in pinning the direction of the magnetic moment of adjacent metal films. Coercive fields over 500 Oe were obtained for Co overlayers on NiO films but the exchange bias field was generally less than 100 Oe and was not strongly dependent on the roughness. The beneficial effects of this strong pinning were offset to some degree by higher switching fields required in spin-valve structures deposited over the Co. We also made reactively sputtered oxide antiferromagnetic films which had smoother surfaces than those made by postdeposition oxidation. [S0021-8979(96)55508-3]

I. INTRODUCTION

Properties of antiferromagnetic NiO, CoO, and NiO–CoO mixtures as magnetic bias layers have recently been extensively investigated because of their potential advantages in fixing the orientation of one of the layers in a spin-valve or giant magnetoresistance (GMR) structure.[1–3] The resulting oxide layers are chemically stable, insulating, and can be simply and reproducibly made. Most work has used reactive sputtering to prepare the oxide films; results of using bulk single crystals[2] and molecular-beam-epitaxy (MBE) grown films[4] for magnetic bias have also been reported. While roughness has been identified as a factor increasing both coercivity and exchange bias field, the undesirable effects of roughness on the coercivity of overlying "soft" layers have not been reported. Roughness may increase exchange bias by increasing the amount of interface area available while coercivity is increased by the distribution of dipolar magnetic fields around magnetic defects or structures, which can thus act as traps or barriers for domain walls. The basic aspects of antiferromagnetic oxides in providing exchange bias to adjacent layers were explored by Miekeljohn and Bean[5] and later by Malozemoff;[6] they found that atomic exchange fields of over 10^6 Oe were drastically reduced by the averaging over random spin orientations in practical materials: In effect, the statistical deviations from zero of the number of surface spins in a given direction, within an exchange correlated region, determine the strength of coupling.

We have made Ni oxide films by postdeposition oxidation of metal films and by reactive sputtering, and observed their effects on the magnetic properties of overlying GMR structures. While our motivation in studying *ex situ* oxidized films was directed toward ease of fabrication, our study of spin-valve structures made on these films, which were found to have varying roughness, has been useful in elucidating the effects of roughness on coercivity and exchange bias and switching fields. The roughness was found to promote large values of the coercivity and moderate exchange bias, both of which are effective in pinning the orientation of magnetic metal overlayers. Systematic relationships of the oxide layer thickness and of the oxidation temperature to roughness, coercivity, and ferromagnetic resonance (FMR) linewidth were found.

II. EXPERIMENT

Ni metal films were made by either magnetron sputtering or electron-beam evaporation. Metal thicknesses in the range 15–100 nm were deposited, generally on polished Si wafers. Thicknesses were monitored by quartz-crystal oscillator and confirmed by x-ray fluorescence and mass gain. Surface structure was analyzed using an atomic force microscope (AFM) with a depth resolution of about 2 nm. The substrates and the metal films were smooth to at least that level. The oxidation was done in either air or oxygen at temperatures from 400 to 900 °C. During oxidation the film thickness increases by about a factor of 2 in order to accommodate the oxygen; nevertheless, the surfaces remained adherent and crack free. X-ray diffraction showed the films to be the correct structure for antiferromagnetic NiO. The reactively sputtered NiO films were made in various mixtures of O and Ar. Metal overlayers of Co, Cu, and Permalloy of about 5 nm each were deposited on both types of oxides by sputtering or electron-beam evaporation to form GMR structures. These thicknesses were chosen to alloy easy permalloy switching rather than to maximize magnetoresistance.

Magnetic measurements were made using vibrating sample magnetometry (VSM), FMR, and magnetoresistance

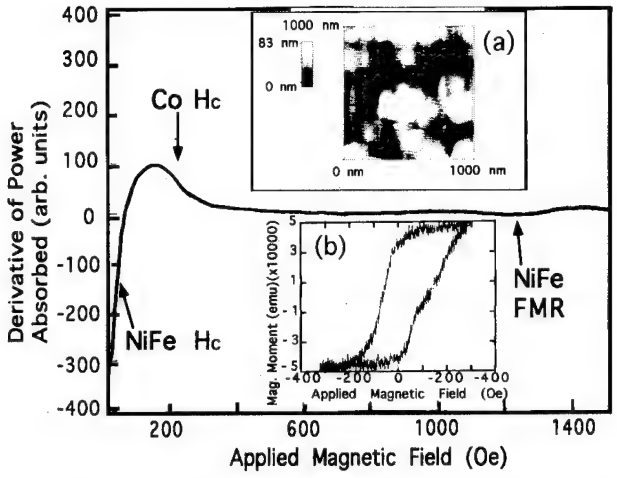

FIG. 1. FMR data of overlying GMR structure. The Co resonance is present but is weak compared to the other features. Insert (a): AFM image of a 200-nm-thick postdeposition-oxidized NiO film; and inset (b): VSM data.

(MR). From the VSM data we found the coercivity of the metal layers and we estimated the exchange field acting on them by the displacement of their loops from the origin. Similar information was obtained from MR data and from the low-field FMR data, in which features of the MR can be seen in the low-field absorptionlike signals.[7]

III. RESULTS AND DISCUSSION

The AFM images for postdeposition-oxidized Ni films [Fig. 1(a)] show very distinct features with a lateral scale up to 100 nm, and with depths of up to 50 nm, for film thicknesses of about 200 nm of NiO. Apparently considerable migration of the Ni occurs during the oxidation process. Since these features are comparable to domain-wall widths, about 100 nm for Permalloy, it is not surprising that quite large coercivities are seen in both the Co and Permalloy layers deposited on this oxide: Figure 1 shows how the coercivities are reflected in the FMR data observed at 9.78 GHz and the VSM data, inset (b). Exchange bias fields acting on the adjacent layer are about 60 Oe. Significant exchange coupling of the magnetic layers through the Cu is not seen. The Co coercivity fell rapidly for oxide thicknesses much less than 50 nm [Fig. 2(a)] and was largest for the lowest oxidation temperatures used [Fig. 2(b)]. The latter effect may be a result of the finer structure of the low-temperature oxidized material since the size of the features is then closer to the typical domain wall size in Co.

Figure 3 shows the AFM image of a typical reactively sputtered NiO layer. The corresponding VSM and MR curves are also shown. The NiO produced in this way has low roughness except for some isolated features, and results in low coercivities of the overlayer while maintaining moderate exchange bias; thicker NiO becomes rougher and produces large coercivity.

Finally, the correlation of the roughness and coercive fields for GMR structures biased by the reactively sputtered NiO layers is shown in Fig. 4.

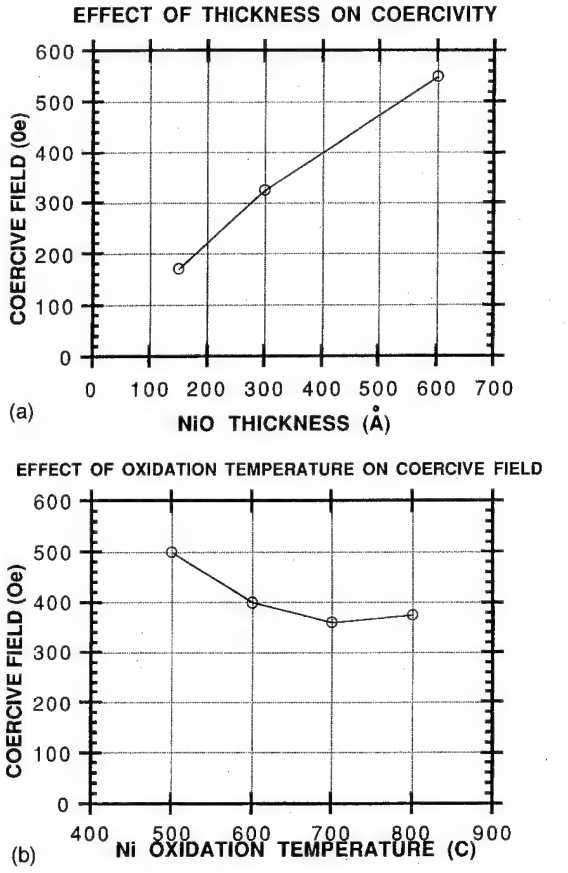

FIG. 2. (a) Effect of NiO film thickness for postdeposition oxidation on the coercive field of an overlying 5 nm Co film. (b) Effect of temperature used for oxidation of the Ni on the coercive field of an overlying 5 nm Co film.

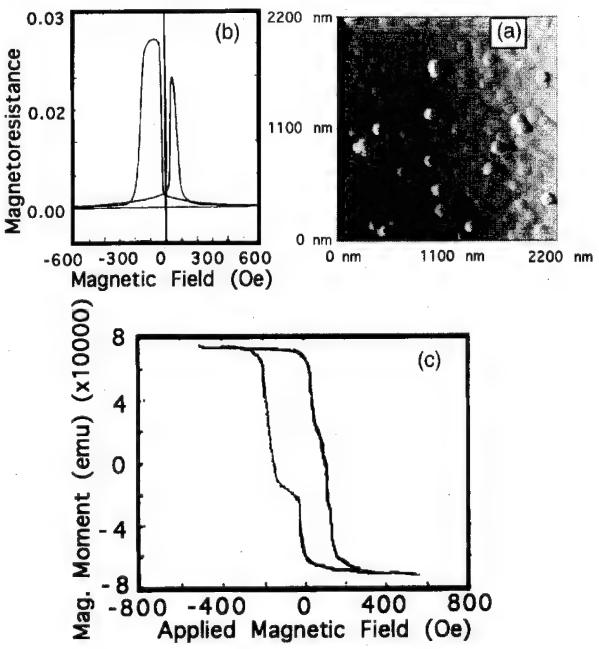

FIG. 3. (a) AFM image of reactively sputtered NiO 170 nm thick, rms roughness in rectangle is 6.2 nm; (b), (c) VSM and MR data, respectively, for this sample.

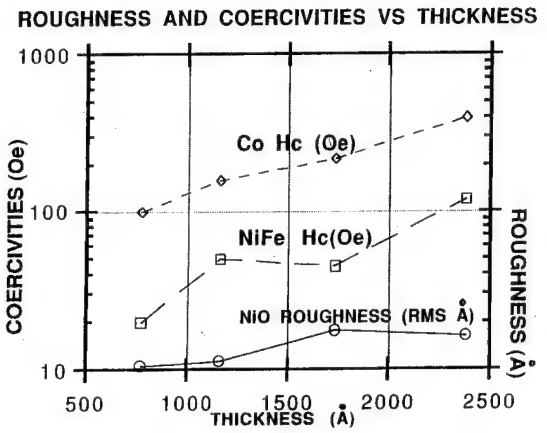

FIG. 4. Effects of increasing thickness on roughness and coercivity for reactively sputtered NiO biased GMR structures.

The effects of the roughness of the thin magnetic films deposited onto rough surfaces on coercivity and linewidth can be understood as arising from the competition between exchange and dipolar energies. The exchange energy can be represented by an effective exchange field of magnitude $H_{\text{exch}}=2A/M(1/L)^2$, where A is the exchange constant, typically 10^{-6} erg/cm for Permalloy, M is the magnetization of about 800 G, and L is the scale of spatial variations of M, here about 50 nm; the magnitude of H_{exch} is thus about 100 Oe. This field, favoring local alignment, competes with the demagnetization, which produces fields on the order of $H_d = 4\pi M \sin\theta$, where θ is the angle of the moment out of the local plane because of the exchange constraint; this field represents a barrier to domain-wall motion, and hence is related to the coercive field. At equilibrium, H_d will thus have the same magnitude as H_{exch}. (This argument suggests that the coercivity becomes very large as L approaches zero. However, for L much less than the wall width, the wall averages over the alternating variations in H_d, which are bounded, and becomes insensitive to them; the distribution is therefore "exchange narrowed" to approximately H_d^2/H_{exch}, which approaches zero for short range, e.g., atomic roughness. The lower coercivity of the reactively sputtered films follows from the reduced scale of its roughness relative to the domain-wall widths.) (The variation of H_d will also be the major contribution to the FMR linewidth of the Permalloy.) The above estimates are in good agreement with the observed values of linewidth and coercivity, at least for the choice of L taken above. They also suggest that the relatively larger coercivity of the Co films is related to its larger A value, nearly three times larger than that of Permalloy. Magnetostrictive effects may also play a role in the coercivity of the Co.

Because of the roughness we were not able to image any domain walls using Bitter decoration; traces over regions of Permalloy magnetization reversal made with reflected light, analyzed using crossed polarizers (Kerr imaging) showed a distinctive change of sign, indicating the potential usefulness of this method in evaluating these materials.

IV. CONCLUSIONS

GMR structures deposited on antiferromagnets grown by oxidation of Ni or Ni–Co metal films produced up to 3% changes in resistance in the range of magnetic fields required to reverse one of the layers with respect to the other. The magnetic fields necessary to reverse the Permalloy are somewhat lower than those required to reverse the Co, leading to a partially anti-aligned state for appropriate field values. For postdepostiion-oxidized NiO bias layers, there is generally an overlap in fields at which some rotation occurs in both magnetic layers, leading to a reduction in the magnitude of the GMR[8] and undesirably large fields of more than 50 Oe to produce the maximum effect. For the smoother NiO produced by reactive sputtering, the switching fields are better separated and the NiFe switching is sharper.

Giant magnetoresistance effect and electric conduction in amorphous-CoFeB/Cu/Co sandwiches

M. Jimbo
Daido Institute of Technology, Nagoya 457, Japan

K. Komiyama and S. Tsunashima
School of Engineering, Nagoya University, Nagoya 464-01, Japan

Giant magnetoresistance (MR) effects have been investigated for spin valve sandwiches using amorphous(a)-$(Co_{0.9}Fe_{0.1})_{80}B_{20}$ alloy layers. In an a-CoFeB/Cu/Co sandwich, a MR ratio as large as 6% was obtained, and a MR curve was found to saturate in a field within 100 Oe. The resistivity is 40–60 $\mu\Omega$ cm. In a CoFeB(4 nm)/Cu(2 nm)/a-CoFeB(2 nm)/NiO(10 nm) sandwich, MR ratios as large as 4% were also obtained. The maximum field sensitivity of the sandwich is about 2.5%/Oe.
 [S0021-8979(96)68208-2]

I. INTRODUCTION

Spin valve structures[1] are attracting great interest since the low field magnetoresistive behavior is suitable for the application to magnetoresistive readout heads and magnetoresistance (MR) memory.[2] We have already reported that giant magnetoresistance (GMR) due to the spin-dependent electron scattering appears in amorphous(a)-CoFeB/Cu/Co sandwiches.[3] In this article, we describe the dependence of the GMR effect and electric conduction on the thickness of magnetic layers for spin valve sandwiches using a-$(Co_{0.9}Fe_{0.1})_{80}B_{20}$ layers. We also show that the GMR effect is obtained in a-CoFeB/Cu/a-CoFeB/NiO sandwiches.

II. EXPERIMENT

Two types of sandwiches shown in Fig. 1 have been used in this investigation. One is the Co/Cu/a-CoFeB sandwiches where the magnetization of the Co layer on the surface side is pinned by the oxidized Co layer.[4] The other is a-CoFeB/Cu/a-CoFeB sandwiches where the magnetization of the outer a-CoFeB layer is coupled with a NiO layer. These sandwiches were prepared using a rf magnetron sputtering system with three targets in a similar manner to that described in a previous article.[3] The composition of the alloy layer is $(Co_{0.9}Fe_{0.1})_{80}B_{20}$, which exhibits nearly zero magnetostriction in an amorphous state.[3] When the $(Co_{0.9}Fe_{0.1})_{80}B_{20}$ layer was deposited to a thickness of 200 nm, the amorphous structure was confirmed with halolike X-ray diffraction patterns. For both sandwiches, a 5-nm-thick SiN layer was deposited first onto a glass substrate as a buffer layer. The SiN layer was sputtered from a Si_3N_4 target at 10 mTorr of Ar pressure. The deposition rate is about 0.1 nm/s. The vacuum of the chamber was broken only after the preparation of the SiN layer, otherwise all the layers were grown successively without breaking the vacuum.

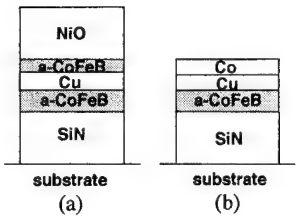

FIG. 1. Constructions of sandwiched films.

III. RESULTS AND DISCUSSION

Figure 2 is the typical MR curves and MH loops for a-CoFeB/Cu/Co sandwiches with CoFeB layers of various thickness. The MR curves were measured with the magnetic field applied in the direction parallel to the easy axis. Large MR ratios were obtained for very thin a-CoFeB layers; at CoFeB thicknesses of 2 nm, the MR ratio reaches a maximum of about 6.5%. The maximum field sensitivity of the sandwich is about 2%/Oe.[3] From MH loops, it is seen that the sandwiches which show large MR ratios exhibit a mag-

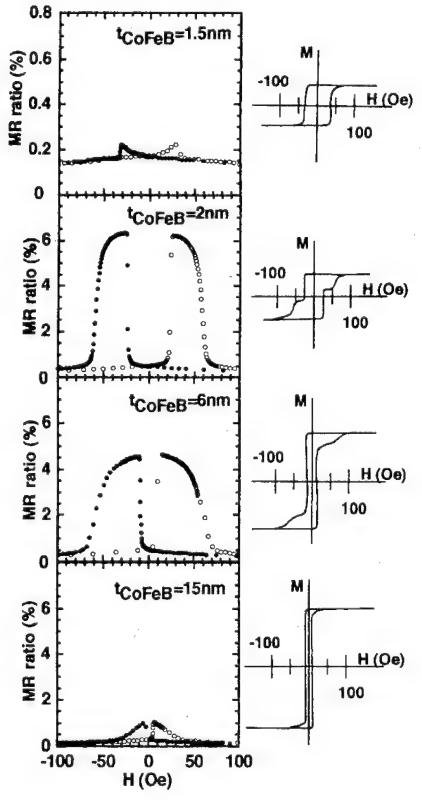

FIG. 2. Typical MR and MH curves for a-CoFeB(t_{CoFeB})/Cu(2 nm)/Co(2 nm) with various CoFeB layer thicknesses.

 0021-8979/96/79(8)/6237/3/$10.00

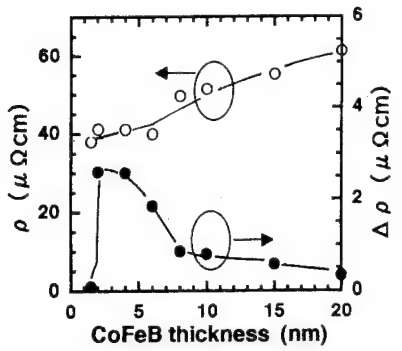

FIG. 3. Dependence of resistivity and resistivity change on CoFeB thickness in a-CoFeB(t_{CoFeB})/Cu(2 nm)/Co(2 nm) sandwiches.

netization process indicative of the antiparallel alignment of the magnetic layers. Increasing the thickness of an a-CoFeB layer, the MR ratio decreased and the two-stage magnetization processes disappeared. Estimating the magnetic moment of Co from the two-stage magnetization loop, the thickness of the Co layer that is still ferromagnetic is presumed to be about 1 nm.

The dependence of ρ(resistivity) and $\Delta\rho$(resistivity change) on the thickness of the CoFeB layer is shown in Fig. 3. When the CoFeB layer is thinner than 5 nm, the resistivity is about 40 $\mu\Omega$ cm and almost constant. This may mean that the resistivity is dominated by Cu (and Co) layers. Then with increasing thickness the resistivity increases gradually toward the value of a-CoFeB(100 $\mu\Omega$ cm). On the other hand, the resistivity change $\Delta\rho$ shows a peak at around 2 or 4 nm. The abrupt decrease above 5 nm is thought to be due to incomplete antiparallel alignment.

The minor loops of the MR curves of a-CoFeB/Cu/Co sandwiches are shown in Fig. 4. The coupling field H_w defined in Fig. 4 is inversely proportional to the thickness of

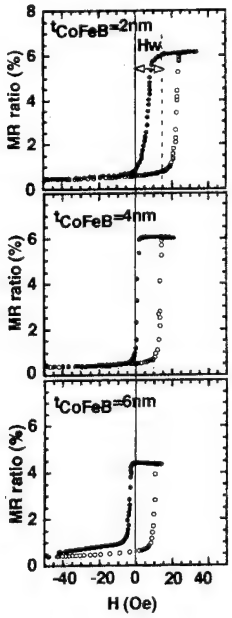

FIG. 4. Minor loops of the MR curves for a-CoFeB(t_{CoFeB})/Cu(2 nm)/Co(2 nm) sandwiches.

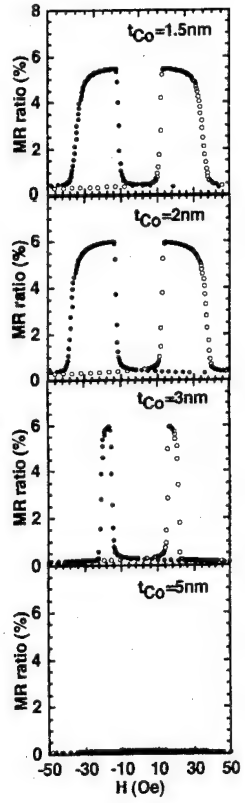

FIG. 5. MR curves of a-CoFeB(4 nm)/Cu(2 nm)/Co(t_{Co}) sandwiches with various Co layer thicknesses.

CoFeB. From the direction of the minor loop shift, the coupling between the magnetic layers is thought to be ferromagnetic.

Figure 5 shows the MR curves of a-CoFeB/Cu/Co sandwiches with Co layers of various thicknesses. The MR ratio showed the maximum for a 2-nm-thick Co layer, and decreased with increasing Co thickness, becoming almost 0% for 5-nm-thick Co. From the MR curves, it is also seen that the field for the magnetization reversal of Co layers gradu-

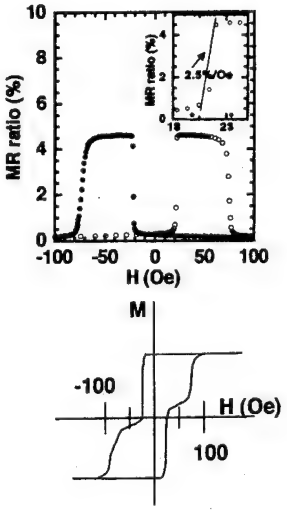

FIG. 6. MR and MH curves for a-CoFeB(2 nm)/Cu(2 nm)/a-CoFeB(2 nm) sandwich.

ally decrease with increasing thickness of Co layers. In the case of the 5 nm Co layer, the magnetization reversal of both Co and *a*-CoFeB layers seems to occurs almost simultaneously.

For *a*-CoFeB/Cu/*a*-CoFeB sandwiches, the MR curve and the MH loop are shown in Fig. 6, where the thicknesses of Cu and two *a*-CoFeB layers are all 2 nm. The MH loop exhibiting two stages is similar to those of Co/Cu/*a*-CoFeB sandwiches shown in Fig. 2. Comparing the MH loops of these two types of sandwiches, it is found that the *a*-CoFeB/Cu/*a*-CoFeB sandwich shows more complete squareness during the magnetization reversal of the pinned (magnetically hard) layer. The obtained MR ratio of 4.5% is comparable to those of Co/Cu/*a*-CoFeB sandwiches. The maximum field sensitivity of an *a*-CoFeB/Cu/*a*-CoFeB sandwich was estimated at 2.5%/Oe from the slope of the MR curve in soft *a*-CoFeB layer.

In conclusion, the sandwiches using *a*-CoFeB layers exhibit giant MR (GMR) due to spin-dependent electron scattering. Relatively large MR ratios of 4%–6% were obtained even when the thickness of amorphous magnetic layers is as thin as 2 nm. This may be related to the very short electron mean free path in amorphous alloys. From the application point of view, a very thin magnetic layer is favorable to reduce the demagnetizing field and will be useful to reduce the size of magnetic devices operating at low fields. Finally, it is well known that the magnetotransport properties of multilayer materials are very sensitive to structural characteristics. Thus the relationship between layer thicknesses, structural properties, and GMR response in these complex amorphous/crystalline sandwiches is currently being studied and will be presented in forthcoming publications.

Size effects and giant magnetoresistance in unannealed NiFe/Ag multilayer stripes

S. C. Sanders, R. W. Cross, S. E. Russek, A. Roshko, and J. O. Oti
Electromagnetic Technology Division, National Institute of Standards and Technology, Boulder, Colorado 80303

We have observed giant magnetoresistance (GMR) in unannealed NiFe/Ag multilayer thin-film stripes. Rectangular stripes having constant thickness and a constant 11:1 length-to-width aspect ratio, but varying widths down to 0.5 μm, were measured. Two types of multilayer configurations were tested, a system of five NiFe/Ag bilayers with 5.5-nm-thick Ag spacer layers, and a system of nine bilayers with 4.4-nm-thick Ag layers. In contrast to the characteristic of annealed NiFe/Ag multilayer stripes, the unnannealed stripes produced increasing GMR ratios for decreasing stripe sizes, with the 0.5-μm-wide stripe of the five-bilayer system exhibiting a $\Delta R/R$ of 2.5%. Barkhausen noise and response broadening also increased with decreasing stripe size, however. The results are discussed in terms of magnetostatic coupling of the NiFe layers within the stripes. [S0021-8979(96)55608-2]

INTRODUCTION

Studying finite-size effects in giant magnetoresistive (GMR) materials is important both for understanding the micromagnetic phenomena as well as for examining suitability for magnetic sensor applications. The multilayer NiFe/Ag GMR system[1–7] is attractive for potential sensor applications due to its high sensitivity (large change in MR per unit field), especially when annealed to form discontinuous multilayers.[2] In this form, the magnetic NiFe layers are broken up into small grains due to Ag diffusion along grain boundaries.[4] These grains interact magnetostatically to induce antiferromagnetic ordering among neighboring grains in adjacent NiFe layers at low fields. The relatively high degree of antiparallel alignment gives rise to GMR values on the order of 5%. When these annealed multilayers are patterned into micrometer-scale features, however, the magnetoresistive response is significantly suppressed, broadened, and characterized by the presence of distinct "jumps" (Barkhausen noise).[8,9] These characateristics are unsuitable for submicrometer sensor applications.

Recently, GMR in patterned unannealed NiFe/Ag multilayers was reported.[10] The unannealed NiFe/Ag is potentially more attractive for applications since the annealing step is avoided. It may also decrease the noise previously observed in small devices,[8,9,11] if the granular characteristics are eliminated. Hylton *et al.*[10] studied unannealed arrays of 2 μm dots consisting of two NiFe layers separated by a Ag spacer. MR measurements carried out on the dot arrays, corrected for the continuous Cr overcoat necessary for electrical contact, gave estimated GMR ratios of 2.5% and a 1.6 kA/m (20 Oe) saturation field. The GMR effect was attributed to magnetostatic coupling induced at the edge of the dots, which causes the magnetization in one layer to align antiparallel to the other layer.

In this study we have patterned unannealed NiFe/Ag multilayers into rectangular stripes of various sizes to examine the role of magnetostatics in unannealed NiFe/Ag multilayers. In particular, the goal was to directly test whether individual stripes having widths on a 1 μm scale could have interlayer magnetostatic coupling sufficiently large to produce GMR, and, if so, whether their MR response contained less noise than their annealed counterparts. Stripes fabricated from five- and nine-bilayer systems both showed increasing GMR amplitude as the stripe width decreased from 16 μm. In both cases, however, saturation fields and noise also increased with decreasing stripe width.

EXPERIMENT

NiFe/Ag multilayer films were fabricated by magnetron sputtering onto SiO_2-coated Si wafers as reported previously.[6] The films were deposited at room temperature in 0.93 Pa (7 mTorr) of Ar, and no magnetic field was applied during the deposition. NiFe was sputtered from a $Ni_{82}Fe_{18}$ alloy target. Two wafers with varying bilayer number n and Ag thickness t_{Ag} were used: Si/SiO_2 (150 nm)/Ta (4.5 nm)/Ag(t_{Ag}/2)/NiFe(2.0 nm)/[Ag (t_{Ag})/NiFe(2 nm)]$_{n-1}$/Ag (t_{Ag}/2)/Ta(11 nm), with $n=5$, $t_{Ag}=5.5$ nm, and $n=9$, $t_{Ag}=4.4$ nm. After deposition the central regions of the wafers were patterned using conventional photolithography and diced into 12.5×12.5 mm^2 chips. Several of the chips were annealed in a rapid thermal annealing furnace for 5 min in a 5% H_2–Ar ambient. These chips were used for direct comparison with the unannealed chips. Rectangular stripes having nominally 11:1 length-to-width aspect ratios were measured at room temperature using a two-probe MR tester. The active areas defined by the Au contact electrodes were one square. Bias currents were scaled approximately with stripe width, with current density $J\sim5\times10^5$ A/cm^2, and the magnetic field was applied in the plane of the stripe. For cross-sectional transmission electron microscopy (TEM) studies, specimens were prepared using standard techniques, including N_2-cooled ion milling. Care was taken to prevent heating in excess of 70 °C during all TEM sample preparation steps.

RESULTS

The central result of this article is illustrated in Fig. 1. Figure 1(a) shows $\Delta R/R$ as a function of applied field for unannealed NiFe/Ag rectangular stripes having $n=5$ and

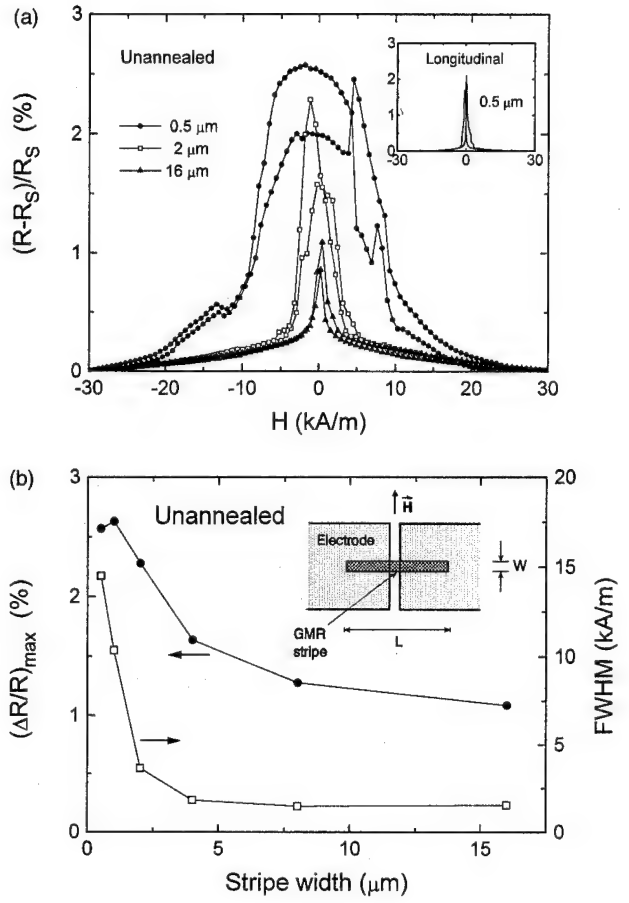

FIG. 1. (a) Magnetoresistive response for unannealed NiFe/Ag multilayer (n=5,t_{Ag}=5.5 nm) stripes. The field was applied in the plane of the stripe and transverse to the long direction. Inset: longitudinal MR for the 0.5-μm-wide stripe. (b) Maximum $\Delta R/R$ and full width at half-maximum data for various stripe widths. Inset: schematic of transverse MR measurement.

t_{Ag}=5.5 nm. The stripes have nominal widths ranging from 0.5 to 16 μm. As the stripe width W decreases, the MR response increases in amplitude and broadens. This is seen more clearly in Fig.1(b), where the maximum $\Delta R/R$ and full width at half-maximum (FWHM) data are plotted as functions of W. As W decreases from 16 to 0.5 μm, maximum $\Delta R/R$ increases from 1.1% to 2.6%, and the FWHM increases from 1.6 to 14 kA/m (20 to 180 Oe). The sensitivity $[d(\Delta R/R)/dH]_{max}$ therefore decreases with decreasing W. The inset of Fig. 1(a) shows $\Delta R/R$ for the 0.5 mm stripe with longitudinal applied field. Although the longitudinal results show trends similar to the transverse results, the magnitude of the longitudinal broadening is much less (1.2 kA/m as opposed to 14 kA/m for the 0.5 μm stripe).

We also measured the MR response for unannealed stripes having n=9 and t_{Ag}=4.4 nm. As in the case of the five-bilayer stripes of Fig. 1, the nine-bilayer samples show the trend of increasing $\Delta R/R$ and broadening with decreasing W. For these stripes, the maximum $\Delta R/R$ increases from 0.4% to 1.9% as W decreases from 16 to 2 μm. The trends that we observe are, therefore, independent of n and t_{Ag} within these ranges.

Noise, in the form of discrete Barkhausen jumps in the MR response, is readily apparent for the smaller stripes in

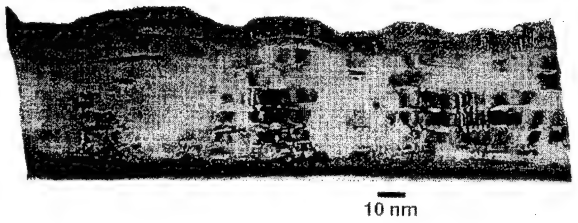

FIG. 2. Cross-sectional TEM micrograph of an unannealed seven-bilayer sample. The GMR multilayer is sandwiched between top and bottom Ta layers. The degree of roughness at the top surface (~5 nm) is typical of the several samples examined.

Fig. 1(a). This may be attributed to a finite granularity (imperfect multilayers), which also produces a nonzero GMR in the larger devices. TEM results on different wafers show a roughening in the unannealed films on the order of a bilayer thickness, as shown in Fig. 2. Previous work has indicated the significance of sputtering gas pressure on film microstructure and properties.[33] The relatively high Ar pressure used during sputtering in this study may introduce some of the observed roughness. Temperatures up to 130 °C are used during photolithography, but these low processing temperatures are not likely to account for the residual granularity and presence of a small GMR component in the larger unnannealed stripes. The Barkhausen noise observed in the response of the small stripes is discouraging for sensor applications. However, processing optimization or biasing optimization, such as increased current density,[9] may diminish the noise problem.

The trend of increasing $\Delta R/R$ with decreasing W for these unannealed stripes is in contrast to annealed stripes. Annealed stripes exhibit decreasing $\Delta R/R$ with decreasing W, as illustrated in Fig. 3 for the n=5,t_{Ag}=5.5 nm configuration (from the same wafer as the unannealed n=5 chip) annealed at 340 °C for 5 min in 5% H_2–Ar. The maximum $\Delta R/R$ decreases from 3.6% to 3.0% as stripe width decreases from 16 to 0.5 μm.

DISCUSSION

In the unannealed stripes, the trend of increasing $\Delta R/R$ with decreasing W is due to the increased thickness-to-volume ratio as W decreases (thickness is constant), and, therefore, the increased relative influence of the stripe edges perpendicular to the layers. As W (and L) decreases, the magnetostatic edge charges become closer. If the layers are fully continuous (not granular), the magnitude of magnetostatic energy per unit volume should be greater for the smaller stripes, leading to increased antiparallel alignment in zero applied field, and a larger maximum $\Delta R/R$. In this case, a larger field is required to overcome the magnetostatic energy and align the layers, leading to a broadened response.

The annealed stripes, in contrast, consist of discontinuous layers, so the increasingly strong effect of the stripe edge charges, with decreasing size, increasingly dominates the intergranular, interlayer magnetostatic interaction that occurs

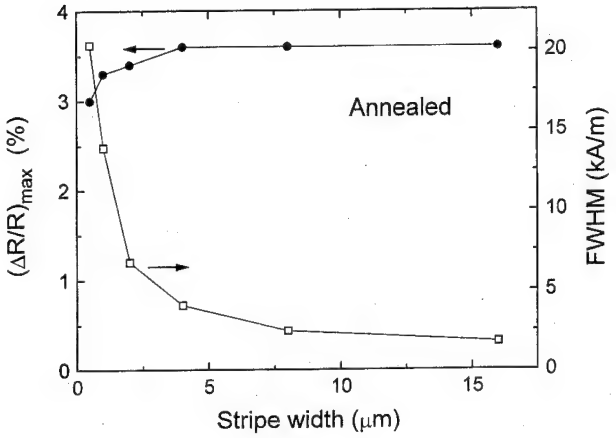

FIG. 3. Maximum $\Delta R/R$ and full width at half-maximum data for various stripe widths in a series of annealed NiFe/Ag stripes having $n=5$ and $t_{Ag}=5.5$ nm. The annealing was carried out in a rapid thermal annealer for 5 min at 340 °C.

due to charges at the grain edges. Some of the zero-field antiparallel orientation is diminished, reducing the maximum $\Delta R/R$ as W decreases.

The increased Barkhausen noise for the smaller samples is attributed to the increased relative contribution of flipping of domains as the domain size becomes an appreciable fraction of the stripe size.

SUMMARY

We have observed increasing GMR amplitudes with decreasing size in rectangular stripes of unannealed NiFe/AG multilayers. This may be attributed to an increasing significance of magnetostatic charges at the stripe edges as film thickness-to-volume ratio increases, given a constant length-to-width ratio. Noise and response width also increase with decreasing stripe size, however, posing a challenge for technological applications such as highly field-sensitive submicrometer magnetic sensors.

Effect of sputter gas on the physical and magnetic microstructure of Co/Cu multilayers

D. M. Donnet,[a] K. Tsutsumi,[b] P. de Haan, and J. C. Lodder
MESA Research Institute and CMO Laboratory, University of Twente, 7500 AE Enschede, The Netherlands

The physical structure of Co/Cu multilayers, sputtered in different gases (Ar, Kr, and Xe) together with the domain structures that these films support have been investigated using electron microscopy in an attempt to explain the differences in their measured magnetoresistance (MR). Both planar and cross-sectional analyses were undertaken. Due to only partial antiferromagnetic coupling submicron domain structures were observed by Lorentz microscopy in all multilayers. The complex nature of these domain structures made classification difficult, although small magnetic field application allowed wall motion and nucleation to be observed. All films were polycrystalline in nature, although average grains sizes differed. However, smoother interfaces together with less well defined crystal boundaries were observed in the Kr and Xe sputtered films. This trend did not correlate with giant MR (GMR) measurements as the Xe sputtered films had the lowest GMR value of the three. © *1996 American Institute of Physics.* [S0021-8979(96)82808-9]

I. INTRODUCTION

Giant magnetoresistance (GMR) is a well known phenomenon in Co/Cu multilayers (MLs)[1–3] with $\Delta R/R$ values as high as 65% having been measured at room temperature. Thus far, the critical condition for GMR has not been fully clarified, although it is clear that the morphology of the MLs plays a major role in determining the degree of magnetoresistance present and some recent reports[4–6] have focused on how the growth mechanism [molecular beam epitaxy, epitaxial (111) oriented or sputter-deposited films] affects the structure and orientation of the films and therefore also their GMR value. Since a critical ingredient in the theory of GMR in MLs is spin-dependent electron scattering at the interfaces[7] (as well as in the bulk), it is of particular interest to what extent interfacial roughness is important in determining the GMR value. Recent studies[8,9] have employed a variety of analytical techniques to investigate this property. The ML morphology can be significantly affected by sputtering conditions, such as sputter gas and pressure, and we deposited similar Co/Cu MLs under different sputter gas environments (Ar, Kr, and Xe). A previous study[10] reported upon the initial findings and x-ray diffraction (XRD) measurements. Subsequently, a transmission electron microscopy (TEM) study was undertaken in which we attempted to correlate the measured GMR values with the film structures (and interfaces) observed. Some preliminary domain results are also presented, although space does not allow a full treatment and this will be covered in a future publication.

II. EXPERIMENT

The Co/Cu multilayers were fabricated by conventional rf-sputter deposition onto Si(100) wafer substrates with a 65 Å Fe buffer layer. The composition of the MLs was typically 15×(14 Å Co+22 Å Cu). Using a nonmagnetic spacer layer at the second peak of the oscillatory coupling region gave reasonably large GMR values with reproducible results.[11] The GMR values were measured by a dc four point method and the MLs were characterized magnetically using a vibrating-sample magnetometer.

Cross-sectional specimens suitable for TEM observation were prepared by the standard method of slicing, polishing, dimpling, and finally Ar ion milling. For planar sections however, specially prepared etched Si wafers with Si_3N_4 "TEM windows"[12] were used as the substrate and allowed for direct observation in the microscope. The MLs on TEM windows were deposited at the same time as those on the Si wafers to ensure that they had similar properties. However small differences are to be expected due to the different substrates used. The microscopes used during this study were a Philips CM-30, operated with an accelerating voltage of 300 kV and equipped with a nonimmersion Lorentz "twin" lens, and a JEOL JEM 3010 high resolution electron microscope (HREM), also operated at 300 kV. Typical magnifications used for bright field imaging were 500 000× and selected area electron diffraction patterns allowed any orientation relationships and texturing to be observed.

Lorentz microscopy was carried out (on the CM-30) at significantly lower magnifications (typically 15 000×), due to the position of the twin lens. Small magnetic fields were applied using the objective lens itself. The Fresnel (or defocus) mode was employed as this is easy to implement in a TEM and gives a clear overview of the domain structure.

III. RESULTS AND DISCUSSION

Ar-sputtered Co/Cu films were deposited at a variety of pressures. The maximum GMR ratio was achieved at 3.1×10^{-2} mbar with deposition rates of 1 and 2 Å/s for Co and Cu, respectively. The deposition rates affect the film morphology and in order to keep both constant during Kr and Xe deposition, different sputtering pressures were used for Kr (2.2×10^{-2} mbar) and Xe (8.3×10^{-3} mbar). For this study we then concentrated on the film which gave the largest GMR value for each sputter gas: 16.5% for Ar, 23.5% for Kr, and 7.5% for Xe. Good reproducibility was achieved for the Ar and Kr cases. Poorer reproducibility was achieved

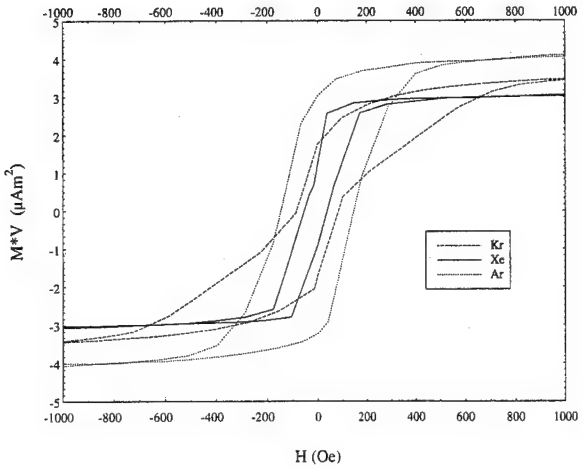

FIG. 1. $M-H$ loops for the three films investigated. Note, differences in saturation values are due to slightly different Co layer thicknesses.

with the Xe films, although it does appear that the maximum GMR measured when sputtering with Xe is significantly lower than when Ar or Kr is used. Figure 1 presents the $M-H$ loops for the three films and it is clear from the shape of the loop for the Kr-sputtered film that it displays the greatest degree of antiferromagnetic behavior ($M_r/M_s=0.5$).

This idea is reinforced when the multilayered structure of the films was observed from cross-sectional TEM images. These are presented in Fig. 2. Due to the similar electron scattering powers of Co and Cu, it is necessary to defocus the objective lens (typically 200 nm) in order to delineate the interfaces. For each film, the individual Co and Cu layers can be distinguished, but it is clear that differences do arise. In particular, the layers in the Ar-sputtered film appear considerably more wavy than in the other two films and there seem to be some areas where the layer thickness is not constant. This could lead to areas where the antiferromagnetic (AF) coupling is not complete and the ML behaves ferromagnetically. In contrast the Kr- and Xe-sputtered layers lie almost perfectly parallel to the substrate surface and only a small amount of waviness is apparent in the Xe case close to the film surface. In all films however, large grains extending throughout the total thickness of the multilayer were observed. Such grains had dimensions of ~20 nm. Planar images (Fig. 3) showed similar differences. Average grain sizes of 20, 15, and 10 nm were measured for the Ar, Kr, and Xe films, respectively. In conjunction with the decrease in grain size, a less distinct grain structure was observed in the Kr and especially the Xe sputtered case. The reduction in crystal size is probably associated with heavier Kr and Xe neutral atoms and the subsequent flatter interfaces as observed in Figs. 2(b) and 2(c). However little or no differences were observed from the planar diffraction patterns: same lattice constant (3.60 Å) measured with only a slight degree of texturing observed in the Xe-sputtered film. HREM images (not shown) of the ML, indicate a highly disordered structure with little or no orientation relationship with respect to the substrate. Large amorphous areas (near the surface of the ML) as well as differently oriented neighboring grains were present. It should be noted however that lattice fringes in

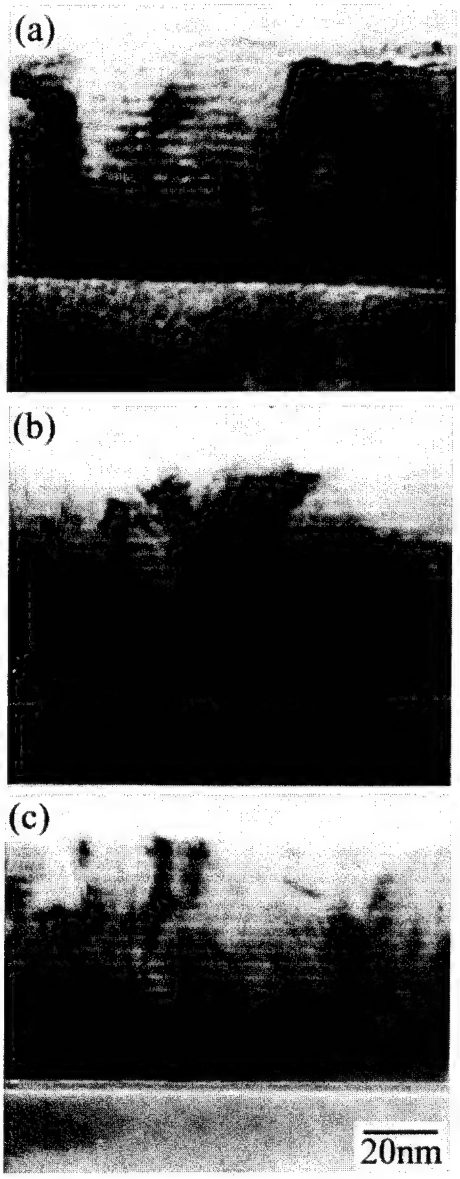

FIG. 2. Cross-sectional TEM images of the Ar (a), Kr (b), and Xe (c) sputtered MLs.

these grains extend through many Co and Cu layers undisturbed. This disorder may have an effect on the degree of GMR found in these films by increasing the number of spin dependent scattering centers.

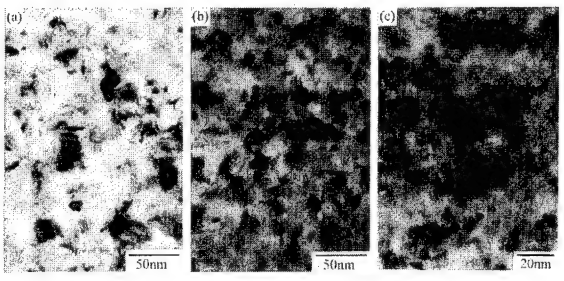

FIG. 3. Planar TEM images of the Ar (a), Kr (b), and Xe (c) sputtered MLs.

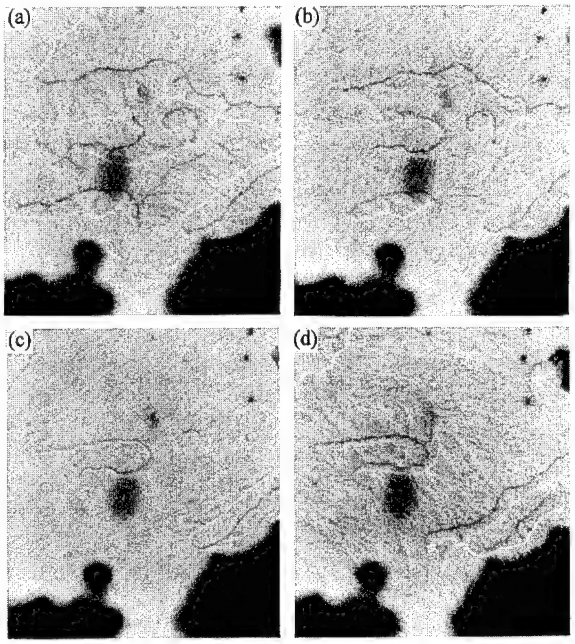

FIG. 4. Domain (Fresnel) images of the Kr-sputtered ML in the ac-demagnetized state (a) and with small fields applied (b)–(d).

These results appear to be in agreement with the earlier XRD experiments which indicated that well oriented films were not required for large GMR values and which revealed a tendency to more amorphous behavior with heavier sputtering gas. To investigate the lower GMR ratio for the Xe-sputtered film we carried out resistance measurements on a Co film grown under similar conditions. This revealed considerably higher resistivity compared to Co films grown in Ar and Kr. We have attributed this high value to the presence of Xe in the film and thus it is also likely that Xe is present in the ML. This would lead to much lower mobility of the atoms and could contribute to the amorphouslike structure in Fig. 3(c). It is also probable that this larger resistivity could lead to a larger number of spin independent scatterings which would have the effect of diminishing the GMR ratio.

With regards to the domain structures that these MLs support, very little qualitative differences were observed. Figure 4 presents Fresnel images of the Kr-sputtered film in an ac-demagnetized state and as magnetic fields were applied. We will concentrate on this film, but the discussion pertains equally well to the Ar and Xe sputtered films. A small (submicron) complex in-plane structure is observed with magnetization ripple present in the domain interiors. The most interesting effects were viewed when small magnetic fields were applied to the film. To do this the film was tilted so that it experienced a small degree of the vertical remanent field from the objective lens (<20 Oe). Thus only very small fields were required for nucleation or domain wall motion. The walls moved with great ease, thus changing the domain dimensions. However, the general shape of the domains remained constant implying that there were a great deal of pinning points available in the ML. Also of interest is the 360° wall nucleated in Fig. 4(c). When the film was finally saturated (not shown) only ripple remained. It should be noted that some of the domain contrast does arise from the Fe buffer layer. A future publication dealing, in more detail, with the domains will investigate MLs deposited on other (or no) buffer layers.

IV. CONCLUSIONS

We have grown a series of Co/Cu ML films with different sputter gases. In general, good reproducibility was attained, although still some more work is required to find the optimum Xe sputtering conditions. All films are polycrystalline with small grains (10–20 nm) although the Xe case has a significantly less distinct crystal structure which may be explained by the presence of Xe in the film. We have observed that deposition in a Kr environment leads to flatter layers with better AF coupling and a larger GMR ratio with respect to Ar-sputtered MLs. Despite comparable layer smoothness, interfacial sharpness and lattice constant in the Xe-sputtered film, it has significantly diminished AF coupling and GMR and we are currently involved in further research to determine the cause of these differences.

We report measurements of the thermoelectric power (S) and electrical resistivity (ρ) in sputtered multilayers of M(10 Å)/$Au_{25}Cu_{75}(t)$ (with M=Co or Ni) directly grown on Si (100), and in UHV—evaporated Pt 20 Å/Ni(x) multilayers grown on Si(111). The multilayers have thicknesses t=21 Å, 23 Å, and x=19.5 Å, 39 Å, and the data spans the temperature range 10–300 K. All the samples exhibit an anomalous thermopower at high temperatures, with a huge maximum in S and a sharp peak in the temperature derivative dS/dT at a characteristic temperature T^*, e.g., ~190 K for Ni/Pt and ~260 K for M/$Au_{25}Cu_{75}$ multilayers. In all cases the thermopower decreases abruptly at T^*, from a giant positive value ($S \approx 80$ μV K^{-1} in Ni/Pt and $S \approx 12$–50 μV K^{-1} in M/$Au_{25}Cu_{75}$) to values close to zero below T^*. The electrical resistivity also displays an anomaly over the same temperature range, characterized by a rapid resistivity enhancement $\Delta\rho \sim 1$ $\mu\Omega$ cm (within $\Delta T \sim 60$ K) when T decreases below T^*. This produces a sharp minimum in the derivative $d\rho/dT$ at T^*. The shape of the $S(T)$ anomaly is remarkably similar in all cases (mutatis mutandis) for $\rho(T)$, suggesting a general underlying physical mechanism. We found that a suitable buffer (e.g., 100 Å Pt in Ni/Pt, Fe50 Å in Co/$Au_{25}Cu_{75}$ and 50 Å in Ni/$Au_{25}Cu_{75}$) suppresses the anomalies, indicating a structural-related underlying effect. In this case, S values are small and negative (as occurs with Ni and Co), exhibiting the usual smooth variation over the whole temperature range. At this stage, it is not clear what is the precise physical mechanism responsible for the observed anomalies. Interfacial atomic mixing in the nonbuffered multilayers may cause individual magnetic atoms or clusters to have entirely nonmagnetic environments (Au, Cu, or Pt in our samples). This situation could give an anomalous transport contribution, through conduction electron scattering at virtual bound states (VBS) localized in the (3-D) magnetic atoms. A sharp peak occurs in the local density of states, $N(E)$, at a characteristic energy E_L. A giant thermopower may result when the Fermi level is close to E_L ($S \propto dN/dE$; very large). The VBS model successfully explains large S values observed in bulk noble metals diluted with 3-D magnetic impurities such as Co and Ni.[1] However, the standard treatment does not lead to a sharp cutoff-temperature, below which $S(T)$ gets negligible. Another contribution is the usual s-d electron transition mediated by phonon scattering. This leads to a thermopower proportional to the energy derivative of the splitted ferromagnetic 3D band density of states at E_F, which can be very large when sub-band filling is almost complete. Co–Ag granular films are prepared by molecular-beam epitaxy to enable a detailed structural study to be conducted in conjunction with magnetotransport properties. It is demonstrated that the shape, size, location, and segregation of the magnetic Co grains and the morphology of the surface depend on the growth temperature. Detailed transmission electron microscopy reveals inherent differences between samples prepared at room temperature and those prepared at high temperature. Small clusters of only a few atoms are found to be present in the matrix of the low-temperature samples significantly affecting the spin diffusion length. Well-crystallized regions of both Co and Ag are found in the high-temperature samples, however, the Co grains remain relatively small in size even at the highest growth temperatures. © *1996 American Institute of Physics.*

I. INTRODUCTION AND EXPERIMENTAL DETAILS

Giant magnetoresistance (GMR) is caused by the change in spin-dependent scattering in a composite material (either a multilayered film[1] or granular material[2]) when the relative orientation of the magnetic regions is changed by the application of a magnetic field. Both the magnitude and field dependence of the observed GMR in heterogeneous alloys is strongly affected by the structure of the films. The magnetization process of the ferromagnetic regions is controlled by their shape and crystal anisotropy. In addition to the total resistivity of the material being affected by structural defects and grain size, the spin diffusion length in the paramagnetic matrix is greatly reduced by any magnetic impurities present[3] as well as the particle size and distribution due to the jitterbug spin depolarization mechanism.[4] In this study the GMR films were prepared by molecular-beam epitaxy (MBE) in order to complete an integrated study of the structure, magnetic and transport properties. We investigate the effect that growth temperature has on the shape, size, location, and segregation of the magnetic Co grains and the morphology of the surface.

Co–Ag films were coevaporated by MBE at three different growth temperatures: 0 °C (LT), 250 °C (MT), and 450 °C (HT). A Ru buffer layer was first deposited onto the mica substrates at 700 °C, followed by either 640 Å of Co–Ag at LT, 385 Å at MT, or 377 Å at HT and then a capping layer of 30 Å of Ru. A wide range of compositions was prepared, but in this transmission electron microscope (TEM) study we concentrate on a single composition of 45 at. % Co.

The structure of all these samples has been extensively studied by a wide range of techniques both *in situ* by reflection high-energy electron diffraction (RHEED) and *ex situ* by x-ray diffraction, atomic force microscopy (AFM), and TEM. The RHEED patterns for the LT samples indicated that some degree of epitaxy was present throughout the structure with a diffuse single crystal pattern. In contrast at MT and HT two separate sharp diffraction patterns were observed simultaneously indicating a far greater degree of segregation. The results of these measurements and their magnetic and transport properties can be found in previous references.[5,6] Figure 1 shows the x-ray $\theta/2\theta$ scans for the $Co_{45}Ag_{55}$ samples prepared at the three growth temperatures. The Ag

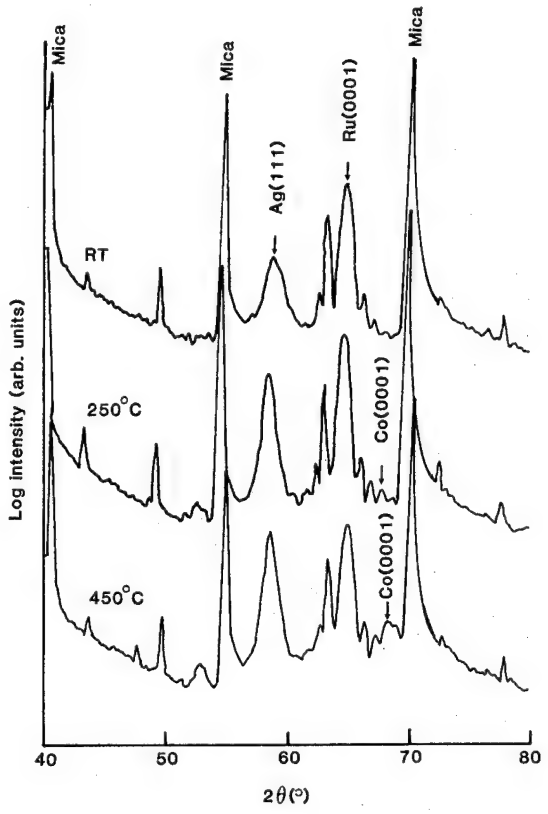

FIG. 1. X-ray $\theta/2\theta$ scans of $Co_{45}Ag_{55}$ prepared at three growth temperatures. The unidentified peaks arise from the mica and are left unindexed for clarity.

 0021-8979/96/79(8)/6247/3/$10.00

peak is relatively broad and less intense at LT and its position slightly shifted from the HT and MT samples. The Co peak is not visible at all at LT, emerging gradually as the deposition temperature and segregation improves. However, even at HT the Co peak is very weak and quite broad which may be a consequence of small grains of Co. This is consistent with the coexistence of high-quality RHEED patterns for HT Co,[5,6] as the RHEED coherence length is 50 Å. These results show the importance of analyzing the samples by TEM in order to quantify the grain size and degree of segregation for the three different growth temperatures. Both in-plane and cross-section TEM studies were made of three 45 at. % Co samples prepared at LT, MT, and HT. A TEM model TOPCON 002B with a point-to-point resolution of 1.8 Å was used. Energy-dispersive x-ray analysis (EDAX) with a probe area of 50–100 Å fitted to the TEM enabled composition analysis in different regions of the samples.

FIG. 2. TEM plan-view micrograph of $Co_{45}Ag_{55}$ prepared at 0 °C.

II. ELECTRON MICROSCOPY

In general the medium-temperature sample had a structure intermediate between the low- and high-temperature samples, but was much closer to the HT one. The MT and HT will therefore be considered together.

A. Low-temperature sample

Diffraction patterns observed from different areas of the sample indicated that there were two distinct regions. The first is region (1), where there is some segregation between the Ag and the Co. Here, spots related to the fcc structure of both the Co and Ag are visible along with spots deriving from the Ru hcp. Note that the Co is crystallized in its metastable fcc phase at low temperature. This may be due to the reduced mobility of the Co atoms which do not reach their bulk equilibrium position. The resulting strain energy can be minimized in the fcc phase. Region (2) is where only the Ag fcc and Ru hcp spots are visible, but there is nothing from the Co indicating that the Co is still well dispersed. From the coherence length of the beam, the lack of any regions with Co hcp structure is evidence for the fact that there are no significant areas of the sample with this structure.

The presence of a high degree of strain and many areas of dislocations in the plan-view micrographs support the idea that strain is responsible for the stabilization of the fcc Co. Two distinct regions are again observed. Region (1) is clearly two phase with inclusions of the order of 100 Å diameter that EDAX showed to be either Co rich (greater than 80%) or Ag rich. In some cases, as shown in Fig. 2, the contrast surrounding an inclusion is clear evidence of the presence of strain, while in other cases the inclusions are surrounded by a ring of strain relieving dislocations. On close examination it can be seen that the orientation of the lattice planes within the grains is the same as in the matrix. In region (2) EDAX analysis of the matrix indicated that it remained a mixture of Co and Ag with an average composition of 45 at. % Co. A cross section of a region of the matrix is shown in Fig. 3. There is a large scale-wavelike contrast caused by dislocations perpendicular to the well-oriented (111) planes which we do not believe to be due to the Moiré effect. These dislocations may represent a composition variation and their arrangement often gives the form of cigar shapes with aspect ratios up to 5:1. The atomic arrangement of the matrix is observed to be primarily fcc although on careful examination small clusters of hcp structure are visible as indicated in the figure. These may be evidence of small Co hcp clusters of order 20–30 Å diameter although it is estimated that these clusters make up only 4%–8% of the matrix so the remaining Co must be in the fcc phase. This result supports previous x-ray analysis of LT samples of varying composition

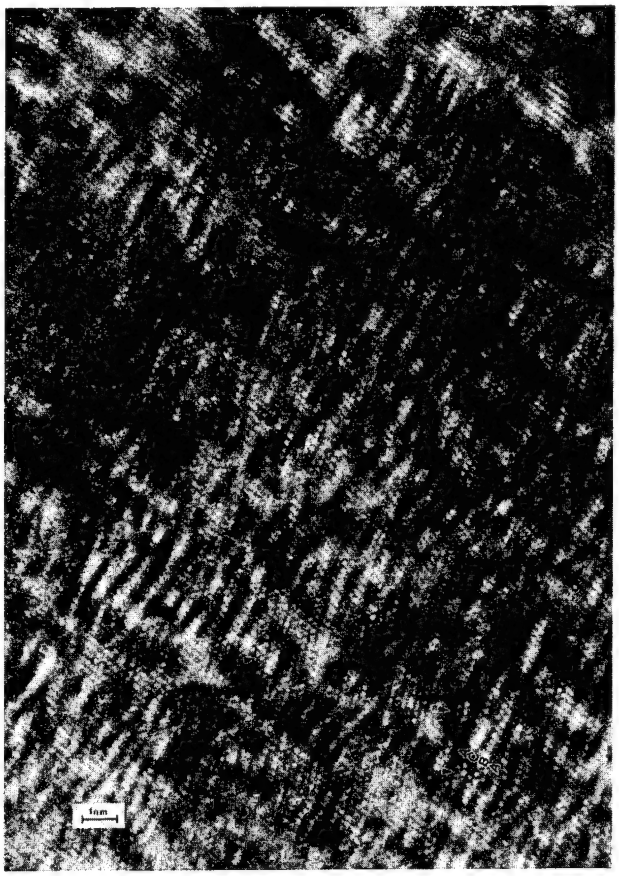

FIG. 3. TEM cross section of $Co_{45}Ag_{55}$ prepared at 0 °C. The letters represent lattice planes and the arrows point to small hcp clusters.

which attributed the divergence of the measured Ag lattice spacing from the bulk value to the presence of up to 8% Co impurities in the matrix.[5,6]

B. High- and medium-temperature samples

In these cases clear diffraction spots for fcc Ag and hcp Co and Ru are visible. In contrast to the LT sample the plan-view micrographs show little contrast which is a result of the improved crystalline quality with the presence of fewer dislocations. The Co is now stabilized in its hcp phase which is related to the reduced amount of strain in the sample.

Cross-sectional TEM revealed that some areas of the sample consist of pure Ag throughout the thickness, and in other regions where the bulk of the film is Co–Ag there is a layer of pure Co adjacent to the Ru buffer layer. It is also apparent that the thickness of the Ag regions (150 Å) is about half those of the Co–Ag regions (350 Å). Such a thickness variation across the sample was also noted in the AFM scans.[5,6] These AFM images indicated arrays of raised areas 150–200 Å high with flat surfaces about 5000 Å in diameter separated by 1000 Å.

Periodic contract in the CoAg region normal to the film plane was also observed. This may derive from dislocations present due to the composition and hence lattice variation from Co to Ag. The lattice planes do not follow the waves of this modulation but remain well oriented.

The high-crystalline quality of the HT sample can be seen in Fig. 4. Typically there is a very clear array of dislocations between the Ru buffer and a region of pure Co (just out of view of the photograph). The period of the dislocations contrast (32 Å=15 planes) is related to the 8% mismatch in lattice parameter between the Co and Ru. Above the Co region there is a second array of dislocation contrast (shown in the figure), but in this case the period is reduced to seven atomic planes. These upper regions contain CoAg and Ag as determined by EDAX. Here two Co and Ag regions are separated by an array of dislocations. The lattice planes can be counted on either side of the dislocations and here there is a ratio of seven Co atomic planes to six Ag planes which roughly corresponds to the expected lattice mismatch of these materials. This region of the sample is therefore well segregated, but into relatively small areas of Co and Ag.

III. DISCUSSION

Significant differences were seen between the LT and elevated temperature samples. At LT both the Ag and Co show (111) fcc structure accompanied by strain and dislocations. Cross sections reveal a homogeneous structure broken up by stacking faults with small clusters (10–20 atoms) of Co in a hcp structure. These small Co impurities, too small to be observed in the diffraction patterns, have a significant effect on the spin diffusion length reducing the GMR as discussed in Refs. 5 and 6. In contrast the high-temperature samples display segregated phases of fcc Ag and hcp Co with little evidence of any strain. In addition, cross sections show a step profile regions of the film with pure Ag and

FIG. 4. TEM cross section of $Co_{45}Ag_{55}$ prepared at 450 °C.

mixed CoAg regions which both have the Ag lattice parameter. In the mixed region, there is evidence of small pure Co filaments (23×10 $Å^2$) with the Co bulk lattice parameter. Surprisingly, at the Ru/CoAg interface a pure Co layer 20–30 Å thick was found separated from the CoAg by an array of dislocations.

Spin-dependent scattering in the nonmagnetic layers of annealed Co/Cu multilayers

H. Laidler and B. J. Hickey[a)]
Department of Physics, The University of Leeds, Leeds, LS2 9JT, United Kingdom

Annealing a multilayer is expected to promote diffusion at the interfaces. We have found that the interface roughness and giant magnetoresistance of Co/Cu (111) multilayers, grown by molecular-beam epitaxy on sapphire substrates, remain unchanged during anneals of up to 320 °C despite the zero-field resistivity having doubled. We explain this large increase in resistivity as due to the formation of an alloy between the top Cu layer of the multilayer and the Au protective cap. We propose that scattering in the AuCu alloy is spin dependent. We discuss this idea in the light of mean free path effects and the density of states of the entire sample. © *1996 American Institute of Physics.* [S0021-8979(96)55908-9]

The origin of the spin-dependent scattering which is the basis of the giant magnetoresistance (GMR) still remains a problem both theoretically[1] and experimentally. In particular, much research has concentrated on the role of interface roughness in magnetic multilayers. Recent growth studies of Co/Cu multilayers by Harp *et al.*[2] and Xu *et al.*[3] have indicated that the highest GMR occurs in samples with the highest degree of structural perfection. Zhang *et al.*[4] annealed sputtered Co/Cu multilayers and found that although the GMR decreased, the effect on the interfaces was too subtle to be deduced from the low-angle specular x-ray data. Without identification of whether the interface roughness had changed, it was difficult to deduce conclusions about the role of interface scattering.

Measurement of the buried interfaces in a multilayer is difficult and we have previously emphasized[5,6] the extreme care needed in interpreting x-ray data, the most widely used technique for analyzing structural changes. Systematic changes in low-angle specular x-ray scattering, which have been reported by other investigators as being interface roughness changes, could be explained by changes taking place in the capping and buffer layers. They can cause phase shifts in the x-ray waves resulting in changes to the Bragg peak height. Interface roughness can only be reliably determined from diffuse x-ray scattering. We have already reported[5] that the annealing of the Co/Cu multilayers discussed here caused no change in interface roughness. In this article we present a discussion of the role that the metallurgical changes in the capping layer play in the spin-dependent scattering.

The (Co 11 Å/Cu 8 Å)$_{20}$ multilayer was grown by molecular-beam epitaxy (MBE) onto a sapphire substrate using buffer layers of Nb (60 Å) and Cu (30 Å) to obtain high-quality growth. A 40 Å Au cap was laid to prevent the top layer of Cu from oxidizing. The sample was cut into identical pieces, checked first for uniformity by resistivity and x-ray measurements, and each annealed in a stream of oxygen-free nitrogen for 45 min at 200, 260, 290, and 320 °C, respectively, while a fifth was left unannealed. Further details of the growth, x-ray, and magnetotransport measurements have been reported elsewhere.[5] Room-temperature magneto-optical Kerr effect (MOKE) measurements were made on all samples in fields up to 2 T.

The resistivity measurements performed at 4.2 K are shown in Table I. Although ρ_s, the saturation field resistivity, more than doubled for the highest annealing treatment, $\Delta\rho$ scales with it resulting in little change to the GMR. The saturation field also remained unchanged for each sample at 4 T. Figure 1 shows the longitudinal MOKE curves for the unannealed and 320 °C samples. There is no evidence of any change in magnetization which is consistent with no change in the GMR.

Extensive x-ray measurements have been made on these samples using synchrotron radiation and have been reported elsewhere.[5] They have shown that there is no evidence of any changes in roughness of the Co/Cu interfaces. Thomson, Riedi, and Hickey[7] have performed nuclear-magnetic-resonance (NMR) measurements on these samples and have found that although there is evidence of a small relaxation of the strain in the interior of the Co layers, there is very little change to the interfaces. Also the x-ray rocking curves through the high-angle Co/Cu(111) peak show no discernible differences between any of the samples, which can be seen in Fig. 2.

The low-angle x-ray measurements did indicate that the surface electron density had increased, not possible from oxidation but true if the Au cap had alloyed with the top Cu layer. Figure 3(a) provides further evidence of this. There are significant changes to the shape of the high-angle θ-2θ x-ray scans between the sapphire and the Co/Cu peak. Simulations of the data have shown that this region depends sensitively on the thicknesses of the Nb and Cu buffers and Au capping layers. The main change on annealing is the disappearance of

TABLE I. Resistivity measurements of the annealed multilayer at 4.2 K.

Annealing treatment	ρ_s ($\mu\Omega$ cm)	$\Delta\rho$ ($\mu\Omega$ cm)	GMR (%)
Unannealed	8.2	3.0	37
200 °C	9.0	3.4	38
260 °C	12.0	4.4	37
290 °C	14.4	4.7	33
320 °C	18.6	5.8	31

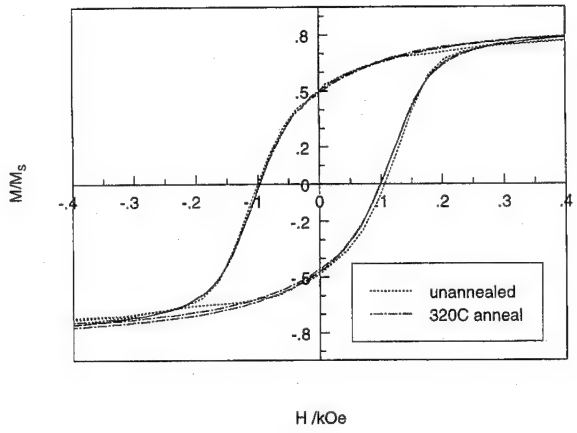

FIG. 1. Room-temperature longitudinal MOKE curves for the unannealed and 320 °C samples showing that the magnetization is unchanged.

the dip at 41° and the appearance of a peak in its place. The peak at 41° corresponds to the lattice constant for a $Au_{35}Cu_{65}$ alloy[8] and the equilibrium phase diagram for the Cu–Au system[9] suggests that an alloy of between 30 and 40 at. % of gold in copper was in fact the most likely to form at the annealing temperatures used. The peak could only be reproduced in this position by a simulation of the multilayer which replaced the top Cu and Au layer with a $Au_{35}Cu_{65}$ alloy.

In order to test the argument that an alloy had formed, a further sample was grown with an extra layer of Co between the multilayer and the Au cap to prevent the Cu and Au alloying. The phase diagram for Co and Au shows that these elements are largely immiscible and there is no stable alloy. This sample was annealed at 320 °C as before and the high-angle x-ray scans are shown in Fig. 3(b). There is very little difference between the two scans, which reinforces the argument that the changes occurring in Fig. 3(a) were due to a CuAu alloy forming.

The conclusion that very little had happened to the Co/Cu interfaces means that these are unusual results compared to many annealing experiments and highlight the importance of choice of substrate, using buffer layers which are immiscible in the multilayer and using nonoxidizing caps.

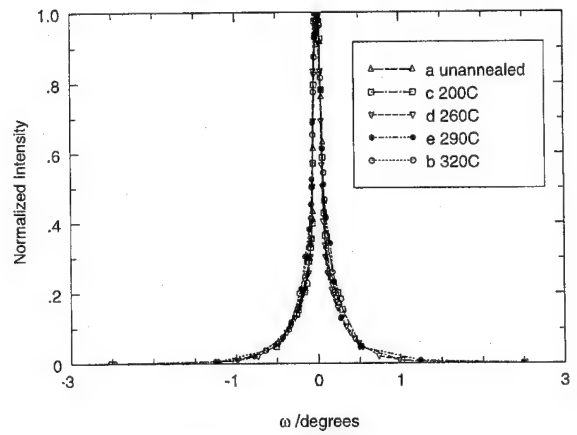

FIG. 2. Rocking curves performed on all samples through the high-angle Co/Cu(111) peak showing that there is no change upon annealing.

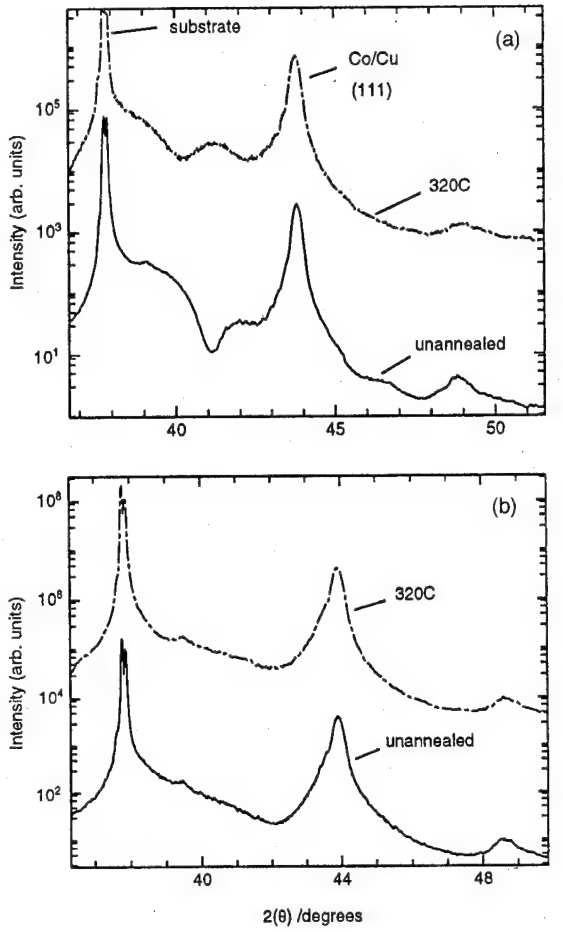

FIG. 3. High-angle θ-2θ x-ray scans of (a) Al_2O_3/Nb 60/Cu 30/(Co 11 Cu 8]$_{20}$/Au 40 and (b) Al_2O_3/Nb 30/Cu 30/(Co 15 Cu 8]$_{20}$/Au 15 multilayers (thicknesses in Å) before and after annealing at 320 °C. The shape of the region between the sapphire and Co/Cu peak is due to the Nb and Cu buffers and the Au cap. Scans are offset for clarity.

Additional weight to the argument comes from the magnetometry and transport; there was no observed change in the MOKE curves and the GMR was virtually unchanged. This experiment demonstrates that with careful planning a GMR system can be designed which is impervious to annealing up to temperatures in excess of 300 °C.

It may seem surprising that the alloying of the capping layer which comprises just 20% of the sample could cause such a large increase in resistivity. We have observed that both $\rho(0)$ and $\rho(B_s)$ increase in proportion such that the GMR remains much the same for different annealing conditions. We know that in samples such as these the shorter of the two mean free paths is about 400 Å,[10] which is comparable with the thickness of the sample. Normally capping and buffer layers are considered as low-resistance layers which act as shunts for the current through the sample and thereby reduce the GMR. This interpretation applies when the mean free path is sufficiently short so that the layers can be regarded as resistors acting in parallel.[11] When the mean free path is long, as in this case, the layers effectively act as resistors in series.

Now it can be understood why the cap, which forms only a small part of the total sample, can have a large effect

TABLE II. Comparison of the resistivity at 300 K and the GMR at 4.2 K for the two multilayers described in Fig. 3.

	ρ_0 (300 K)/$\mu\Omega$ cm	GMR % (4 K)
Cu/Au cap unannealed	19.3	35
320 °C	35.7	31
Co/Au cap unannealed	18.8	36
320 °C	21.9	33

on the sample resistivity. Previous work on CuAu alloys[12] have found that an increase of 0.3 $\mu\Omega$ cm at. % of Au in Cu is seen. This indicates that an increase of approximately 10 $\mu\Omega$ cm would be expected. Table II summarizes the magnetotransport measurements of the original annealed sample and the Co/Au cap sample before and after annealing at 320 °C. Comparison of the changes in resistivity upon annealing in each sample is consistent with the rise expected for formation of the alloy if the layers act as resistors in series.

Within the two-current model we can find simple expressions for $\rho(0)$, $\rho(B_s)$, and the GMR in terms of the resistivity of the separate spin channels (ρ_+ for the up spin and ρ_- for the down spin) and the asymmetry parameter $\alpha = \rho_-/\rho_+$,

$$\rho(0)=\frac{\rho_+}{4}(1+\alpha),$$

$$\rho(B_s)=\rho_+\frac{\alpha}{(1+\alpha)},$$

$$\frac{\Delta\rho}{\rho}=\frac{(1-\alpha)^2}{4\alpha}.$$

The GMR does not change therefore the scattering in the cap must be spin dependent. If the additional scattering were spin independent, the GMR should decrease. The additional resistance due to the alloyed cap is added to the resistance of each spin channel as a factor which multiplies ρ_+ and ρ_-. In other words, the individual scattering rates have increased by the same proportion. The density of final states, even for scattering in the cap, is asymmetric with respect to spin because it is the density of states of the whole sample which must be considered. The scattering in the cap is therefore spin dependent because it is determined by the density of available states. The increase in the zero-field and saturated-field resistivities is explained by the increase in ρ_+ and the constant GMR is a result of a constant α. This idea is borne out by the data in Table I where increases in resistivity after annealing are in the same proportion for both $\rho(0)$ and $\rho(B_s)$.

The clear conclusion from the annealing experiments we have performed is that the interface roughness of Co/Cu multilayers does not change significantly despite very large changes being observed in the zero- and high-field resistivities. Provided the multilayer is not destroyed by excessive annealing, the GMR is resistance to the changes in resistivity and it would seem that where large changes are observed, they are likely to be associated with changes in other layers rather than the Co/Cu itself.

Interfacial roughness of Fe–Cr GMR superlattices (abstract)

W. Dmowski and T. Egami

Fe–Cr superlattices exhibit giant magnetoresistance effect which can be utilized in magnetic recording heads. There are many studies indicating the role of the interfacial structure on the magnetoresistance effect. To elucidate this point we have performed x-ray diffraction study of three [Fe(30 Å)/Cr(12 Å)]$_{10}$ superlattices which had been sputtered in 4, 7, and 10 mTorr of Ar. We used position sensitive detector in horizontal setup to collect simultaneously specular scattering intensity (z component of the scattering vector **Q** perpendicular to the film) and off-specular intensity with Q_y parallel to the plane of the sample. This technique[1] allows to evaluate interfacial roughness at various length scales. Short range roughness may be due to interdiffusion, while some medium range roughness is also present, and could have effects on transport phenomena. In conventional low angle diffraction analysis these contributions are intermixed. From the Fourier transform of the scattered intensity distribution in $Q_x - Q_y$ plane the interfacial height fluctuation function $g(r)$ can be obtained (r is a lateral spacing). Figure 1 presents $g(r)$ obtained for three samples of Fe–Cr. It is apparent that 4 mTorr sample is very different than 7 and 10 mTorr in terms of interfacial roughness. We will discuss in detail results of the diffraction studies together with the magnetization and magnetotransport data. © *1996 American Institute of Physics.* [S0021-8979(96)61408-0]

Giant magnetoresistance in evaporated NiFe/Cu and NiFeCo/Cu multilayers (abstract)

A. M. Zeltser and Neil Smith
Eastman Kodak Company, San Diego Laboratories, San Diego, California 92121

The magnetic and transport properties of electron beam evaporated $(Ni_{83}Fe_{17}/Cu)_{10}$ and $(Ni_{66}Fe_{16}Co_{18}/Cu)_{10}$ multilayers (ML) were studied as a function of the Cu spacer and magnetic layer thicknesses (t_{Cu} and t_{NiFe}), annealing conditions and Ta buffer layer thickness. The ML were evaporated in a magnetic field at deposition rates ~ 2 Å/s and background pressure $<5\times10^{-8}$ mbar on Si/SiO_2 substrates at T_s=200 °C. These ML exhibited two unique features: (1) $\Delta R/R$ and the interlayer coupling did not show oscillatory behavior as a function of t_{Cu}; and (2) after magnetic post annealing, $\Delta R/R$ increased from <0.3% in the as-deposited state, to up to ~6% and 7% in Ta/(NiFe/Cu) and (NiFeCo/Cu), respectively. The coupling between the NiFe layers changed from ferromagnetic in the as-deposited state (M_r/M_s~0.9) to essentially antiferromagnetic (M_r/M_s <0.2) after appropriate annealing, and the ML became virtually isotropic in-plane. This is quite different from strong oscillatory behavior of giant magnetoresistance (GMR) previously reported in (NiFe/Cu) as-deposited ML made by ion-beam sputtering.[1] After annealing at 300° and 325 °C for 2 h, the $\Delta R/R$ became ~4.5% and ~6.5% in (NiFe/Cu) and (NiFeCo/Cu) ML, respectively, and remained approximately constant for t_{Cu}=20 to 40 Å. The coupling field generally decreased with an increase in t_{Cu} and t_{NiFe} and after annealing at 300 °C dropped to as low as ~25 and 45 Oe in (NiFe/Cu) and (NiFeCo/Cu) ML, respectively. The $\Delta R/R$ of Ta/(NiFe/Cu) ML increased with the thickness of Ta buffer layer from 30 to 70 Å. The high-angle θ–2θ x-ray scans of (NiFe/Cu) ML showed (111) texture, essentially independent of annealing temperature. The low-angle x-ray diffraction did not reveal roughening of the Cu–NiFe interfaces as a result of annealing. In many respects the GMR behavior of these ML is similar to that reported in sputtered "discontinuous" NiFe/Ag.[2] However, in contrast to the latter, the resistivity of NiFe/Cu monotonically increases with annealing temperature. This suggests that lattice interdiffusion is more prominent in the NiFe–Cu system, consistent with a greater equilibrium solubility of Cu in the NiFe matrix compared to that of Ag. It is believed that Cu diffusion along the NiFe grain boundaries creates *intra*-layer magnetic discontinuity in NiFe and promotes *inter*-layer antiferromagnetic coupling between adjacent NiFe layers, which then gives rise to the observed GMR.[3] Evaporated NiFe/Cu ML showed very small hysteresis and uniform GMR properties throughout the thickness, which makes them good candidates for GMR–DMR heads.[4] [S0021-8979(96)61508-X]

Based on a semiclassical model, the transport properties in systems of cylindrical or spherical magnetic granules are investigated analytically. It is shown that the conductivities as well as the magnetoresistance of these systems depend strongly on the size of the granules. In particular, there is always an optimum granular size for the magnetoresistance. © *1996 American Institute of Physics.* [S0021-8979(96)79808-0]

Recently, there has been much interest in the study of giant magnetoresistance (GMR) in magnetic inhomogeneous systems[1–7] both experimentally and theoretically. For multilayer structures, almost all the low-temperature features of GMR could be understood by semiclassical models[8–12] or quantum theories[13–15] by including spin-dependent interface scattering and bulk scattering. Previous theoretical investigations[5,16] on the GMR in granular systems are based on the assumption that transport in these systems is quite close to that in multilayered systems with current perpendicular to the layers. However, differing from those in multilayered structures, both the distributions of the electric field and currents are spatially varied in these three-dimensionally inhomogeneous systems. Therefore, it is valuable and interesting to develop a theory which includes spatial variations in the electric field and in the currents.

In this article, we present a semiclassical description of the GMR in magnetic granular systems, in which the spatial variations of the electric fields and the currents are considered. A new formalism of the position-dependent current is developed. In particular, analytical expressions for the resistivity are obtained. We focus our attention on systems of cylindrical magnetic granules. We find that both the GMR and the resistivities depend strongly on the granular sizes and that there is always an optimum granular size for the GMR.

Let us consider a general inhomogeneous system in which charge carriers are scattered by impurities and rough interfaces. For convenience, we do not include the spin degrees of freedom for a while. In the presence of an external electric field, the steady-state transport properties in this system can be described by the following effective Boltzmann equation:[17]

$$\mathbf{v}\cdot\nabla g + g/\tau = e\mathbf{v}\cdot\mathbf{E}^{\text{eff}}, \tag{1}$$

where τ is the position-dependent relaxation time and g is a function characterizing the deviation of the distribution function f from the equilibrium distribution f_0, which satisfies the relation $f=f_0+g(\partial f_0/\partial\epsilon)$. Since interface scattering is also considered as impurity scattering in thin mixing films,[14] the entire scattering effect is included in the position-dependent relaxation time $\tau(\mathbf{r})$. $\mathbf{E}^{\text{eff}}(\mathbf{r})$ is the effective internal field to be determined from the continuity condition of the current.

In general, the position-dependent current is related to the electric-field by a two-point conductivity tensor $\sigma_{\alpha\beta}(\mathbf{r},\mathbf{r}')$, such that

$$J_\alpha(\mathbf{r}) = \int d^3r'\,\sigma_{\alpha\beta}(\mathbf{r},\mathbf{r}')E^{\text{eff}}_\beta(\mathbf{r}'), \tag{2}$$

where the summation is indicated by two same coordinate labels. By using the path-integral approach,[12,14] we solve the Boltzmann Eq. (1) and obtain

$$\sigma_{\alpha\beta}(\mathbf{r},\mathbf{r}') = C_e r_{0\alpha} r_{0\beta}\Phi(\mathbf{r},\mathbf{r}'), \tag{3}$$

with

$$\Phi(\mathbf{r},\mathbf{r}') = \frac{1}{4\pi|\mathbf{r}-\mathbf{r}'|^2}\exp\left[-\int_{\mathbf{r}'\to\mathbf{r}}\frac{du''}{\lambda(\mathbf{r}'')}\right], \tag{4}$$

$C_e=3n_e e^2/2mv_F$, $\hat{\mathbf{r}}_0=(\mathbf{r}-\mathbf{r}')/|\mathbf{r}-\mathbf{r}'|$, and $\lambda(\mathbf{r})=v_F\tau(\mathbf{r})$. The integral in Eq. (4) is along the straight line connecting the points $\mathbf{r}$ and $\mathbf{r}'$, and du'' is the element of line at the point $\mathbf{r}''$. The effective field $\mathbf{E}^{\text{eff}}$, determined by combining Eq. (2) with the continuity condition for the current, is found to be[17]

$$\mathbf{E}^{\text{eff}} = \mathbf{E}^{\text{ex}} - \nabla\mu, \tag{5}$$

where $\mu = GD_\beta E^{\text{ex}}_\beta$ with

$$G=(1-\Phi\Lambda)^{-1}=1+\Phi\Lambda+\cdots, \tag{6}$$

$D_\alpha(\mathbf{r},\mathbf{r}')=r_{0\alpha}\Phi(\mathbf{r},\mathbf{r}')$, and $\Lambda(\mathbf{r},\mathbf{r}')=\delta(\mathbf{r}-\mathbf{r}')/\lambda(\mathbf{r})$. Here, GD_β represents the integral $\int d\mathbf{r}''G(\mathbf{r},\mathbf{r}'')D_\beta(\mathbf{r}'',\mathbf{r}')$. The constant $\mathbf{E}^{\text{ex}}$ in the above expressions is actually the external field, since

 0021-8979/96/79(8)/6255/3/$10.00

$$\mathbf{E}^{\mathrm{ex}}=\langle \mathbf{E}^{\mathrm{eff}} \rangle, \tag{7}$$

where $\langle \cdot \rangle$ means taking the average over the whole system.

Now let us turn to investigate transport in granular systems within the framework of a mean-field treatment. We consider the N_p-particle system to be realized by adding one particle to the system of N_p-1 particles. The effective field in the system of N_p-1 particles is written as $\mathbf{E}^{\mathrm{bc}}$, which is essentially the sum of the applied field and the field produced by the accumulated charge on the N_p-1 particles. The N_p-particle problem is then treated approximately as that of an isolated particle in the background field $\mathbf{E}^{\mathrm{bc}}$. The above considerations can be explicitly represented as

$$\mathbf{E}^{\mathrm{eff}}=\mathbf{E}^{\mathrm{bc}}-\nabla(G_1 D_{1,\beta} E^{\mathrm{bc}}_{\beta}). \tag{8}$$

A Subscript 1 has been used to indicate that the parameters are associated with the single-particle case. The background field $\mathbf{E}^{\mathrm{bc}}$ will be determined from the boundary condition (7). Equation (8) is highly useful for us to determine the effective electric field in the N_p-particle system, because we need only to solve the problem of an isolated particle in the background electric field. We wish to point out that Eq. (8) is appropriate only in the small region near the central particle. Nevertheless, using this equation in the region of every particle, we are able to obtain the field in the whole system.

To obtain the average conductivity analytically, we now take the local limit, i.e.,

$$\sigma^{c}_{\alpha\beta}(\mathbf{r},\mathbf{r}')=\sigma(\mathbf{r})\,\delta_{\alpha\beta}\delta(\mathbf{r}-\mathbf{r}'), \tag{9}$$

where $\sigma(\mathbf{r})=ne^2\lambda(\mathbf{r})/2mv_F$.[18] Since $\nabla\times\mathbf{E}^{\mathrm{eff}}=0$, it is convenient to define an effective scalar potential by

$$\mathbf{E}^{\mathrm{eff}}(\mathbf{r})=-\nabla U^{\mathrm{eff}}(\mathbf{r}). \tag{10}$$

We consider first the system composed of parallel ferromagnetic cylinders of radius a in a nonmagnetic medium. The electric field is assumed to be applied along the z axis and perpendicular to the cylinders. For simplicity, $\lambda(\mathbf{r})$ is taken to be the constant λ_0 in the medium, λ_F in the particles, and λ_I in the mixing films, respectively. If we consider all granules to be identical cylinders, the equation of continuity for the current becomes Poisson's equation in all regions. In this case, the effective potential in the $x-y$ plane has the form

$$U^{\mathrm{eff}}(\rho,\varphi)=-\sin(\varphi)\begin{cases} E^{\mathrm{bc}}\rho+D/\rho, & \rho>a+d \\ C_1\rho+C_2/\rho, & a+d>\rho>a. \\ E^{F}\rho, & a>\rho \end{cases} \tag{11}$$

Here D, C_1, C_2, and E_F are constants to be determined from the continuity of the scalar potential and the current at $r=a$ and $r=a+d$. For example, the electric field in the inside region of the particles E_F is found to be $E^F=\gamma_F E^{\mathrm{bc}}$ with $\gamma_F=2\lambda_0/(\lambda_0+\lambda_F+\lambda_0\lambda_F R_I/a)$. We have assumed that d is much less than a, so that only the ratio $R_I=d/\lambda_I$ is of significance.

Now, we need to calculate the average of the effective electric field. We emphasize that even when the thickness goes to zero, the contribution from the field in the interlayer cannot be neglected. In terms of Eq. (7), we obtain

$$E^{\mathrm{ex}}=[(1-f)+(\gamma_F+\gamma_I)f]E^{\mathrm{bc}}, \tag{12}$$

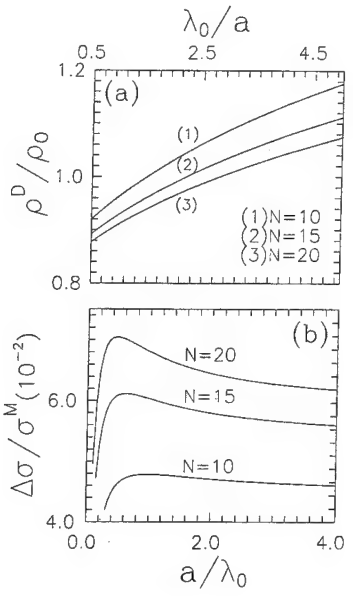

FIG. 1. (a) Resistivity ρ^D as a function of λ_0/a and (b) percent of GMR $\Delta\sigma/\sigma^M$ as a function of a/λ_0 in systems of cylindrical granules for several spin-asymmetry factors N. The other parameters are $f=0.3$, $\lambda_F^{\uparrow}=0.6\lambda_0$ and $R_I^{\uparrow}=1.0$.

where f is the volumetric filling factor, and $\gamma_I=\lambda_F R_I\gamma_F/a$. The average conductivity is evaluated from $\langle J\rangle/E^{\mathrm{ex}}$.

In order to elucidate the GMR effect, the spin degrees of freedom need to be included. We focus on the cases where the spin diffusion length is much larger than the mean free path, so that the total conductivity is the sum from the two spin channels, and for each channel the previous formulas can be extended straightforwardly. Let λ_I^s and λ_F^s, with $s=\uparrow$ for the majority spin and $s=\downarrow$ for the minority spin, denote the mean free path of electrons in the mixing films and in the particles,[8] respectively then we arrive at

$$\frac{\sigma^D}{\sigma_0}=\frac{2(1-f)+f(\gamma_F^{\uparrow}\lambda_F^{\uparrow}+\gamma_F^{\downarrow}\lambda_F^{\downarrow})/\lambda_0}{2(1-f)+(\gamma_F^{\uparrow}+\gamma_F^{\downarrow}+\gamma_I^{\uparrow}+\gamma_I^{\downarrow})f}, \tag{13}$$

for the demagnetized state, and

$$\frac{\sigma^M}{\sigma_0}=\sum_{s=\uparrow,\downarrow}\frac{(1-f)+f\gamma_F^s\lambda_F^s/\lambda_0}{2(1-f)+2(\gamma_F^s+\gamma_I^s)f}, \tag{14}$$

for the magnetized state, with $\sigma_0=ne^2\lambda_0/mv_F$.

The GMR effect is measured by $\Delta\sigma=\sigma^M-\sigma^D$, which can be found to be always positive. Its amplitude is defined as $\Delta\rho/\rho^D=\Delta\sigma/\sigma^M$ with $\rho^D=1/\sigma^D$, $\rho^M=1/\sigma^M$, and $\Delta\rho=\rho^D-\rho^M$. For simplicity, we here assume the spin-asymmetry factors in the particles and in the mixing film are of the same value $N=\lambda_F^{\downarrow}/\lambda_F^{\uparrow}=R_I^{\uparrow}/R_I^{\downarrow}$ although they are quite different. In Fig. 1(a), we plot the resistivity as a function of the inverse of radius, which is approximately in linear proportion. The GMR is shown in Fig. 1(b). There is always an optimum radius for the GMR. To understand this feature, we notice that there two factors that determine the GMR. On one hand, since the number of atoms at interfaces is inversely proportional to the radius, the proportion of the spin-dependent interface scattering to the total scattering increases with decreasing size of the cylinders. On the other hand, the

smaller the radius, the more easily the currents pass by the cylinders, an effect which results in the decrease in the spin dependence of the scattering of the electrons. The competition between these two factors leads to a maximum of the GMR.

The above calculations can be extended straightforwardly to the case of spherical granules. We can find that eqs. (13) and (14) are still valid if the parameters γ_F^s and γ_I^s are represented as

$$\gamma_F^s = \frac{3\lambda_0}{2\lambda_0 + \lambda_F^s + 2\lambda_0 \lambda_F^s R_I^s a}, \tag{15}$$

$$\gamma_I^s = 2\lambda_F^s R_I^s \gamma_F^s / a. \tag{16}$$

In summary, we have presented a new and efficient approach to calculate the conductivity in inhomogeneous systems based on the effective Boltzmann equation. Within a mean-field framework, we employ our formal theory to investigate in detail the GMR effect in cylindrical magnetic granular systems.

[18] Beyond the local limit, only a numerical solution of $\sigma_{\alpha\beta}(\mathbf{r},\mathbf{r}')$ can be obtained in terms of Eqs. (5) and (6). As far as the distance of particles is significantly larger than the mean free path, the conclusion obtained in the following is still expected qualitatively.

Giant magnetoresistance in granular Fe–MgF_2 films

T. Furubayashi and I. Nakatani
National Research Institute for Metals, Tsukuba 305, Japan

The giant magnetoresistance effect observed in granular Fe–MgF_2 films, which consist of metallic particles embedded in an insulating medium, is reported. Large negative magnetoresistance (MR) with a magnitude up to 7.5% at 78 K was observed in semiconducting films with the Fe composition below the percolation threshold. Field dependence of the MR is well described by the form proportional to the square of the magnetization. The MR effect in this system seems to arise from the tunneling conductance between the Fe particles depending on the relative relation of the magnetization direction. © *1996 American Institute of Physics.* [S0021-8979(96)56008-3]

I. INTRODUCTION

Much attention has been attracted by granular materials consisting of ferromagnetic metallic particles dispersed in a metallic matrix in view of the giant magnetoresistance (GMR).[1–3] On the other hand, electric conductance of systems consisting of metallic particles in an insulating matrix has been also extensively investigated.[4,5] When the metal content is below the percolation threshold, conductance in such systems is considered to originate in a tunneling current between metallic particles separated by an insulating barrier. Gittleman and co-workers[4] reported negative MR in granular Ni–SiO_2 films. They suggested that the MR arises from the effect that tunneling conductance depends on the relative direction of the magnetization between neighboring particles. Although the MR ratio is not large (<1% at room temperature), the sign is independent of the direction of the current to the magnetic field, similarly with GMR effect in granular metal–metal films. Mitani, Ohnuma, and Fujimori recently found large negative MR reaching the amplitude of 8% in granular Co–Al–O films,[6] which consist of Co particles separated by Al_2O_3.

Tunneling junctions with ferromagnetic electrodes have been extensively investigated. Miyazaki and Tezuka[7] observed that the conductance of a tunneling junction Fe/Al_2O_3/Fe changes with the amplitude reaching 30%, depending on the relative angle of the magnetization of each Fe electrode. Thus, it seems possible to obtain large MR in granular metal–insulator systems by using Fe, although MR effects in granular Fe–insulator systems have not yet been reported so far.

In this work, we investigated MR effects in granular Fe–MgF_2 films. It has been shown that the two materials are immiscible and that granular systems consisting of Fe particles in MgF_2 can be obtained.[8] The relationship between MR and magnetization curves was examined.

II. EXPERIMENT

The samples were prepared by coevaporating two sources of Fe and MgF_2 in a vacuum better than 5×10^{-6} Pa. The films were deposited onto glass substrates, which were kept at temperatures T_s of 300 or 400 K. The deposited amount of each material was monitored by respective quartz oscillator. The thickness of the films is typically 30–200 nm. Electric resistance was measured by the conventional dc four-terminal method. The magnetization curves were measured by an alternating gradient magnetometer.

From transmission electron microscopy (TEM) observations of the samples with the volume fraction x of Fe studied here, it was found that the films have a granular structure with the Fe grain size of around 3 nm. Figure 1 shows a typical TEM photograph. The electron-diffraction patterns showed the bcc structure of Fe.

III. RESULTS AND DISCUSSION

Negative MR was observed as typically shown in Fig. 2. Magnetic field was applied in the direction parallel to the film plane. No significant difference was observed between MR curves taken in the longitudinal (current parallel to field) and the transverse (current perpendicular to field) geometry. The MR in this material is isotropic.

The magnetization curve at room temperature in Fig. 2 shows superparamagnetic behavior with no hysteresis. The blocking temperature T_B, below which the magnetization curve has hysteresis, was found to be about 200 K for this sample from the magnetization measurements. The MR curves below T_B showed hysteresis correspondingly to the magnetization curves as shown in Fig. 2(b) at 78 K. The MR ratio, $[\rho_0 - \rho(H)]/\rho_0$, where ρ_0 is the maximum at each temperature, is 4.0% at 297 K and 7.5% at 78 K with the applied field $\mu_0 H = 0.9$ T.

The resistivity ρ under zero magnetic field and the MR ratio with $\mu_0 H = 0.9$ T, measured in the transverse geometry at room temperature, are summarized in Fig. 3 against the Fe

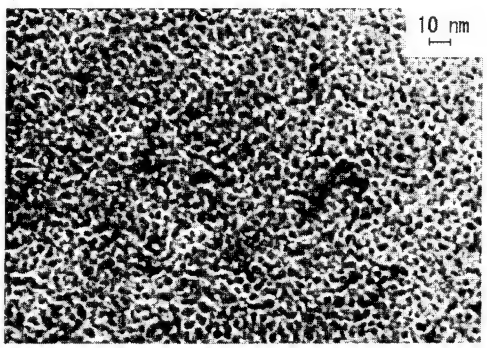

FIG. 1. TEM micrograph of granular $Fe_{0.42}(MgF_2)_{0.58}$ deposited at T_s =400 K.

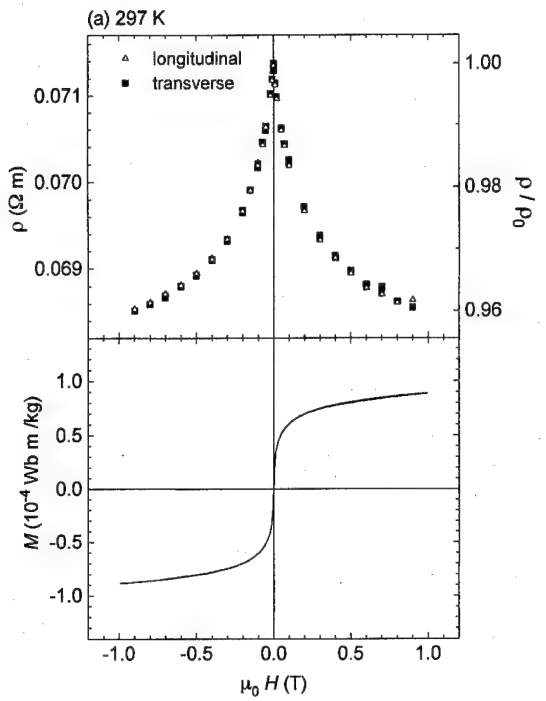

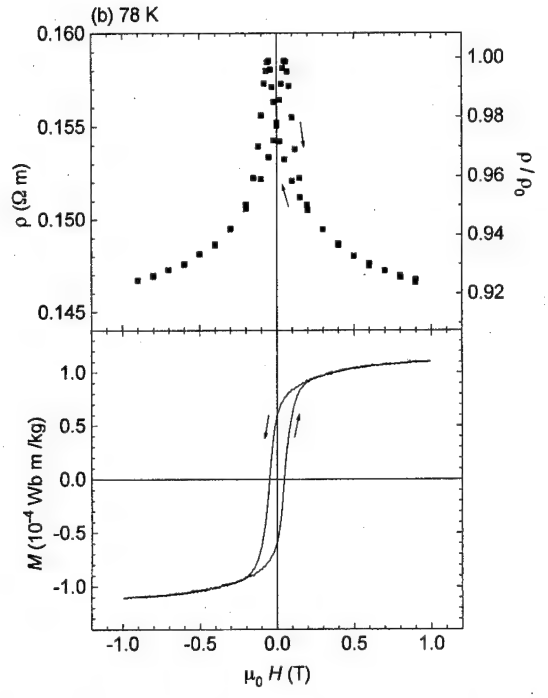

FIG. 2. Electric resistivity and magnetization plotted against magnetic field for the sample with the volume composition $Fe_{0.42}(MgF_2)_{0.58}$ deposited at T_s=400 K; measured at (a) 297 K and (b) 78 K. Magnetic field was applied in the direction parallel to the film plane.

volume fraction x. The large MR ratio was observed for samples with large resistivity, i.e., small Fe fraction.

Temperature dependence of the resistivity was examined for the samples with large MR. The resistivity increased with decreasing temperature as shown in Fig. 4. The result shows no metallic percolation path in these films. The Fe content in these samples is below the percolation threshold. The electrical resistivity in granular systems consisting of metallic

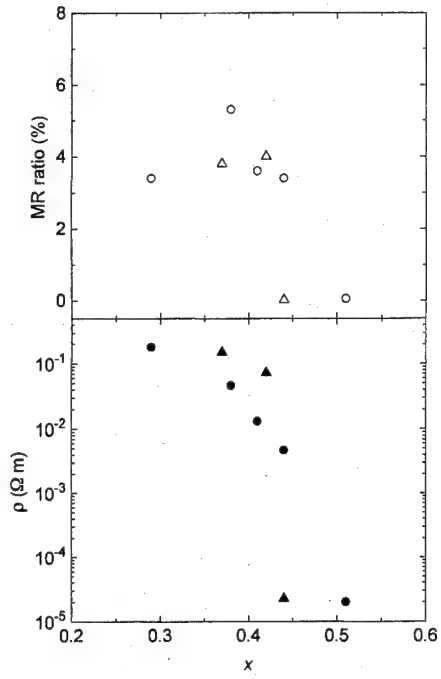

FIG. 3. MR ratio $[\rho_0-\rho(H)]/\rho_0$ with $\mu_0 H$=0.9 T, and zero-field resistivity are shown against the volume fraction x of Fe at room temperature. Circles are for the samples prepared at T_s=300 K and triangles are for T_s=400 K.

particles separated by an insulating matrix was theoretically investigated in terms of tunneling conductance between particles.[5] It was shown that the temperature dependence is expressed by

$$\rho \propto \exp(T/T_0)^{-\alpha}, \tag{1}$$

with α=1/2. It seems in Fig. 4 that log ρ is mostly linear to $T^{-1/2}$ according to the above relation. However, the data can be also fitted to the form (1) with α=1/4, which is derived

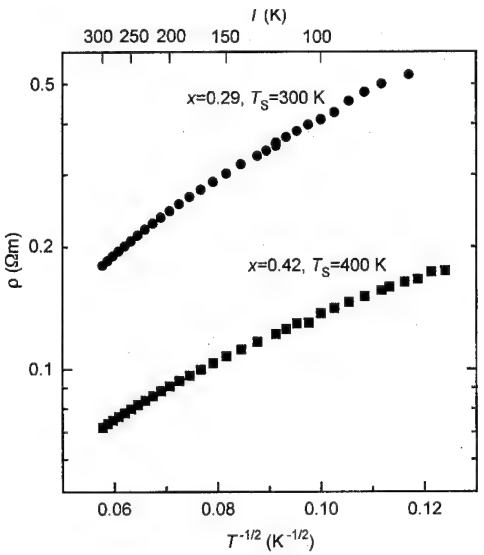

FIG. 4. Resistivity plotted against $T^{-1/2}$, where T is the temperature, for each sample with the Fe volume fraction x prepared at the substrate temperature T_s.

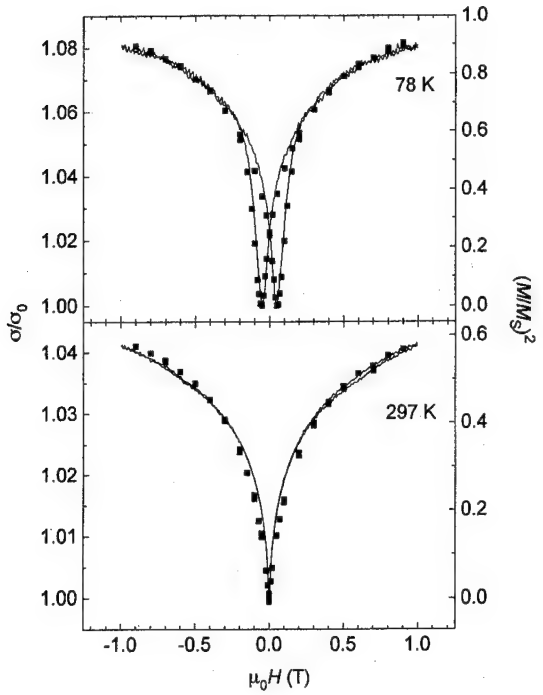

FIG. 5. Solid squares denote conductance σ normalized by the minimum value σ_0 for the same sample as Fig. 2. Solid curves indicate $(M/M_s)^2$, where M_s is the value of M at 10 K with $\mu_0 H=1$ T.

from the theory of variable range hopping[9] for amorphous semiconductors. It is difficult at present to determine the value of α. Measurements at lower temperatures would be required.

The field dependence of the MR is discussed in terms of tunneling conductance. The tunneling conductance between two neighboring particles i and j is expressed by[10] $G=G_0[1+\Gamma(\mathbf{m}_i\cdot\mathbf{m}_j/m^2)]$, where $\mathbf{m}_i$ is the magnetization vector and G_0 and Γ (>0) are constants. If all the particles are uniform and the correlation between $\mathbf{m}_i$ and $\mathbf{m}_j$ can be neglected, we obtain the conductivity σ of the film by taking the average of $\mathbf{m}_i\cdot\mathbf{m}_j$ as[3,5]

$$\sigma=\sigma_0[1+A(M/M_s)^2], \tag{2}$$

where M_s is the saturation magnetization. The conductance increases when the magnetization of each particle is aligned in the direction of magnetic field. As shown in Fig. 5, the experimental data are well expressed by the form of Eq. (2).

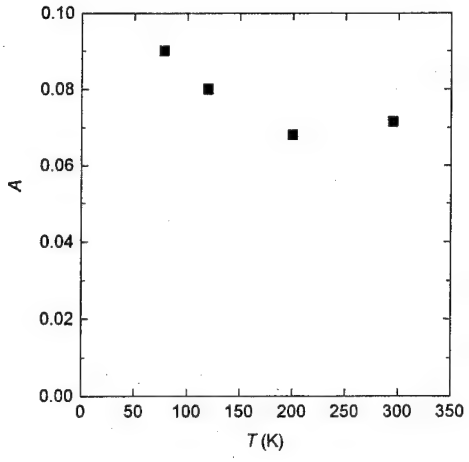

FIG. 6. The coefficient A in Eq. (2) obtained at each temperature for the sample shown in Figs. 2 and 5.

Thus, the field dependence of the MR is understood as the result of tunneling conductance. The coefficient A weakly depends on temperature as shown in Fig. 6.

IV. SUMMARY

The MR effect in granular Fe–MgF_2 films, which consist of metallic particles in an insulating matrix, was investigated. Negative and isotropic GMR with the MR ratio up to 7.5% was observed. The field dependence is approximately proportional to the $(M/M_s)^2$ term. The GMR effect in this system seems to arise from tunneling conductance depending on the relative direction of the magnetization of neighboring particles.

The influence of Ni on the microstructure and GMR of the Co–Cu alloy granular films (abstract)

S. Y. Zhang and Q. Q. Cao
Department of Physics, Nanjing University, Nanjing, Peoples Republic of China

The microstructure and Giant Magnetoresistance (GMR) in Co–Cu and Co–Ni–Cu alloy granular films prepared by dc magnetron sputtering technique was discussed. The microstructure of Co–Ni–Cu alloy granular films observed by XRD, SEM, and HRTEM examinations showed even microscopic tissue in which nanoparticles of Co–Ni were well-distributed, much different than that of Co–Cu alloy granular films in which full-grown microparticles of Co were embedded in Cu matrix. By Magnetic Hysteresis Measurement and Neel's superparamagnetism theory, the mean size of the Co–Ni particles in Co–Ni–Cu alloy granular films was estimated to be 2 to 4 nm, much smaller than that in Co–Cu alloy granular films. These results indicated that owing to the existence of Ni in Co–Ni–Cu alloy granular films the phase segregation was not a nucleation and growth process as that of Co–Cu alloy granular films but due to spinodal decomposition which was reported for the first time in granular films. It was also found that when samples dropped from room temperature to low temperature, the GMR boomed in Co–Ni–Cu alloy granular films, on the contrary to the behavior of Co–Cu alloy granular films. This fact meant that the Co–Ni–Cu alloy granular films with proper Ni content might have no response to the temperature change. Furthermore, the GMR as a function of magnetic density in Co–Ni–Cu alloy granular films is of much better linearity than that in Co–Cu alloy granular films. © *1996 American Institute of Physics.* [S0021-8979(96)61608-9]

Real-space analysis of inhomogeneous scattering versus superlattice-potential effects for magnetotransport (abstract)

Horacio E. Camblong
Department of Physics, University of San Francisco, San Francisco, California 94117

Spin-dependent scattering has usually been regarded as the basic mechanism for giant magnetoresistance (GMR), following the seminal quasiclassical work of Camley and Barnás. When this mechanism is considered, the correct quantum-mechanical treatment of magnetotransport in multilayers is provided by the real-space Kubo approach.[1] In addition, band-structure effects due to imperfect matching of the Fermi surfaces of the constituent materials of the superlattice have been regarded as another source of GMR.[2] It turns out that a real-space approach to superlattice effects is both straightforward and intuitive. In effect, a solution of this *unified* model of inhomogeneous scattering and superlattice potentials is accomplished by deriving the real-space Green's function, which is a direct generalization of that of Ref. 2, but with a wavevector that is obtained by solving the dispersion relation for a Kronig-Penney model. It is shown that spin-dependent scattering remains the dominant mechanism, even though it is somewhat modified by the presence of superlattice potentials; that is, GRM is mainly due to a "short-circuit effect" rather than due to a "channeling effect." The corresponding "internal quantum size effects" (due to potential barriers) are not easily observable because of, among other factors, the exponential suppression of the one-particle propagator in the presence of the relatively short mean free paths in multilayers; this "geometrical effect" is an outstanding feature of magnetic multilayers as their giant magnetoresistance is governed by strong scattering at the interfaces. Finally, due to interdiffusion, the standard usage of reflection coefficients is shown to be incorrect. © *1996 American Institute of Physics.* [S0021-8979(96)61708-8]

Magnetic tunneling effect in $Fe/Al_2O_3/Ni_{1-x}Fe_x$ junctions

N. Tezuka and T. Miyazaki
Department of Applied Physics, Faculty of Engineering, Tohoku University, Sendai 980-77, Japan

The dependence of the magnetoresistance ratio, $\Delta R/R_s$, on the Ni content has been studied in $Fe/Al_2O_3/Ni_{1-x}Fe_x$ $(0 \leq x \leq 1)$ tunneling junctions. The value of $\Delta R/R_s$ at 4.2 K increased with increasing x and exhibited a maximum of ~35% at $x=0.8$. The result is discussed by taking into account the spin-polarization of ferromagnetic electrodes. © *1996 American Institute of Physics.* [S0021-8979(96)82908-2]

I. INTRODUCTION

The pioneering work concerning the magnetic tunneling effect was conducted first by Julliere.[1] He formed Fe/Ge/Co junction and measured the conductance at $T<4.2$ K under different magnetic fields as a function of applied voltage. The relative change of conductance, $\Delta G/G$, was ~14%, where ΔG is the difference of conductance between the two values corresponding to parallel and antiparallel magnetizations of the two ferromagnetic electrodes, and G is the conductance in the state of antiparallel magnetization. After his report several attempts were made in order to prepare a junction with large conductance (or resistance) ratio. The highest value of $\Delta R/R_s$ at room temperature reported before 1991 was only 2.7%,[2] and far less than the value expected from the theory taking into account of ferromagnetic electrode spin-polarizations. Recently, we have found a giant magnetoresistance (MR) ratio of 30% at 4.2 K and 18% even at room temperature in $Fe/Al_2O_3/Fe$ junction.[3] Also, various junctions with combinations of magnetic electrodes exhibiting a relatively large MR ratio at room temperature were successfully prepared by us[4] and by Moodera *et al.*[5] and it was shown that MR ratio is roughly proportional to the products of spin-polarizations of both ferromagnetic electrodes.[4] However, in these experiments the ferromagnetic electrodes used were pure metals, permalloy and/or 50FeCo alloys, and no experiment for the junctions with the ferromagnetic composition varied systematically is reported.

The spin-polarizations of Fe–Ni binary alloys were measured systematically[6] and their values were relatively large. This article describes the dependence of MR ratio in $Fe/Al_2O_3/Ni_{1-x}Fe_x$ tunnel junctions on x, and discusses briefly the results in the light of the spin-polarizations.

II. EXPERIMENT

The magnetic electrodes were prepared by electron beam evaporation. On the other hand, the aluminum film was prepared by rf sputtering because more smooth Al surface would be obtained by the sputtering than evaporation method. First, 1000 Å thick Fe film was deposited through a mask to form a long narrow strip (1 mm wide 15 mm long) on to a glass substrate. The growth rate was 3–6 Å/s. The pressure during evaporation was $\sim 1\times10^{-6}$ Torr. Next, an aluminum film was sputtered through a mask in a circular form with a 5 mm diameter. The thickness was 55 Å. The system base pressure was lower than 1×10^{-6} Torr and an Ar pressure during sputtering was 1.5 mTorr. The typical growth rate was 5.6 Å/s. Then the sample was taken out from the vacuum vessel and the aluminum was oxidized in air at room temperature for 24 h. Finally, a counter-electrode film was evaporated through a mask to form a cross strip of dimension 1×15 mm^2. In order to vary the induced magnetic anisotropy and/or coercive force for both electrodes, the substrates temperature were kept at 200 °C for the base electrode and at room temperature for the counter-electrode except $Fe/Al_2O_3/Ni_{0.8}Fe_{0.2}$ junction. In the case of this junction, the substrate was at room temperature for both electrodes. The

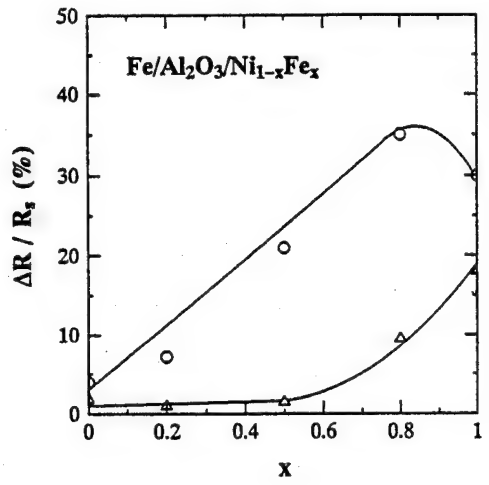

FIG. 2. MR ratio at 4.2 K (○) and 300 K (△) as a function of Fe content in Fe–Ni electrode.

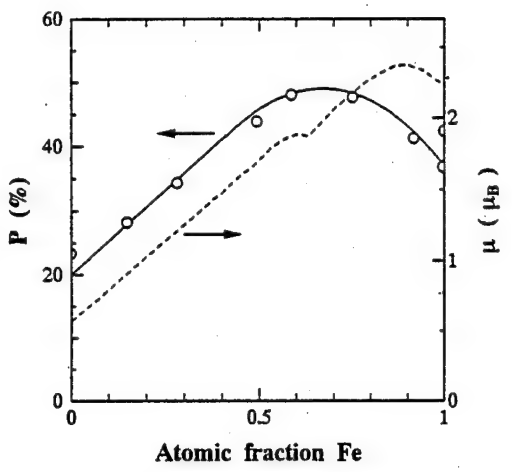

FIG. 3. The spin-polarization (○) and magnetic moment (- - -) at 0 K for Fe–Ni binary alloys (Ref. 6).

MR was measured by a dc four probe method in magnetic fields up to 200 Oe in the temperature range from 4.2 to 300 K. Magnetic hysteresis loop was measured by a vibrating sample magnetometer.

III. RESULTS AND DISCUSSION

Figure 1 shows the magnetic field, H, dependence of the resistance, R, measured at 4.2 K for the junctions with different Fe content in the counter-electrode. In these R vs H curves, the sharp change in resistance at smaller magnetic fields corresponds to the coercive force of the first Fe layer for $x=1$, 0.8, 0.5, and 0 junctions. While, in the case of $x=0.2$ junction, the change is due to the magnetization process of $Ni_{0.8}Fe_{0.2}$ (permalloy) layer. All those R vs H curves corresponded well with their magnetic hysteresis loops. Both resistances at parallel and antiparallel magnetizations decreased with increasing temperature.

The values of the tunneling barrier height and width were estimated by the analysis of current–voltage measurement. The current–voltage data at 4.2 K were fitted by Simmons' theory.[7] For all the junctions, the values of the barrier height were 0.1~0.3 eV and the width were ~45 Å. Here it should be noted that the barrier height is much smaller than that expected for Al_2O_3 barriers. The reason will be described shortly at the end of this section.

Figure 2 shows the dependence of the MR ratio on x at 4.2 and 300 K. The MR ratio at 4.2 K increases with x and exhibits a maximum around $x=0.8$. Namely, the MR ratio of $x=0.8$ is larger than that of $x=1$ which corresponds the $Fe/Al_2O_3/Fe$ junctions. Since one electrode of the junctions examined in this experiment is always pure Fe, we expect that the dependence of the MR ratio on x is merely due to the counter-electrode of Fe–Ni alloy films. In Fig. 3 we replotted the spin-polarization, P, and magnetic moment, μ, reported by Paraskevopoulos *et al.*,[6] as a function of Ni content for Fe–Ni alloy. As seen in Fig. 3, both P and μ increase with x and exhibit a broad peak at $x=0.7$ and $x=0.9$, respectively. The dependence of MR ratio on x is very similar to that of magnetic moment rather than that of spin-polarization.

We also measured the dependence of MR ratio and the resistance (current at a constant voltage) as a function of temperature between 4.2 and 300 K. The MR ratio at 300 K is much smaller than that at 4.2 K. Furthermore, its dependence on x is quite different from that at 4.2 K.

Stratton[8] has discussed the dependence of the tunneling current on temperature. By fitting our experimental data to the relation obtained by him, we obtained the barrier height. The values are between 0.1 and 0.3 eV for all the junctions, which agree well with those obtained from current–voltage data.

The theoretical treatments of the magnetic tunneling effect have been conducted by also Julliere[1] and successively by Maekawa and Gafvert[9] and Slonczewski.[10] They expressed the conductance ratio instead of the MR ratio by using spin-polarization. If we express the MR ratio in the same manner, it can be expressed as

$$\Delta R/R_s = 2P_1P_3/(1-P_1P_3), \tag{1}$$

where R_s is the resistance in the state of parallel magnetization. P_1 and P_3 are the spin-polarizations of base and counter electrodes. By using the data on the spin-polarization shown in Fig. 3, we are able to estimate the MR ratio by Eq. (1). In order to confirm this relationship, we plotted MR ratio at 4.2 K as a function of $2P_1P_3/(1-P_1P_3)$ in Fig. 4. In Fig. 4 the data reported by us[2–4] and by others[1,5,9,11] are also plotted. The straight line shows the ideal value expected from the spin-polarizations coefficient. We can see that the junctions with larger spin-polarization electrode exhibits higher MR ratio. However, the experimental value of MR ratio is much lower than that expected from the spin-polarization except for some junctions.

In order to obtain information to understand the reason of smaller value of MR ratio, especially at room temperature, than that expected from spin-polarization and/or low barrier potential, the profile of Auger spectroscopy was examined perpendicular to the surface of the sample. In this

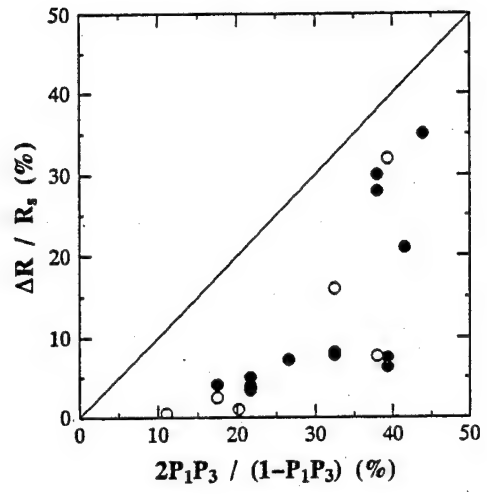

FIG. 4. Experimental and theoretical (straight line) values of MR ratio as a function of $2P_1P_3/(1-P_1P_3)$. ●: reported by us (Refs. 2–4), ○: reported by others (Refs. 1,5,9, and 11).

examination, the sample was prepared separately from that measured magnetic tunneling effect. The preliminary data suggest that the actual barrier is not pure Al_2O_3 but a mixture of Al_2O_3 and AlO_x or magnetic oxide. Further there exists a remaining metallic aluminum without oxidization. The mixture of oxide may behave as a semiconductor with a small energy gap. Such a phenomenon explains the occurrence of low barrier potential. With lowering the barrier height, the MR ratio decreases as suggested by Slonczewski.[10] The increased barrier width due to the extra oxidization also decreases the MR ratio.[12] Furthermore, the pressure of native oxide can cause spin flipping in the tunneling process giving a low MR ratio.

More detailed structure analysis of the insulator of the tunneling junction is now in progress and will be presented elsewhere in the near future.

Spin polarized tunneling in half-metallic ferromagnets (abstract)

C. T. Tanaka
Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

J. S. Moodera
Bitter Magnet Lab, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

We present a study of spin polarized tunneling in tunnel junctions in which one of the conducting layers is a half-metallic ferromagnet (HMF). HMF are unique in that the Fermi level of these materials intersect the majority spin electron band, while the minority band has an energy gap near the Fermi level. Hence, HMF simultaneously have both metallic and semiconducting characteristics, and theory predicts that the conduction electrons are 100% spin polarized. As a result, the magnetoresistance in magnetic multilayers or trilayer tunnel junctions is expected to be significantly higher than with conventional ferromagnetic materials. Two important parameters affecting the performance of these junctions are the smoothness of the HMF surface and its surface composition. Tunnel junctions consisting of a layer of NiMnSb, a barrier layer of Al_2O_3, and a layer of aluminum were prepared and studied for their tunneling properties. Surface analysis of HMF films was done using Auger depth profiling and AFM.

Co/Mn multilayers were prepared by rf sputtering onto single-crystal MgO and sapphire substrates resulting in, respectively, (001)- and (111)-oriented layers. The structure was thoroughly analyzed by x-ray scattering in various geometries (Q. Wang *et al.* to be published). For the magnetic investigations, ferromagnetic resonance (FMR) was applied. Complementary measurements employed the magneto-optical Kerr-effect (MOKE) and Faraday balance magnetometry. Results for the in-plane anisotropy, the surface anisotropy, the magnetization, and the FMR linewidth are presented. The comparison with other Co-based multilayer systems indicates that both the structural and the magnetic properties of the Co/Mn system are more complicated than in the case of systems with a presumably weaker electronic interaction at the interface [see also K. Ounadjela *et al.*, Phys. Rev. B **49**, 8561 (1994)]. © *1996 American Institute of Physics.* [S0021-8979(96)44408-1]

Thermal effects in magnetization, anisotropy, and interface width in Fe/Cu multilayers (abstract)

Magnetic properties of Fe/Cu multilayers have been investigated as a function of temperature using dc magnetization and ferromagnetic resonance techniques. The samples were prepared via dc sputtering resulting in equal thickness elemental layers ranging in modulation wavelength from 1 to 30 nm. The interface anisotropy remains nearly constant at 0.32 erg/cm^2 through the 4–300 K temperature range, which is in stark contrast to large thermal effects observed in Ni-based systems.[1] Relative increases in magnetization with decreasing temperature range from 3% in the 30 nm sample to 27% in the 1.0 nm sample. This indicates an interface region in which the magnetization is more strongly temperature dependent than the interior of an Fe layer. By plotting magnetization as a function of the inverse layer thickness, we obtain the temperature dependence of the width of this interfacial region. © *1996 American Institute of Physics.* [S0021-8979(96)44508-X]

Study of magnetic reorientation phenomenon and magnetic properties of Pd/(Pt/Co/Pt) multilayers

Ying Xiao, Jun-Hao Xu, and K. V. Rao
Department of Condensed Matter Physics, Royal Institute of Technology, S-100 44 Stockholm, Sweden

Pd/(Pt/Co/Pt) modulated multilayer films have been prepared at substrate temperatures ranging from room temperature to 350 °C by *e*-beam evaporation using various buffer layers. All these films exhibit perpendicular magnetic anisotropy with square polar Kerr hysteresis loops at room temperature. However, we observed a magnetic reorientation from a perpendicular anisotropy to an in-plane anisotropy at temperatures close to the Curie temperature T_C. The reorientation temperature T_R is found to depend strongly on the nonmagnetic Pd-spacer thickness in these Pd/(Pt/Co/Pt) multilayers. Over the room temperature to T_R range, we observe a linear temperature dependence of magnetic coercivity. AFM and STM characterization of the role of buffer layers on the microstructure, the dependence of coercivity and squareness of the Kerr hysteresis loops on the buffer layers of Au, Pt, and Al are also presented. © *1996 American Institute of Physics.* [S0021-8979(96)24108-5]

I. INTRODUCTION

Good thermal stability and ideal square Kerr hysteresis loops of magneto-optical (MO) media are essential to achieve excellent MO device performances. It is well known that with increasing temperature competing anisotropies especially arising from intersurface at layers cause a rotation of the easy axis from a perpendicular to an in-plane magnetic orientation in ultrathin films of Fe/Cu (100), Fe/Ag (100), Co/Au (100), etc.[1–5] This magnetic reorientation also exists in multilayers and may be a source of thermal instability of the multilayered MO media. Thus, it is important to study the magnetic reorientation phenomenon and relate it to thermal stability of MO multilayers like Pt/Co and related multilayers. On the other hand, squareness of the Kerr hysteresis loop is one of the main factors determining the writing speed, and signal to noise ratio of MO recording devices. It is thus of interest to clarify the role of thin film processing parameters and the use of buffer layers in achieving perfect square Kerr hysteresis loops of MO media. There exist very few reports in literature about processing techniques to control squarenesses of the Kerr hysteresis loops of MO thin films and multilayers.

Recently, Pd/(Pt/Co/Pt) modulated multilayer system with enhanced perpendicular anisotropies and magnetic coercivities compared to the Pt/Co and Pd/Co multilayers has been reported.[6,7] In this article we present our recent experimental results of the temperature dependences of the perpendicular magnetic anisotropy, coercivity, and Kerr rotation of some *e*-beam evaporated Pd/(Pt/Co/Pt) multilayers. We also discuss buffer layer effects on the squareness of the Kerr hysteresis loop and influences of grain structures on the coercivity of the multilayers.

II. EXPERIMENT

The Pd/(Pt/Co/Pt) modulated multilayer films were sequentially deposited by *e*-beam evaporation in a Leybold L560 Universal Deposition System with one electron gun and four crucibles. The deposition rates were kept below 0.5 Å/s for all elements at a base pressure of 1.5×10^{-6} Torr. Glass, Si, and surface oxidized Si were used as substrates. They were mounted on a homemade resistive heater base during deposition. The thickness as well as deposition rate of each metal layer were determined and controlled by means of a computer with a previously calibrated quartz thickness monitor. The thicknesses of the Co and Pt layers were fixed at 3 and 2 Å, respectively, while the Pd layer thicknesses were varied from 3 to 12 Å. Some of the multilayer films were grown on Al, Ag, Au, and Pd/Pt buffer layers. Films and buffer layers were grown at temperatures in a range from room temperature to 350 °C. Before deposition, substrates were heated up to 500 °C under the base pressure to thermally clean substrate surfaces.

The magneto-optical Kerr rotations of the multilayer films were measured over a temperature range from 30 to 250 °C with a Kerr loop tracer at wavelength of 800 nm, in magnetic fields up to 13.5 kOe. The magnetic hysteresis loops of the multilayers were measured at temperatures ranging from 5 to 350 K using a SQUID magnetometer. Low angle and high angle x-ray diffraction (XRD) measurements were carried out to verify the superlattice structures and determine the textures of the multilayered films. Surface microstructures of the films were characterized by the means of scanning tunneling microscopy (STM) and atomic force microscopy (AFM) with a Burleigh Personal SPM.

III. RESULTS AND DISCUSSIONS

High angle XRD measurements on the Pd/(Pt/Co/Pt) multilayer films grown under different deposition conditions reveal that most of the multilayers exhibit the fcc (111) texture along the film normal. Small angle XRD analyses suggest that these multilayers have the expected periodic structure and reasonable sharp interfaces.

Kerr hysteresis loop measurements indicate that all Pd/(Pt/Co/Pt) multilayers exhibit perpendicular magnetic anisotropy at room temperature. However, with increasing temperature the degree of the squareness of Kerr hysteresis loops decreases continuously, as shown in Figs. 1(a)–1(d). In addition, the magnetic coercivities of the Pd/(Pt/Co/Pt) multilayer films are found to decrease linearly with increas-

 0021-8979/96/79(8)/6267/3/$10.00

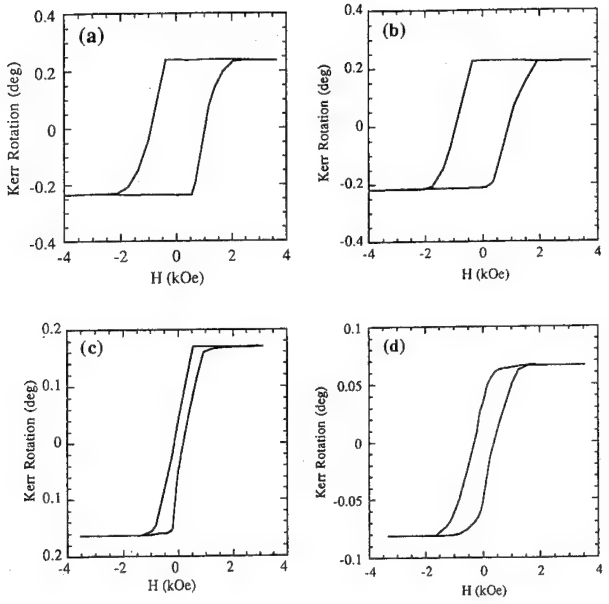

FIG. 1. Kerr hysteresis loops at (a) 30 °C, (b) 100 °C, (c) 180 °C, and (d) 230 °C for a [Pd-3 Å/(Pt-2 Å/Co-3 Å/Pt-2 Å)]$_{15}$ multilayer film deposited at room temperature on oxidized Si.

ing temperatures. In Fig. 2, the determined coercivities for four multilayer films are plotted against temperature. At certain temperatures the multilayers suddenly lose their perpendicular anisotropies. The transition temperature T_R (from a perpendicular anisotropy to an in-plane anisotropy) is found to be a function of the Pd nonmagnetic spacer thickness t_{Pd} of the Pd/(Pt/Co/Pt) multilayers. Figure 3 gives the temperature dependence of remanent magnetization for Pd-3,6,9,12 Å/(Pt-2 Å/Co-3 Å/Pt-2 Å) multilayers. In the inset of this figure the Pd layer thickness dependence of T_R of the multilayers is shown. This indicates that T_R decreases with increasing nonmagnetic spacer thickness. However, the film with t_{Pd} of 3 Å has a slightly lower T_R than that of the film with t_{Pd} of 6 Å. This may be due to a higher degree of interlayer mixing in the film with t_{Pd} of 3 Å which results in a reduction of the perpendicular anisotropy in this film.[7]

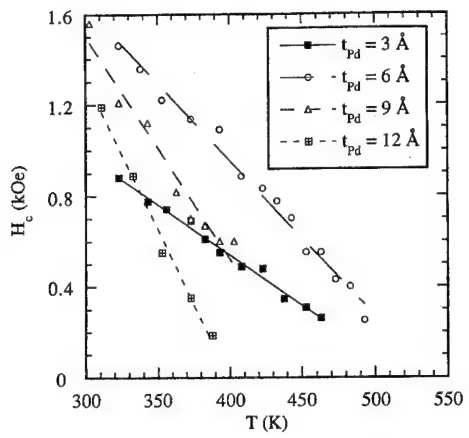

FIG. 2. Temperature dependences of magnetic coercivities for [Pd-3,6,9,12 Å/(Pt-2 Å/Co-3 Å/Pt-2 Å)]$_{15}$ multilayer films deposited at room temperature on oxidized Si.

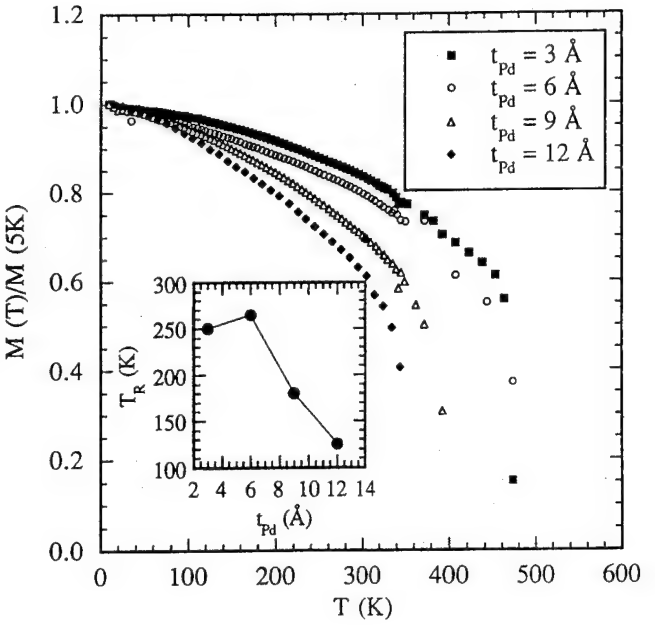

FIG. 3. Temperature dependences of remanent magnetization for [Pd-3,6,9,12 Å/(Pt-2 Å/Co-3 Å/Pt-2 Å)]$_{15}$ multilayer films deposited at room temperature on oxidized Si. Inset: Magnetic reorientation temperature as a function of Pd layer thickness.

The observed magnetic reorientation could arise from the large entropy for the in-plane magnetization which becomes more important at elevated temperatures.[8] The direction of magnetization is also determined by the competition between uniaxial, i.e., surface anisotropy, and shape anisotropy. At a certain temperature, when the temperature dependent perpendicular anisotropy $K_u(T)$ is smaller than the saturation magnetization $2\pi M_s(T)$, the easy axis will turn from the film normal to the plane of the film. If the fourth order anisotropy cannot be neglected as compared to the second order anisotropy at elevated temperatures, a canted orientation of a uniform magnetization could also exist. The observed magnetic reorientation could thus be due to a combination of the above discussed cases. In order to improve the thermal stability of MO media at some temperatures, one needs to tailor the materials to obtain suitably high T_R's. In the case of Pt/Co and related multilayers, an appropriate thin nonmagnetic spacer is essential to enhance the coupling between neighboring Co layers, and thus to achieve a high T_R of the multilayers.

It is found that Pd/(Pt/Co/Pt) multilayers grown on Pd/Pt and Au buffer layers exhibit high coercivities in a range from 5 to 10 kOe, but the squarenesses of these multilayers prepared under various deposition conditions are far from being ideal. However, multilayer films deposited on Al buffer layer under certain deposition conditions exhibit ideal square Kerr hysteresis loops, although the coercivities of these films are relatively low. Figure 4 shows a few Kerr hysteresis loops of some Pd/(Pt/Co/Pt) multilayers deposited on different buffer layers. As seen in Fig. 4, the best square loop is achieved in the multilayer film grown at 250 °C on an Al-100 Å buffer layer deposited at room temperature. High Kerr rotations of

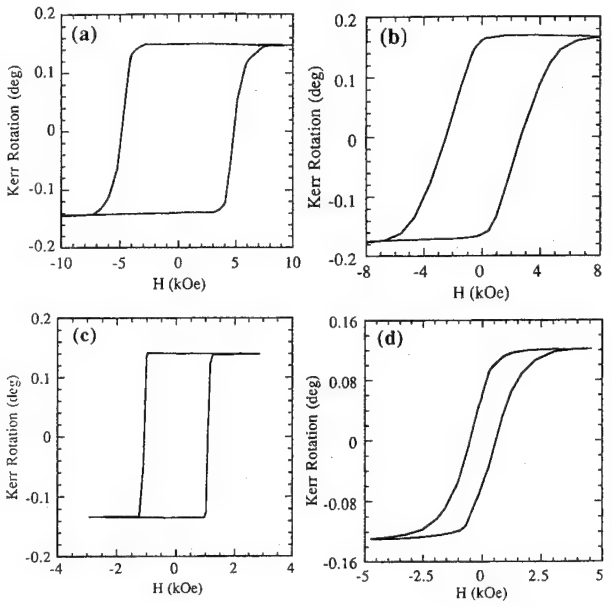

FIG. 4. Kerr hysteresis loops of [Pd-3 Å/(Pt-2 Å/Co-3 Å/Pt-2 Å)]$_8$ multilayer films deposited on oxidized Si with (a) Pd/Pt, (b) Au, (c) Al, and (d) Ag buffer layers.

0.41° in the blue light regime and 0.32° at 800 nm wavelength are observed for the Pd/(Pt/Co/Pt) multilayer film deposited at 350° on an Al-100 Å buffer layer. A detailed study of the wavelength dependencies of the Kerr rotations for films deposited with various kinds of buffer layers will be reported elsewhere.

It is known that not only the crystallographic properties of substrates significantly affect many properties of deposited films, but also the chemical properties of the substrates determine film growth models, such as layer-by-layer growth, island growth and the combination of them. The use of buffer layers can improve both crystallographic and chemical compatibility between films and substrates. Usually ideal square magnetic hysteresis loops reflect a high degree of uniformity of the film structures. In this regard, two extreme cases are amorphous and single-crystal films. Thus, films deposited on Al buffer layers should have superior crystalline quality compared to those films grown on other buffer layers. Since all multilayers grown on glass, Si, and oxidized Si with Al buffer layers exhibit ideal square Kerr hysteresis loops, the chemical properties of Al should play a more important role in promoting the growth of the superlattice structure than its crystallographic properties.

STM and AFM analyses indicate that multilayers grown on Al buffer layers have smooth surface morphologies, while films deposited on Au and Pd/Pt buffer layers exhibit big grain structures and relatively rough surface morphologies. It is noted that those films with large grain structures usually have high coercivities. This observed correlation between large grains and high coercivities is consistent with our previous results.[7]

IV. SUMMARY

A magnetic reorientation from a perpendicular anisotropy to an in-plane anisotropy has been observed at temperatures close to T_Cs in the Pd/(Pt/Co/Pt) modulated multilayer films. This magnetic reorientation may be caused by the large entropy for the in-plane magnetization which becomes more important at elevated temperatures or by the competition between uniaxial anisotropy and shape anisotropy. The use of Al buffer layers improves both squareness and Kerr rotation of the Pd/(Pt/Co/Pt) multilayers. This may be due to the suitable chemical and crystallographic properties of Al which promote superior growth of the superlattice structure resulting in an ideal squareness of Kerr hysteresis loop and a high Kerr rotation of 0.41° in the blue light regime.

Structural anisotropy of Tb/Fe multilayers

Y. Fujiwara, X. Y. Yu, S. Tsunashima, and S. Iwata
Department of Electronics, Nagoya University, Nagoya 464-01, Japan

M. Sakurai and K. Suzuki
Institute for Materials Research, Tohoku University, Sendai 980, Japan

We have investigated the local structural anisotropy of Tb/Fe multilayers using linear polarized synchrotron radiation. X-ray absorption measurements were performed at Fe K edge (7.1 keV) using normal and glancing angle incident photon. From the Fe extended x-ray absorption fine structure (EXAFS), the local structural anisotropy was found for all multilayers as a slight difference of oscillation amplitude between the two incident directions. From the Fourier transformed EXAFS spectra, it is found that the local structural anisotropy shows the maximum at bilayer period of about 1 nm, where perpendicular magnetic anisotropy also shows the maximum value in various rare-earth/transition metal multilayers. © *1996 American Institute of Physics.*
[S0021-8979(96)35508-6]

I. INTRODUCTION

Rare-earth-transition metal (RE-TM) amorphous alloys have been studied for magneto-optical (MO) recording media, and the origin of their perpendicular magnetic anisotropy has been debated with great interest.[1,2] Now, the problem still of the magnetic anisotropy of RE-TM amorphous alloys is still being discussed and several models are proposed.[3,4] But the relationship between the structure and magnetic properties are still unclear because the structural analysis of RE-TM alloys is difficult due to the structural complexity of the amorphous state. Extended x-ray absorption fine structure (EXAFS) spectroscopy is a useful probe providing the informations of short-range atomic structures. In the EXAFS spectroscopy, highly polarized synchrotron radiation gives an opportunity for the angular-resolved analysis of a disordered structure. Recent EXAFS study indicated that the magnetic anisotropy in amorphous RE-TM alloys is correlated with the local structural anisotropy.[5,6]

In our previous work[7–9] as well as in Ref. 10, the magnetic anisotropy of RE/TM multilayers was found to change with the bilayer period showing the maximum at bilayer periods of around 1 nm. In order to study this behavior from the viewpoint of the local structure, we have investigated the local structural anisotropy of amorphous Tb/Fe multilayers, especially its dependence on the bilayer period utilizing the EXAFS spectroscopy with linear polarized synchrotron radiation. In this article preliminary results of EXAFS analysis is presented.

II. EXPERIMENT

The aim of this study is to confirm the dependence of structural anisotropy on bilayer period. So, multilayers with various bilayer periods and an alloy film for comparison were prepared by rf magnetron sputtering method, where Ar gas pressure and deposition rate were 30 mTorr and about 2.4 Å/s, respectively. The bilayer period was controlled by the rotation speed of the substrate holder. All samples were deposited on the 76.5-μm-thick polyimide substrate with Si_3N_4 under and over layers to prevent the magnetic layers from the oxidation. The total thickness of magnetic layers in all films was about 240 nm. The content of Tb in both alloy and multilayers is 35 at. % and the thickness ratio of Tb to Fe in multilayers is about 1.1:1. Composition analysis was performed by electron probe microanalysis (EPMA), and multilayered structures were confirmed by small-angle x-ray diffraction.

X-ray absorption measurements were carried out utilizing the simple transmission mode with two ionization chambers with a Si(111) double-crystal monochromator. Several sheets of samples were piled up to a suitable absorption length of about 5 μm. In order to obtain the structural anisotropy, x-ray absorption measurements were performed with two sample directions, where the film plane was put in perpendicular (E in-plane) to or almost parallel (10°, E out-of-plane) to the incident photon. EXAFS measurement were carried out for Fe K edge and Tb L_3 edge. Here only results for Fe K edge are reported. It was difficult for Tb L_3 edge to analyze the data because of the low S/N ratio.

III. RESULTS AND DISCUSSION

Compositionally modulated structure was confirmed from the diffraction peaks of the small-angle x-ray diffraction. As shown in Fig. 1, low-angle peaks were observed in the Tb/Fe multilayers with bilayer periods thicker than 1 nm. In the case of glass substrate, higher-order peaks were clearly shown in x-ray diffraction patterns,[9] while in this study, higher-order peaks do not appear even if the bilayer period is as thick as 3.7 nm. This might be due to the difference of flatness of interface of multilayers between glass and polyimide substrates. However, it is supposed that the multilayers grown on polyimide substrates locally keep the multilayered structure in the same manner as those on glass substrates. In high-angle x-ray diffraction patterns, no apparent peak was observed except for the hallow centered at about 25° from the polyimide substrate.

The Fe EXAFS oscillations presented in Fig. 2 are generated by the theoretical background subtraction from the raw absorption spectra and are weighted with k^3. E in-plane denotes the film plane structure and E out-of-plane denotes the structure almost perpendicular to the film plane.

 0021-8979/96/79(8)/6270/3/$10.00

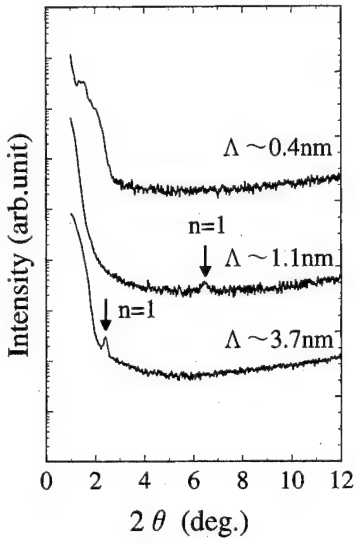

FIG. 1. Small-angle x-ray diffraction patterns of Tb/Fe multilayers, where Δ is bilayer period.

As shown in Fig. 2, the shape of Fe EXAFS oscillations observed for Tb/Fe multilayer and alloy films are similar to each other. In this figure, oscillation amplitudes are found to begin decreasing at $k \sim 8(1/\text{Å})$ in contrast to pure Fe EXAFS which represents strong oscillation up to $k \sim 15(1/\text{Å})$. This suggests that the sample structure is in amorphous state.

It is also found that the frequency of the oscillations for all films is almost the same. This implies that the distances between the absorbing and backscattering atoms are almost the same for all multilayers. Whereas, slight structural anisotropy is seen in all multilayers as the difference in peak to peak amplitude between E in-plane and E out-of-plane oscillations, while no difference is found in the alloy film. This shows that structural anisotropy is induced in the amorphous multilayers.

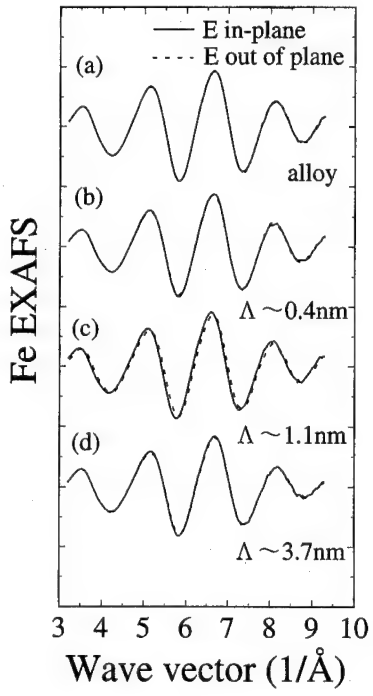

FIG. 2. Fe EXAFS oscillations measured for Tb/Fe multilayer and alloy films.

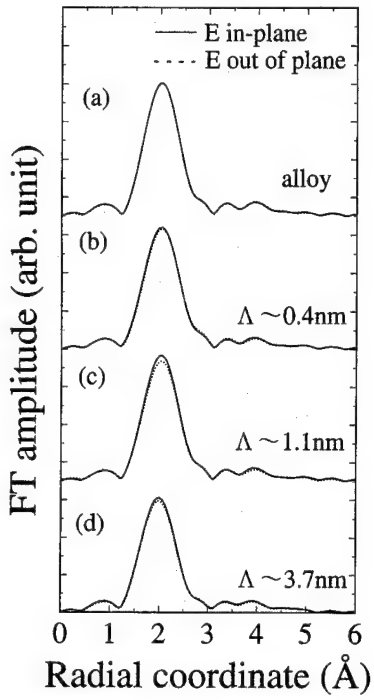

FIG. 3. Fourier transformed Fe EXAFS measured for Tb/Fe multilayer and alloy films.

In this study, structural anisotropy was not found in the alloy film, while considerable structural anisotropy was observed by Harris *et al.*[5,6] This difference may suggest that the anisotropic structure of amorphous RE-TM alloy and multilayers is sensitive to the preparation conditions. We have made the samples of 35 at. % Tb by the rf magnetron sputtering onto polyimide substrates, while Harris *et al.* made experiment on the samples with less than 26 at. % Tb by the ion beam sputtering onto glass substrates, where incident atom energy is much higher than our case and this will strongly affect the film structure.

The Fourier transformed (FT) Fe EXAFS spectra derived from k-space Fe EXAFS signals in Fig. 2 are shown in Fig. 3. The FT EXAFS is directly related to the local environment around the central Fe atom in real space. It is seen that a broad nearest-neighbor peak is centered at about 2 Å for all multilayer and alloy films. These peak positions are thought to be shifted 0.4–0.5 Å from the actual distances owing to the effect of the atomic potentials on the photoelectron wave function.[11] In the case of this study, the actual distance between the absorbing atom and nearest neighbors is estimated to be about 2.4–2.5 Å. This means that the nearest neighbors are Fe atoms judging from the atomic radii of constituent atoms, Fe~1.24 Å and Tb~1.78 Å.

We can further estimate from the difference of the shape of FT EXAFS between E in-plane and E out-of-plane spectra. It can be seen in Fig. 3 the peak height is slightly different between the two cases. This difference shows the presence of the structural anisotropy. If we assume the Debye–Waller like factors for each directions are the same, it can be

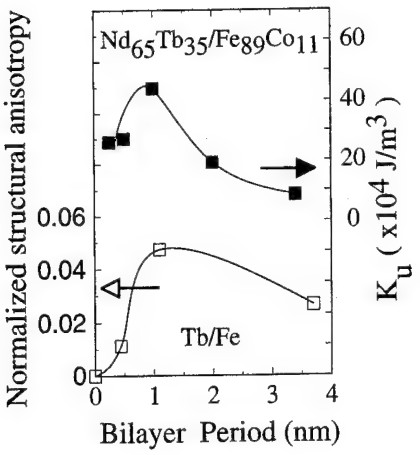

FIG. 4. Normalized structural anisotropy of Tb/Fe multilayers and perpendicular magnetic anisotropy of NdTb/FeCo multilayers as a function of bilayer period.

considered the structural anisotropy is mainly due to the difference of Fe-Fe nearest-neighbor coordination, since both the position and half width are almost the same for each directions. The structural anisotropy is seen to increase up to the bilayer period of around 1 nm and then decrease. This behavior may be explained by the interlayer mixing of about 1 nm thick existing in the multilayers, considering the results of small-angle x-ray diffraction measurement. When the bilayer period is less than the thickness of interlayer mixing, the structural anisotropy increase with increasing bilayer period. While, when the bilayer period become larger than the thickness of interlayer mixing, the each layer approaches pure metal and the local structural anisotropy will go down.

The dependence of the local structural anisotropy on the bilayer period is shown in Fig. 4 together with that of the perpendicular magnetic anisotropy measured in our previous work.[7–9] Here the structural anisotropy is quantitatively expressed as the difference of the peak height of FT EXAFS normalized by those of E in-plane spectra. It is thought that the enhanced perpendicular magnetic anisotropy in RE/TM multilayers is strongly correlated with the enhanced local structural anisotropy.

Comparing the results of EXAFS experiment with those of the small-angle x-ray diffraction, it is noted that both the magnetic and the structural anisotropy become the maximum when the small-angle diffraction peaks become so small that only the first peak is detected.

IV. CONCLUSION

The dependence of structural anisotropy on bilayer period have been studied for Tb/Fe multilayers. The structural anisotropy shows the maximum at bilayer period of around 1 nm. The dependence of local structural anisotropy on the bilayer period well corresponds to that of the perpendicular magnetic anisotropy. It seems that the structural anisotropy and the perpendicular magnetic anisotropy become their maximum when the bilayer period is roughly equal to the thickness of interlayer mixing.

For Tb-Fe-Co(MO)/Al bilayered films, dependence of perpendicular magnetic anisotropy constant $K_{u\perp}$ on MO layer thickness t_{MO} of 3–300 nm and Al layer thickness t_{Al} of 5 and 100 nm has been investigated. For either t_{Al}, easy magnetization direction was normal to film plane at t_{MO} above 4 nm. $K_{u\perp}$ of films with t_{Al} of 5 nm increased drastically with increasing t_{MO} for $t_{MO}<10$ nm and then assumed a constant value of 4×10^6 erg/cm^3 which is two times larger than that with t_{Al} of 100 nm. This difference in $K_{u\perp}$ between them may be attributed to stress induced anisotropy. Estimation of rotational hysteresis loss W_r and its integral R suggests that the mechanism of magnetization reversal may be attributed to incoherent curling mode. © *1996 American Institute of Physics.* [S0021-8979(96)24208-1]

INTRODUCTION

Amorphous films of rare earth-transition metal (RE-TM) alloy such as Tb-Fe-Co and Gd-Tb-Fe are commonly used for magneto-optical storage media. However, high storage capacity and direct overwriting system are required in order to use effectively the magneto-optical disks. For this purpose, the multilayered films composed of many ultrathin layers of these RE-TM alloys are of great current interest for fundamental studies and practical uses.[1–4] In the multilayered films, a large perpendicular magnetic anisotropy constant $K_{u\perp}$ is essential to obtain the minimum size and good regularity of reversed magnetic domains written in the RE-TM alloy films.

There are only a few reports[1,3,4] on the perpendicular magnetic anisotropy in nanometer-thick Tb-Fe-Co films. The authors have found that the strong Kerr rotation enhancement[5,6] was observed at the short wavelength of 400 nm and Tb-Fe-Co(MO) layer of thickness t_{MO} below 10 nm in the MO/Al bilayered films deposited by the facing targets sputtering (FTS) apparatus.

In this study, the perpendicular magnetic anisotropy was investigated for the MO/Al films with various t_{MO} of 3–300 nm and the Al layer thickness t_{Al} of 5 and 100 nm. In addition, the rotational hysteresis loss W_r was measured for the specimen films with t_{MO} of 5–9 nm and was related to the mechanism of magnetization reversal.

EXPERIMENTALS

The Tb-Fe-Co(MO)/Al bilayered films were deposited on plasma-free glass slide substrates using the facing targets sputtering (FTS) apparatus.[5–7] Both layers were deposited at the Ar pressure P_{Ar} of 0.5 mTorr. Deposition rates of MO and Al layers were 100 and 50 nm/min, respectively. The thickness of MO layer t_{MO} was varied in range from 3 to 300 nm and that of Al layer t_{Al} was 5 and 100 nm. Magnetic measurements were performed using a vibrating sample magnetometer (VSM) and a torque magnetometer with magnetic fields H_m up to 15 kOe. The perpendicular magnetic anisotropy constant $K_{u\perp}$ was determined by the method proposed by Miyajima *et al.*[8]

RESULTS AND DISCUSSION

The composition of TbFeCo(MO) layer was Fe-Co richer side of the compensation composition. The coercivity H_c of MO layers ranged from 1.08 to 7.8 kOe.

All the MO/Al bilayered films with MO layer thickness t_{MO} above 4 nm showed the rectangular Kerr hysteresis loops.

Figure 1 shows the t_{MO} dependence of $K_{u\perp}$ for the Al layer thickness t_{Al} of 5 and 100 nm. For either t_{Al}, $K_{u\perp}$ increased drastically with increasing t_{MO} for $t_{MO}<10$ nm and then assumed almost constant value at t_{MO} above 15 nm. The constant value of $K_{u\perp}$ for t_{Al} of 5 nm was found to be about 4×10^6 erg/cm^3 which is two times larger than that for t_{Al} of 100 nm. Thus the easy magnetization direction was perpendicular to the film plane at t_{MO} of greater than about 4 nm for either t_{Al}. As described in the previous paper,[6] Kerr rotation angle θ_k at wavelength of 400 nm took a sharp maximum peak at t_{MO} of 5 nm where $K_{u\perp}$ changed drastically. The t_{MO}

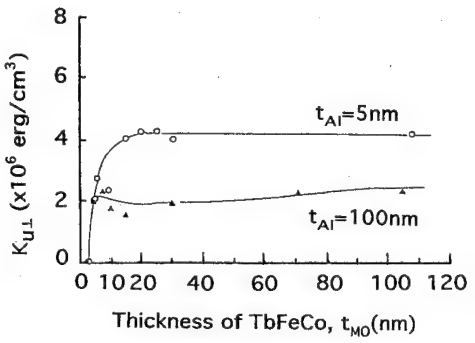

FIG. 1. Thickness (t_{MO}) dependence of perpendicular anisotropy constant $K_{u\perp}$ for t_{Al} of 5 and 100 nm.

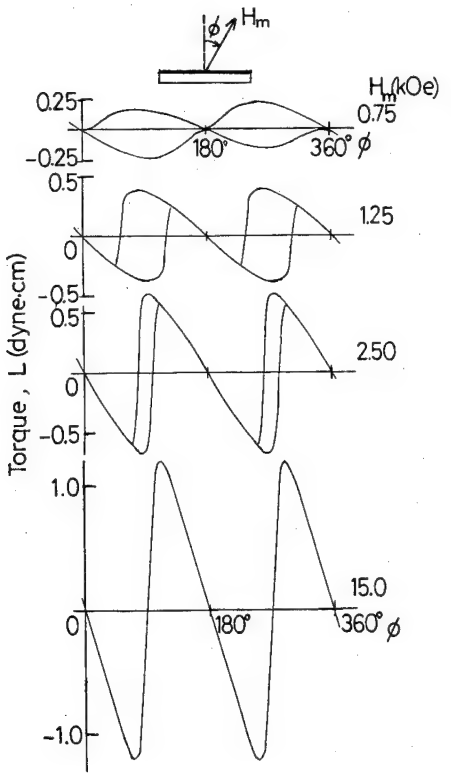

FIG. 2. Torque curves for specimen films with t_{MO} and t_{Al} of 5 nm at various magnetic fields H_m.

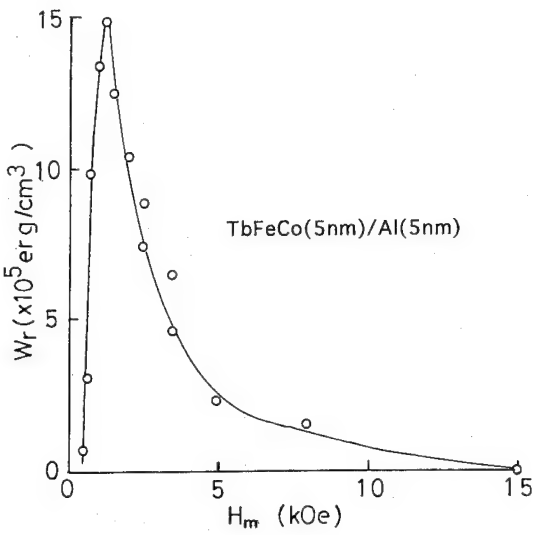

FIG. 3. H_m dependence of rotational hysteresis loss W_r for specimen film with t_{MO} and t_{Al} of 5 nm.

value of 4 nm is in agreement with the minimum thickness of Tb-Fe layer for which the easy magnetization direction is normal to the film plane in the Tb-Fe/SiO multilayers.[9] Moreover, the t_{MO} value was comparatively close to the grain size (~8 nm) observed in the dense, uniform and columnless Tb-Fe-Co films.[7]

The difference in $K_{u^\perp}$ between the films with t_{Al} of 5 and 100 nm could be attributed to the inverse magnetostriction effect. $K_{u^\perp}$ may be considered to be the sum of $K_{u\ in}$ and K_u[ME], where $K_{u\ in}$ is due to the atomic ordering or single-ion anisotropy and K_u[ME] is due to magnetoelastic energy. K_u[ME][3,4] is defined as $-(3/2)\cdot\lambda\cdot\sigma$, where λ is magnetostriction constant[10] and has a positive value of the order of 10^{-4}, and σ is the internal stress of compression or tension. In this study, σ for the 50-nm-thick Tb-Fe-Co layers deposited at Ar pressure of 0.5 mTorr was compressive, i.e., negative value of order of 10^9 dyne/cm^2.

When the Al layer with t_{Al} of 100 nm is deposited on the Tb-Fe-Co layer with t_{MO} above 20 nm, the resultant stress may approach close to zero, because the stress in Al layer is tensile,[11] i.e., positive value of 10^9 dyne/cm^2. On the other hand, for t_{Al} of 5 nm, the resultant stress seems to be compressive, i.e., negative, because the stress in Al layer with t_{Al} of 5 nm is negligibly small. Thus, the difference in $K_{u^\perp}$ between the films with different t_{Al} can be attributed to mainly to magnetoelastic energy K_u[ME].

In order to determine the rotational hysteresis loss W_r,[12] the clockwise and anticlockwise torque curves for several specimen films were measured at various magnetic fields H_m.

Figure 2 shows the typical different torque curves of the specimen film with t_{MO} and t_{Al} of 5.0 nm. As seen in this figure, the rotational hysteresis loops were observed at H_m of 0.75, 1.25, and 2.50 kOe, while they were not observed at H_m of 15 kOe. W_r is defined as

$$\int_0^{2\pi} L d\,\phi,$$

where L is the torque of the specimen film and ϕ is the angle between the magnetic field H_m and the easy magnetization direction normal to the film plane.

Figure 3 shows the H_m dependence of W_r for the specimen film with t_{MO} and t_{Al} of 5 nm. With increasing H_m, W_r rose very drastically to a sharp maximum peak at H_m of 1.2 kOe and then decreased gradually and vanished at H_m of about 15 kOe. The H_m corresponding to the peak H_m[peak] is close to the coercivity H_c of the specimen film. The field at which W_r reduces to zero was estimated to be about 9.5 kOe. This value is in good agreement with the anisotropy field H_k corresponding to $2K_{u^\perp}/M_s$. $K_{u^\perp}$ and M_s of this specimen film were 1.93×10^6 and 408 emu/cm^3, respectively.

Similar W_r versus H_m curves were observed in the specimen films with t_{MO} below 10 nm and H_c of about 1–2 kOe.

The rotational hysteresis integral,[12]

$$R\left\{=\int_0^{\infty}(W_r/M_s)d(1/H_m)\right\}$$

was calculated for the specimen films with t_{MO} and t_{Al} of 5 nm. The value of R was evaluated to be 1.46 when the demagnetizing field[13] of $4\pi M_s$ was taken into consideration.

Figure 4 shows the dependence of W_r/K_u on H_m/H_k. It revealed a sharp maximum peak at H_m/H_k of about 0.14. These results suggest that the mechanism of magnetization reversal of the bilayered films may be explained based on the incoherent curling mode for aligned and random as-

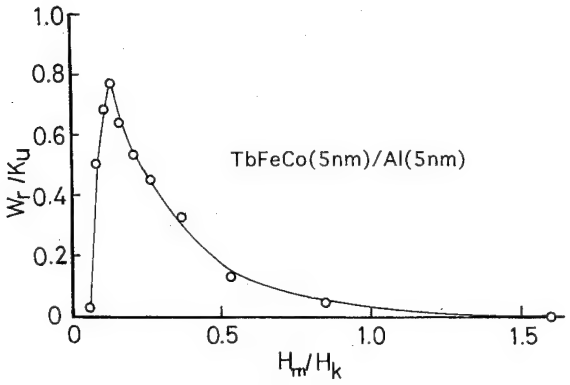

FIG. 4. Dependence of W_r/K_u on H_m/H_k for specimen films with t_{MO} and t_{Al} of 5 nm.

semblies of infinite magnetic cylinders. These results seemed to agree well with those of the Gd-Tb-Fe films.[14]

CONCLUSION

The Tb-Fe-Co(MO)/Al bilayered films with various MO and Al layers thicknesses, t_{MO} and t_{Al}, respectively, have been deposited using the FTS apparatus. The dependence of perpendicular magnetic anisotropy constant $K_{u\perp}$ on t_{MO} and t_{Al} were investigated. At t_{Al} of 5 and 100 nm, the easy magnetization direction was normal to the film plane at t_{MO} above 4 nm. The results of evaluation of the rotational hysteresis loss W_r and its integral R suggest that the mechanism of magnetization reversal in the MO/Al bilayered films with nanometer thick MO layer may be due to an incoherent curling mode.

Studies of anisotropic and giant magnetoresistance in Co/Cu(111) epitaxial multilayers

J. C. A. Huang, Y. H. Lee, Y. M. Hu, and T. C. Chang
Physics Department, National Cheng-Kung University, Tainan 701, Taiwan

Co/Cu(111) multilayers, [Co(17 Å)/Cu(8 Å$<t_{Cu}<$14 Å)]$_{30}$, have been prepared on Co(70 Å) buffer layers on Al_2O_3(0001) substrates by molecular beam epitaxy. From the longitudinal and transverse magnetoresistance (MR) measurements, it is observed that MRs consist of two components with a small anisotropic MR (<2%) component at low field sitting on top of the giant MR (up to 22%) component at higher field. The AMR effect strongly correlates with the abundance of hcp stacking of Co, which tends to decrease with the increasing of Cu spacer thickness. The AMR saturation fields (1–3 kOe) coincides with those of the magnetization. It is suggested that the observed AMR effect is due to scattering from the hcp-phase Co layers in the multilayers. This together with the large saturation field (30–40 kOe) obtained from the entire MR curves indicate that the observed GMR effect may result from the Co-Cu interfacial spin-dependent scattering. © *1996 American Institute of Physics.* [S0021-8979(96)24308-8]

I. INTRODUCTION

Anisotropic MR (AMR≤5%) has commonly been observed in pure ferromagnetic materials for many years.[1,2] Recently, the giant magnetoresistance (GMR) in magnetic multilayers has become the subject of considerable interest both from scientific and advanced technological point of view.[3–6] Note that GMR is quite different from AMR. AMR is basically an effect due to the spin-orbital interaction,[1,7] while GMR effect is related to the spin configuration change of neighboring ferromagnetic layers from the antiferromagnetic (AF) coupling state to the ferromagnetic (F) coupling state.[8] Further, GMR is isotropic with respect to the relative direction between the field H and current I, while AMR depends strongly on relative direction of H and I.

Giant MR (GMR) was first realized in the Fe/Cr multilayers.[3] Accompanied with the GMR effect, oscillatory exchange coupling phenomena were discovered in many magnetic multilayers.[6] Particularly, Co/Cu multilayers have attracted much attention because of the giant MR values. In addition, Co/Cu is a suitable system to verify the mechanism of oscillatory exchange coupling because of the relatively simple nature of the Cu Fermi surface.[9] Although GMR effect is widely explained in correlation with the spin configuration change of the successive ferromagnetic layers, increasing evidences were shown, however, that scattering from interfacial states between the ferromagnetic and nonferromagnetic layers could be more important for GMR effect in some multilayer systems.[3,10,11]

In this investigation, we report the structural and magnetic characterizations of Co/Cu(111) multilayers prepared by MBE. The effect of structure upon magnetic and magnetotransport properties has been systematically studied.

II. EXPERIMENTAL PROCEDURES

The epitaxial Co/Cu(111) multilayers presented here were grown on Co buffer layers (70 Å) on Al_2O_3(0001) substrates by molecular beam epitaxy (Vacuum Product model MBE-930) system. Pure elements (99.99%) of Co, Cu were evaporated from an e-beam evaporator and a Knudsen cell, respectively. The base pressure of the system before deposition was less than 4×10^{-10} Torr. To enable the growth of high-quality samples, polished and epitaxial grade Al_2O_3 substrates were chemically precleaned and rinsed in an ultrasonic cleaner. They were then outgassed at 1000 °C for 1 h under ultra-high-vacuum condition in the MBE chamber. Buffer layers of 70 Å Co were deposited on substrates at about 400 °C to initiate the multilayer growth. The deposition rates for Co and Cu were controlled at about 0.1 Å/s. A series of [Co(17 Å)/Cu(t_{Cu}Å)]$_{30}$ (with the Cu spacer layer thickness t_{Cu} designed to be 8, 10, 12, and 14 Å) multilayers were then prepared at about 150 °C.

The surface structures of the films were *in situ* examined by reflection-high-energy electron-diffraction (RHEED). The bulk structures and the superlattice period were determined by x-ray diffraction (XRD). The magnetic properties and MRs of all the samples were studied by using a commercial (quantum design) SQUID magnetometer in a magnetic field up to 50 kOe with measuring temperature at 10 K. MR measurements were carried out by standard dc four-point probe technique with I and H in the plane of the layers. Transverse and longitudinal MRs were measured with $I\perp H$ and $I\|H$, respectively.

III. RESULTS AND DISCUSSIONS

Figure 1 shows a typical RHEED pattern of fresh Cu(111) surface during the growth of Co/Cu multilayers. Similar RHEED feature was observed on the growing surface of Co. As can be seen from the RHEED pattern, the crystal surface was rather smooth and nice indicating high-quality epitaxial multilayers. Figures 2(a)–2(d) show the high-angle XRD spectra for the Co/Cu(111) multilayers for a fixed Co thickness of 17 Å and variable Cu layer thickness t_{Cu} (in one bilayer). To avoid the enormous Al_2O_3(0001) substrate peak at $2\theta\sim41°$, the range of x-ray spectra is limited to above 42.5°. The large peaks located at about $2\theta\sim43.7°$, indexed as fcc(111), lie in between the positions of bulk fcc Cu(111) and bulk fcc Co(111), as illustrated in the inset of Fig. 2. The fcc(111) peaks are likely due to the strain effect between the Cu and Co layers with close lattice parameters

 0021-8979/96/79(8)/6276/3/$10.00

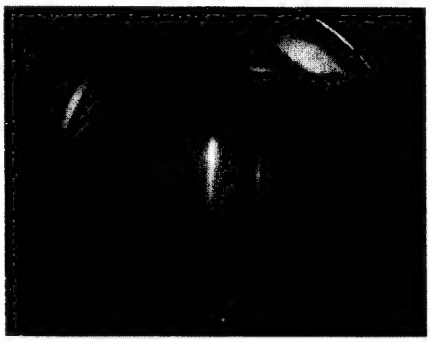

FIG. 1. Typical RHEED of Cu(111) surface view along [01$\bar{1}$] direction during the growth of the Co/Cu multilayers.

of 2.087 and 2.051 Å. Similar strain effect was also found in sputtered Co/Cu multilayers in the other work.[12] The fcc(111) peak slightly shifts toward the bulk fcc Cu(111) positions as t_{Cu} increased (see Fig. 2). By average each shift corresponds to an increase of the interatomic spacing of about 2.2×10^{-3} Å. This is quite reasonable since the lattice parameter of fcc Cu is slightly larger than that of the fcc Co.

Shown in Fig. 2 includes the satellite peaks (indexed as S) corresponding to the periodicity of the multilayers. In addition, for each XRD spectrum there is a very small yet broad peak around $2\theta\sim51°$, which corresponds to the position of the fcc(200) peak. Interestingly, one can also observe a rather strong peak near the fcc(111) for samples (a) and (b). This peak coincides with the position of bulk hcp Co(0002). The existence of hcp Co(0002) phase is likely due to a large concentration of stacking faults in the multilayers.[12] Furthermore, the Co(0002) peak intensity decreases with the increasing of the Cu spacer layer thickness for the multilayers (see Fig. 2).

Figures 3(a)–3(c) show the magnetization, longitudinal and transverse MRs for the [Co(17 Å)/Cu(10 Å)]$_{30}$ multilayer. Here MR is defined as $[R(H)-R_{min}]/R_{min}$, as usual, where R_{min} is the minimum (at saturated field) of measured electrical resistance. Basically, both longitudinal and transverse MRs possess almost the same curves, saturation field (~30 kOe) and GMR values (up to about 11%) for field larger than 3 kOe. For small magnetic field (≤3 kOe) the longitudinal MR curve exhibits a small dip (~0.5%, negative), while the transverse MR curve displays a sharp spike (~1%, positive). This low field anisotropic behavior together with the obvious hysteresis for both MR curves correlate strongly with the magnetization loops, as shown in the inset of Fig. 3. Note that this AMR phenomenon has a strong link with the hcp phase of Co in the multilayers, as discussed below. In addition, the distinct saturation fields for the magnetization (3 kOe) and the entire MR curves (30 kOe) point to the separate mechanisms between the observed GMR effect and the bulk scattering from the magnetic (Co) layers. The M-H loop shown in Fig. 3 indicates that the magnetic layers are largely ferromagnetically coupled, suggesting that the AF coupling between the magnetic layers may not be responsible for the observed GMR effect. Similar result was also observed by Barlett *et al.* in MBE grown Co/Cu(111) multilayers.[13] It has been proposed that superparamagnetic states at the interface, for the Cu conduction electron band being patially polarized in proximity to the Co layers, are responsible for the high saturation field of GMR curves in MBE grown Co/Cu multilayers.[13,15] We thus believe that interfacial spin-dependent scattering appears to be a dominant factor for the GMR effect in the Co/Cu(111) multilayers.

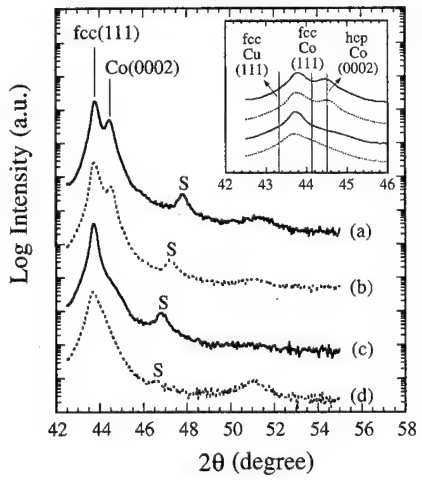

FIG. 2. High angle x-ray diffraction spectra from samples: (a) [Co(17 Å)/Cu(8 Å)]$_{30}$, (b) [Co(17 Å)/Cu(10 Å)]$_{30}$, (c) [Co(17 Å)/Cu(12 Å)]$_{30}$, and (d) [Co(17 Å)/Cu(14 Å)]$_{30}$. The positions corresponding to the bulk fcc Cu(111), fcc Co(111), and hcp Co(0002) are illustrated by the vertical lines.

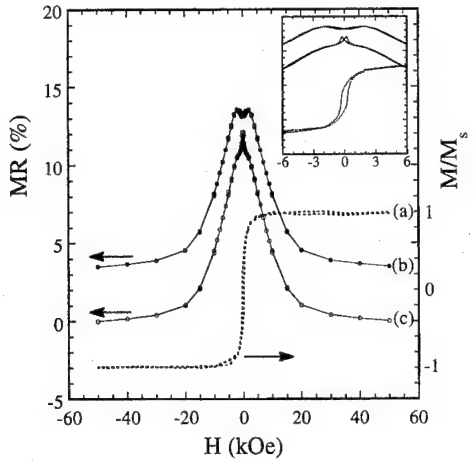

FIG. 3. The magnetization and MR as a function of applied magnetic field H at 10 K for [Co(17 Å)/Cu(10 Å)]$_{30}$ multilayer showing (a) hysteresis loops of magnetization, (b) longitudinal MR ($I\|H$), and (c) transverse MR ($I\perp H$).

Shown in Figs. 4(a)–4(d) are the longitudinal MR curves for sample (a) to sample (d) with increasing t_{Cu}. Note that similar features of longitudinal and transverse MRs in sample (b) also exist in sample (a). Compared to sample (b), sample (a) possesses larger GMR saturation field (~40 kOe) and smaller AMR (and magnetization) saturation field (~1 kOe), as shown in Figs. 4(a)–4(b). The AMR effect for sample (a) is slightly stronger [than sample (b)] with the longitudinal dip (see inset of Fig. 4) and transverse spike each of about 1%. On the other hand, the AMR effect completely disappears for sample (d) [see Fig. 4(d)], that is, the

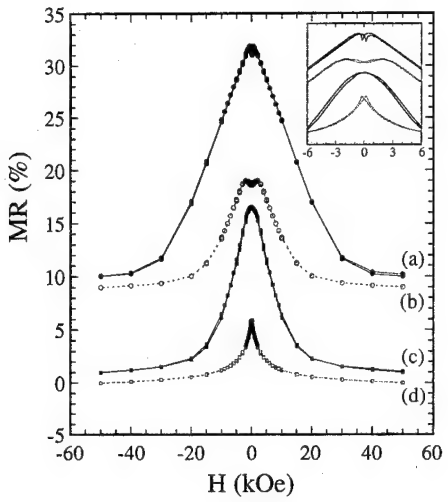

FIG. 4. The longitudinal magnetoresistance as a function of applied field at 10 K from samples: (a) $[Co(17\ Å)/Cu(8\ Å)]_{30}$, (b) $[Co(17\ Å)/Cu(10\ Å)]_{30}$, (c) $[Co(17\ Å)/Cu(12\ Å)]_{30}$, and (d) $[Co(17\ Å)/Cu(14\ Å)]_{30}$.

same longitudinal and transverse MRs at low or high field (isotropic GMR behavior) is found. For sample (c), the MR curve [Fig. 4(c)] appears to be an intermediate configuration between the typical pure GMR effect [like Fig. 4(d)] and the combination of the AMR and GMR effect [like Figs. 4(a) and 4(b)].

Finally we discuss the connection between the observed AMR effect and the hcp phase of Co in the multilayers. By comparison Figs. 4(a)–4(d) with the XRD spectra in Figs. 2(a)–2(d), it is quite easy to see a trend that the AMR effect decreases with the reducing of the hcp Co(0002) intensity. It is suggested that the observed AMR effect could be mainly due to scattering from the hcp Co layers of the multilayers. The strong correlation between the AMR and hcp phase of Co could be owing to the dominance of the anisotropic effect of the hcp phase (uniaxial anisotropy) over than that of the fcc phase.[14] So far, however, we are not able to quantitatively determine the ratio of the fcc and hcp phase of Co in the multilayers.

In summary, we have presented the structural and magnetic characterizations of Co/Cu(111) epitaxial multilayers. A small AMR component at low field sitting on top of a large GMR component extended to higher field has been observed. The AMR effect strongly correlates with the abundance of hcp stacking in the Co layers, which tends to decrease with the increasing of Cu spacer layer thickness. The AMR saturation fields coincides exactly with those of the magnetization. It appears that the observed AMR effect is mainly due to the scattering from the hcp-phase Co layers in the multilayers. This together with the large saturation field obtained from the entire MR curves indicate that the observed GMR effect may result from the Co-Cu interfacial spin-dependent scattering.

Effects of discharge pressure on the properties of Ag/Ni superlattices prepared by facing-target sputtering

X. T. Zeng and H. K. Wong
Department of Physics, the Chinese University of Hong Kong, Shatin, Hong Kong

Giant magnetoresistance (GMR) effect in magnetic multilayered thin films is strongly affected by interface roughness. We prepared $[Ag/Ni]_{60}$ superlattices on Corning's 7059 glass substrates using a novel facing-target sputtering method and observed that the interface roughness can be controlled by varying the discharge pressure (P_{Ar}). The samples prepared at $P_{Ar}\approx 10$ mTorr exhibit sharpest interfaces, good (111) texture, and largest GMR effects ($\Delta\rho/\rho_s=9\%$ at room temperature). Lower P_{Ar} promotes interface mixing while higher P_{Ar} results in much rougher interfaces and emergence of structural defects. Both cases weaken the antiferromagnetic coupling strength and thus reduce the MR effect. When $P_{Ar}\geqslant 30$ mTorr, we observed a further degradation of the multilayered structure. The GMR effects in these samples disappeared. Low-temperature annealing can improve the flatness of the interfaces and film structure, while higher-temperature annealing (>300 °C) decomposes the multilayer structures. © *1996 American Institute of Physics.*

I. INTRODUCTION

It is generally believed that the interface roughness in magnetic multilayers plays an important role in the spin-dependent scattering process.[1–8] However the mechanisms involved are still subject to discussions since the scattering processes at the interfaces may lead to an increase or decrease of the giant magnetoresistance (GMR) effects.[1–8] For systems like Ag/Ni or Au/Ni superlattices, the interfaces could be expected to be sharp as the constituents are mutually insoluble even in the liquid state.[9] Recently, Rodmacq *et al.* prepared Ag/Ni multilayers by sputtering and reported some results about their structure and magnetic properties.[4–6] Here, we define $MR=\Delta\rho/\rho_s$, where ρ_s is the resistivity at the saturation field. T. L. Hylton *et al.* reported a GMR value of 6% in weak magnetic field at room temperature in a similar system: $Ag/Ni_{80}Fe_{20}$ superlattices and they attributed the large GMR effect to a discontinuous multilayer structure.[7] However, R. C. Farrow and co-workers have also obtained GMR value of 5.6% in low-field Ag/permalloy multilayers and pointed out that interface roughness can deteriorate the MR effects.[8] Because of this controversy, further experiments to correlate the GMR effects with multilayer microstructure become necessary.

In this article, we prepared the multilayers of Ag/Ni by a facing-target sputtering (FTS) method[10,11] and focused on the effects of the argon discharge pressure (P_{Ar}) on the structure and properties of the films. We found that the multilayers with sharp interfaces have large MR values. X-ray diffraction experiments indicate that the crystalline AgNi alloy phase[9] may be formed in our films when prepared at high-Ar pressure.

II. SAMPLE PREPARATION

The Ag/Ni superlattices were deposited in a sputtering system equipped with four FTS guns.[11] The characteristics of our FTS guns and the sputtering system will be reported elsewhere. Layers of Ag and Ni were alternatively deposited on chemically cleaned Corning's 7059 glass substrates at room temperature. The number of bilayers for each samples was fixed at 60. The discharge current for the FTS guns were maintained at 18 mA. In spite of such a low sputtering power, the deposition rates were not low: about 0.2 nm s^{-1} for Ag and 0.1 nm s^{-1} for Ni. Although the discharge voltage increases at decreasing sputtering pressure, the deposition rate did not vary significantly. Some of the samples were annealed in a vacuum of 4×10^{-7} Torr.

III. STRUCTURAL STUDY

The Ag/Ni samples were characterized with a four circle x-ray diffractometer using Cu $K\alpha$ x-rays. X-ray diffraction (XRD) θ-2θ patterns were obtained with the scattering vector perpendicular to the film plane. The surface morphology of these samples was examined by a scanning electron microscope (SEM). Figure 1 shows the high-angle XRD patterns of samples prepared at different P_{Ar} with a nominal composition modulation of $[Ag\ (1.2\ nm)/Ni(0.81\ nm)]_{60}$. These patterns have an average Bragg peak $(111)_B$ at $2\theta\sim40°$, flanked by a few satellite peaks. The $(111)_B$ position depends slightly on the discharge pressure. No crystallites with other orientations were observed except for those samples prepared at $P_{Ar}\geqslant 30$ mTorr. For the samples deposited at 5 and 10 mTorr, we observed the second-order satellite peaks in both high-angle and low-angle XRD patterns, clearly indicating that these samples have sharper interfaces. Examination of these samples with an SEM also shows that the films prepared at lower pressures have a smoother surface than those prepared at higher pressures. However it does not mean that the lower the sputtering pressure, the better the sample quality. In fact, the sample prepared at 5 mTorr has a slightly weaker low-angle satellite peak than the 10 mTorr sample indicating that the 5 mTorr sample has a layered structure not as good as the 10 mTorr sample. This can be attributed to large interface mixing induced by the bombardment of the energetic sputtered particles.

For those samples prepared at $P_{Ar}\geqslant 30$ mTorr, only weak first order satellite peaks could be observed. The same characteristics were found in the measurements of the low-angle

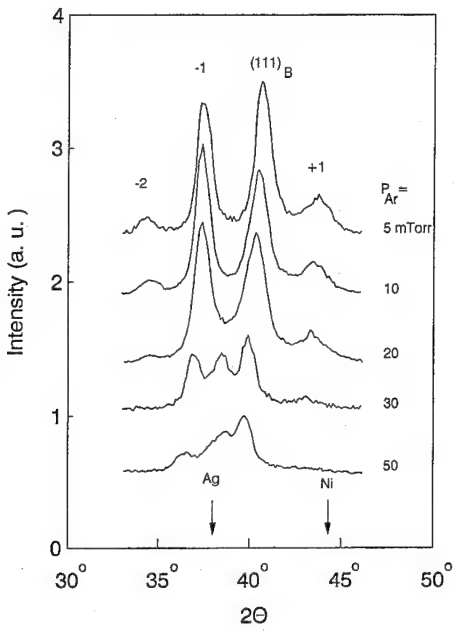

FIG. 1. XRD patterns of $[Ag/Ni]_{60}$ grown at different discharge pressures.

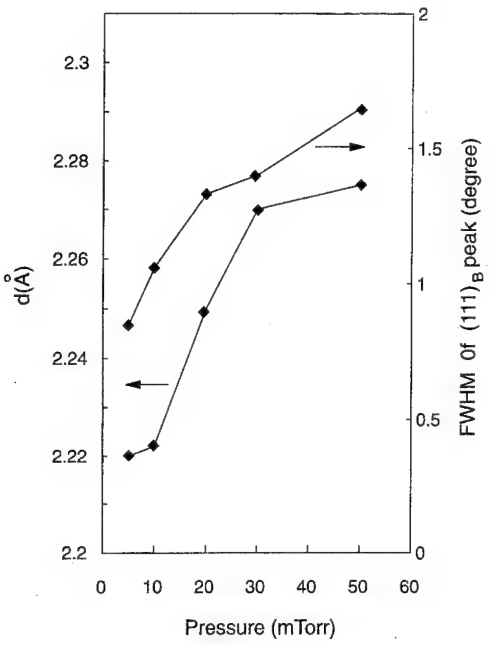

FIG. 2. Dependence of the atomic plane spacing and width of Ag/Ni $(111)_B$ average peaks on the discharge pressure.

satellite peaks. The full-width at half-maximum (FWHM) of these low-angle diffraction peaks for the samples prepared at 5–10 mTorr is much smaller than that for the samples prepared at $P_{Ar}>20$ mTorr. That means that low-pressure samples possess flatter interfaces than the high-pressure samples. The FWHM of the $(111)_B$ is also larger for samples prepared at higher P_{Ar} as shown in Fig. 2. Shown on the same graph is the pressure dependence of the plane spacing d.

The roughness of the interfaces mainly results from the dynamics of the sputtered particles on film surface. With the increase of discharge pressure, the sputtered particles scatter more frequently, which results in a kinetic energy loss. The mobility of these particles deposited on the substrate is significantly reduced, which results in increasing disorder in the atomic arrangement and average spacing between atomic planes. This is supported by our experiments using an electric probe to characterize the FTS discharge plasma at different conditions.[12] It is also expected to have misfit dislocation induced by large lattice mismatch between Ag and Ni. Thus we observed that for Ag/Ni superlattices prepared by FTS technique, there exists an optimum pressure for samples with better superlattice structures. We will see later that the pressure dependence of MR has a similar characteristic.

Other than the rough interfaces, we observed a new diffraction peak in the XRD spectra for samples prepared at $P_{Ar}\geqslant 30$ mTorr. This new diffraction peak was found to position between $(111)_B$ peak and Ag(111) peak. It may be attributed as a new phase of Ag_xNi_{1-x} alloy as observed recently by van Ingen *et al.* using pulsed laser deposition (PLD).[9] Because of the complete immiscibility between Ag and Ni, it is not expected to form an AgNi alloy phase by ordinary approach. In order to know the thermal stability of the structure, we annealed samples at different temperatures (T_a) in high vacuum $(4\times10^{-7}$ Torr) for 30 min. Figure 3 shows the XRD patterns for the annealed samples. When annealed at $T_a<280$ °C, both $(111)_B$ peak and satellite peaks gained intensity with slightly decreased widths, but the peak positions remained unchanged. In the words, the crystal quality and the interface flatness were improved. The annealing shifted the new peak gradually to smaller angle. When $T_a=350$ °C, all peaks mentioned above disappeared and pure Ag(111) and Ni(111) peaks appeared as shown in Fig. 4. That means that the alloy phase, if it exists in the samples, is metastable and the high-temperature annealing decomposed it into pure Ag and pure Ni grains. This result is basically in agreement with that obtained by PLD.[9]

IV. MAGNETORESISTANCE

The magnetoresistance (MR) was measured by the standard 4-point probe method using an ac measurement current of 0.1 mA and a lock-in amplifier. The magnetic field (B) was applied parallel to the film plane and perpendicular to the electric current. The MR of the as-deposited samples was measured at room temperature. Here $MR=[\rho(B)-\rho_s]/\rho_s$. We observed an oscillation of MR with the increase of the Ag layer thickness for samples prepared at 5, 10, and 20 mTorr. The maximal value of MR for all samples was achieved when the thickness of Ag layer was 1.2 nm. The results were reproducible with a deviation of MR value of about 1% for the samples with the same prescribed thickness. Here we focus attention on the effect of the discharge pressure on the MR value. Figure 4 shows the variation of magnetoresistance with discharge pressure. The inset shows the dependence of the magnetoresistance on magnetic field. It is found that the samples prepared at $P_{Ar}=10$ mTorr have the largest MR=9% and the largest saturation field. When $P_{Ar}=5$ mTorr, MR decreases to 6.2%, and the saturation field dropped by about one third. For samples prepared at $P_{Ar}=20$ mTorr, both MR and saturation field rapidly de-

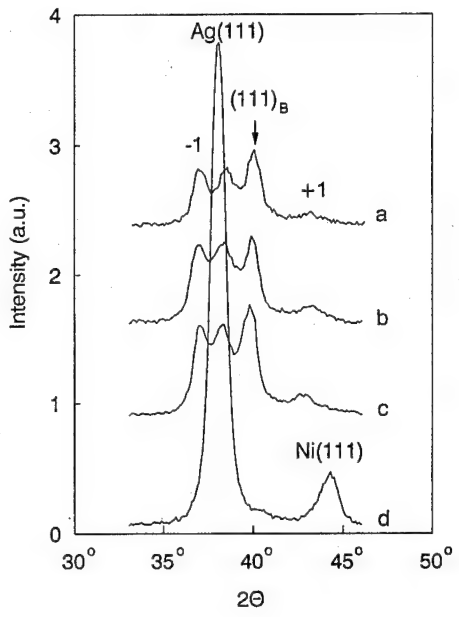

FIG. 3. XRD patterns of the sample grown at 30 mTorr and annealed at different temperatures. (a) As-deposited, (b) 220 °C, (c) 280 °C, and (d) 350 °C.

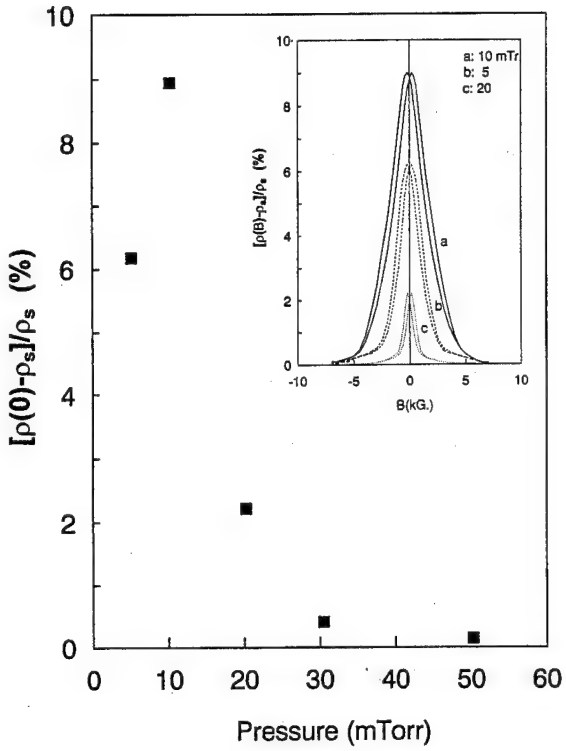

FIG. 4. Variation of the magnetoresistance with discharge pressure. The inset shows the field dependence of the magnetoresistance.

creased. For samples prepared at P_{Ar}=30 mTorr, no MR effect could be clearly observed. Fullerton *et al.* studied the Fe/Cr superlattices at P_{Ar}=4 and 12 mTorr, and concluded that MR is enhanced by the presence of interface roughness.[2] Our experiment covered a wider pressure range. We found that there exists an optimum pressure for preparation of samples with sharp interfaces and large MR. The decrease of MR at lower pressure was attributed to an increase of the interface mixing due to the higher energy of sputtered particles at lower pressure. The increase of roughness and atomic disorder in the layers cause a large fluctuation of spacing thickness which deteriorates the magnetic coupling properties of the layers and diminishes the MR value. This can be reflected by the sample resistivity. With the increase of the pressure, zero-field resistivity ρ_0 varies little, but saturation field resistivity ρ_s obviously increases. This indicates that the samples prepared at high P_{Ar} have many structural defects and rough interfaces which weaken the strength of the antiferromagnetic (AFM) coupling. When no magnetic field is applied, the increasing defect resistance is partially compensated by the decreasing spin-dependent scattering.

V. SUMMARY

We have prepared Ag/Ni superlattices at different discharge pressures on Corning's 7059 glass substrates by a facing-target sputtering method. Detailed structural and electrical measurements indicate that there exists an optimal discharge pressure (~10 mTorr) at which samples can be prepared with sharp interfaces, good (111) texture, large MR (9% at room temperature) and high saturation magnetic field. Lower discharge pressure causes larger mixing of Ag and Ni atoms at the interfaces, and higher pressure results in much rougher interfaces and emergence of structural defects. Both situations weakened the AFM coupling and decrease MR. Low-temperature annealing can improve the flatness of the interfaces and film structure. Annealing at temperatures higher than 300 °C decomposes the multilayered structures.

Co/Cr superlattices with Co layer thickness of 15 Å and Cr layer thickness of 10 Å have been successfully grown on different substrates, such as MgO, Si, and quartz, by molecular-beam-epitaxy. The crystal structure of all samples has been characterized by *in situ* reflection high-energy electron diffraction. Both magnetoresistance (MR) and magneto-optical Kerr effect (MOKE) measurements were used to analyze the magnetic properties of these samples. Excellent epitaxial growth of hcp-Co($1\bar{1}00$)/bcc-Cr(211) superlattices grown on MgO(110) was observed. Co/Cr superlattices were polycrystalline when grown on Si and amorphous when grown on quartz. Isotropic MRs of less than 1% were observed for all polycrystalline and amorphous Co/Cr superlattices. For Co($1\bar{1}00$)/Cr(211) superlattices grown on MgO(110), a transverse MR of 14.2% and longitudinal MR of 0.67% were observed. MOKE hysteresis loops show perpendicular magnetization for polycrystalline Co/Cr superlattices grown on Si, and in-plane isotropic magnetization for amorphous Co/Cr superlattices grown on quartz. MOKE hysteresis loops for Co/Cr superlattices grown on MgO(110) show strong anisotropic behavior between the hard and easy directions. The magnetic properties of Co/Cr superlattices are strongly influenced by the crystal structure of Co and Cr which is controlled by the substrate. © *1996 American Institute of Physics.* [S0021-8979(96)24508-0]

I. INTRODUCTION

Since the discovery of giant magnetoresistance (GMR) phenomena,[1–3] ferromagnetic superlattices have attracted much attention for both fundamental research and industrial applications. Over 50% GMR of Fe/Cr or Co/Cu superlattices have been found, but relatively small magnetoresistance (MR) (<5%) of Co/Cr superlattices was found.[4–6] We have known that the GMR effect mainly comes from the coupling between the ferromagnetic layers. It is different from the anisotropic magnetoresistance (AMR) in ferromagnetic systems,[7] where magnetoresistance depends on the direction of the measurement. It has also been noted that magnetic properties may be influenced by electronic structure, which in turn depends on crystal structure. Since crystal anisotropy is intrinsic to the material, it may effect coupling between the ferromagnetic layers in the superlattice and both MR and magnetization hysteresis loop may have strong anisotropic behavior. The Co/Cr system is suitable for the study of the relationship between the structure and the magnetic property because of its varied structural and magnetic properties. Since Co has a very strong crystal anisotropy, we may also see the strong effect of the magnetocrystalline anisotropy on both MR and magnetization hysteresis loop measurements. For isotropic Co/Cr superlattices, we expect to see isotropic MRs and magnetization hysteresis loops.

In this article, we report measurements of MR and magneto-optical Kerr effect (MOKE) hysteresis loop of different structured Co/Cr superlattices grown on different substrates by molecular beam epitaxy (MBE). These measurements show that Co/Cr superlattices epitaxial grown on MgO(110) are highly anisotropic. Large transverse MR (magnetic field along the in-plane hard axis, Co[$11\bar{2}0$], and current along the in-plane easy axis, Co[0001]) of 14.2% and small longitudinal MR (magnetic field and current both along the in-plane hard axis, Co[$11\bar{2}0$]) of 0.67% were measured, and MOKE hysteresis loops also show strong angular dependence. Isotropic MR of 0.37% and MOKE hysteresis loops were measured on amorphous Co/Cr superlattices grown on quartz. Small MR of 0.13% and perpendicular magnetization were observed on polycrystalline Co/Cr superlattices grown on Si.

II. EXPERIMENT

The growth of the superlattices was carried out by a molecular beam epitaxy system (Eiko EL-10A), equipped with three independent electron beam evaporators. The base pressure of the system is lower than 1×10^{-10} Torr. During the growth of the superlattices, the pressures were kept below 5×10^{-9} Torr, and the growth rates were kept about 0.1 Å/s. The growth rate and film thickness were monitored by a quartz crystal thickness monitor (Leybold Inficon XTC). A 15 keV reflection high-energy electron diffraction (RHEED) is used to *in situ* examine the crystal structure of the film surface throughout all growth. MR measurements were carried out by the conventional four probe technique in a magnetic field up to 50 kOe in a SQUID magnetometer (Quantum design MPMS-5S). Transverse and longitudinal MRs were measured with current perpendicular to the magnetic field and current parallel to the magnetic field, respectively. Magnetization hysteresis loop observations were carried out at room temperature in the longitudinal configuration in a magnetic field up to 2 kOe by a MOKE system. Two con-

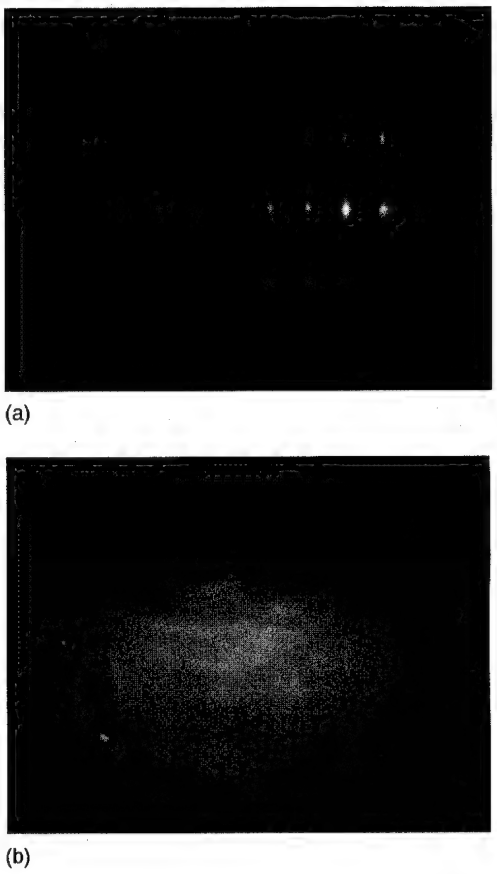

FIG. 1. RHEED patterns of (a) Co($1\bar{1}00$) viewed along [$11\bar{2}0$] of (Co_{15} Å/Cr_{10} Å)$_{40}$ superlattices on MgO(110), (b) Co of (Co_{15} Å/Cr_{10} Å)$_{40}$ superlattices on Si(111).

figurations of MOKE were used: the longitudinal MOKE (LMOKE) in which magnetization lies both in the sample surface and in the incident plane, and the polar MOKE (PMOKE) where magnetization is perpendicular to the sample surface and lies in the incident plane. Prior to the deposition, epitaxial grade substrates were outgassed at 900 °C for at least 1/2 h under ultra-high vacuum in the MBE chamber. The substrate temperatures were kept between 300 and 350 °C during the deposition to reduce the interdiffusion at the interfaces.

III. RESULTS AND DISCUSSION

The crystal structure and the orientation of epitaxial growth for Co/Cr superlattices with Co layer thickness of 40 Å on MgO(110) have been reported previously.[8–11] The unit cell of Co($1\bar{1}00$), 4.07 Å×2.51 Å, matches perfectly with that of Cr(211), 4.07 Å×2.50 Å. Even though the unit cell of MgO(110) is larger, 4.21 Å×2.98 Å, there still exists the epitaxial relationship:

Co($1\bar{1}00$)‖Cr(211)‖MgO(110),Co[$11\bar{2}0$]‖Cr[$\bar{1}\bar{1}1$]‖MgO[$1\bar{1}0$],

and

Co[0001]‖Cr[$0\bar{1}1$]‖MgO[001].

From RHEED observations, as shown in Fig. 1(a), it was confirmed that (Co_{15} Å/Cr_{10} Å)$_{40}$ superlattices have the same

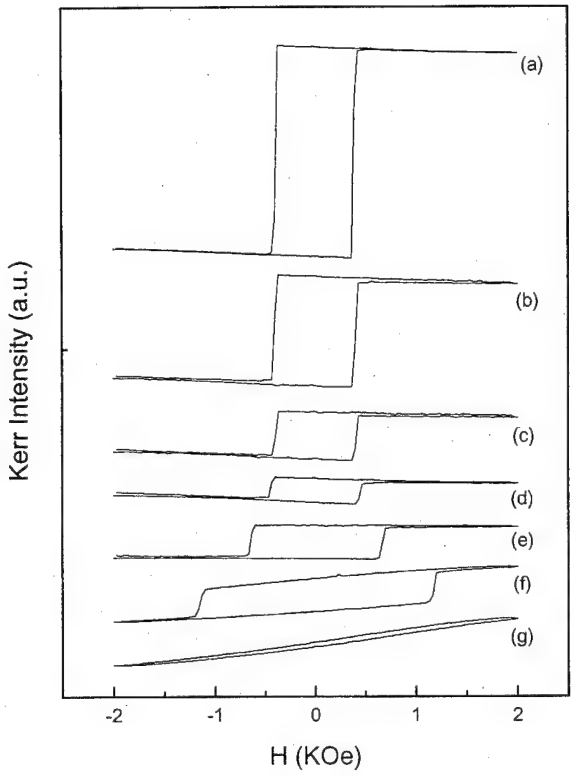

FIG. 2. MOKE hysteresis loops of (Co_{15} Å/Cr_{10} Å)$_{40}$ superlattices on MgO(110) with ϕ=(a) 0°, (b) 15°, (c) 30°, (d) 45°, (e) 60°, (f) 75°, and (g) 90°.

crystal structure and orientation as (Co_{40} Å/Cr_{15} Å)$_{20}$. Hcp-Co($1\bar{1}00$)/bcc-Cr(211) are the crystal structures and orientations of Co/Cr superlattices grown on MgO(110). Co/Cr superlattices grown on Si were polycrystalline, according to the circle-like RHEED picture shown in Fig. 1(b). Samples grown on quartz were amorphous, with a blur picture with no specific pattern in RHEED (not shown). The strong anisotropic behavior of Co($1\bar{1}00$)/Cr(211) superlattices grown on MgO(110) is shown in Fig. 2. A series of longitudinal MOKE hysteresis loops of the Co/Cr superlattices grown on MgO(110) showed that not only in the shape, but also the

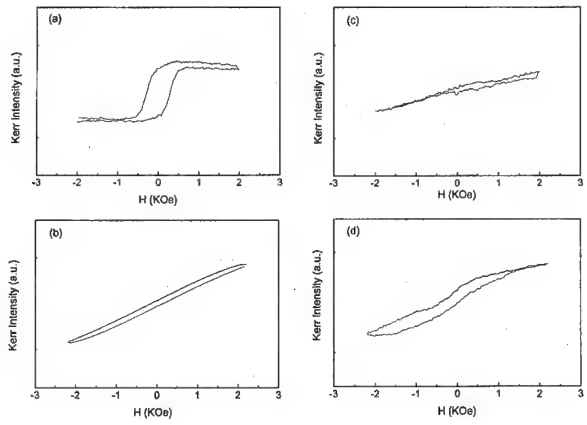

FIG. 3. (a) LMOKE, (b) PMOKE hysteresis loops of (Co_{15} Å/Cr_{10} Å)$_{40}$ superlattices on quartz, (c) LMOKE, (d) PMOKE hysteresis loops of (Co_{15} Å/Cr_{10} Å)$_{40}$ superlattices on Si(111).

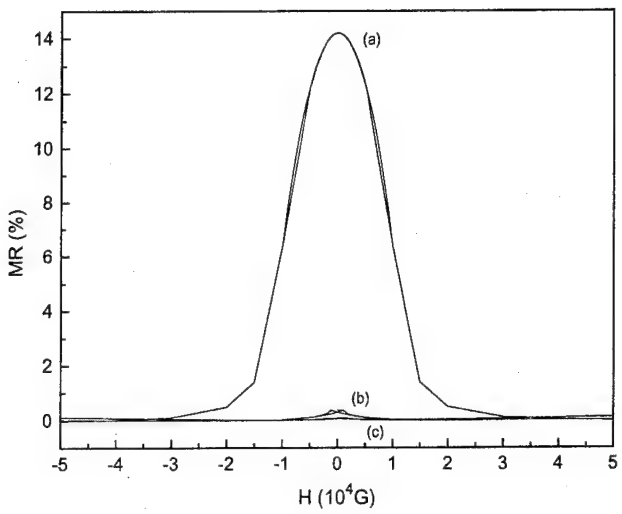

FIG. 4. MRs of $(Co_{15\ Å}/Cr_{10\ Å})_{40}$ superlattices on (a) MgO(110), (b) quartz, and (c) Si(111).

coercive field of the magnetization hysteresis loop changed with angle ϕ from easy axis (ϕ=0°) to hard axis (ϕ=90°). The azimuthal angle ϕ is the angle between the in-plane crystal axis Co[0001] and the applied magnetic field. The tilt of the baseline slope comes from the background signal. The nonangle-dependent magnetization behavior of Co/Cr superlattices grown on Si and quartz is shown in Fig. 3. From the longitudinal and polar MOKE hysteresis loops in Fig. 3(a) and 3(b), Co/Cr superlattices grown on quartz show an in-plane ferromagnetic magnetization, instead of an out-of-plane magnetization. The Co/Cr superlattices grown on Si show no in-plane magnetization, see Fig. 3(c) (LMOKE), but an out-of-plane magnetization, as shown in Fig. 3(d) (PMOKE). Co/Cr superlattices grown on MgO(110) show strong anisotropic behavior not only in magnetization but also in MR measurements with transverse MR of 14.2%, as shown in Fig. 4(a), and the longitudinal MR of 0.67% at 10 K. This anomalous anisotropic MR has also been reported in epitaxial growth of Co/Cr bilayer films on MgO(110).[12] The crystal anisotropy of the Co layers and the spin flip of the Cr layers may be responsible for those results. Amorphous Co/Cr superlattices grown on quartz with in-plane isotropic magnetization showed a small MR of 0.37%, as shown in Fig. 4(b). Polycrystalline Co/Cr superlattices grown on Si with perpendicular magnetization also showed a small MR of 0.13%. These small MRs for Co/Cr superlattices are similar to those reported previously.[4–6]

IV. CONCLUSION

We have demonstrated the influence of different crystal structure and orientation on the magnetic properties of $(Co_{15\ Å}/Cr_{10\ Å})_{40}$ superlattices. Co/Cr superlattices grown on quartz were amorphous with isotropic magnetization and small MR(0.37%). Co/Cr superlattices grown on Si were polycrystalline with perpendicular magnetization and also small MR(0.13%). Anisotropic magnetization and MR were observed on epitaxial Co/Cr superlattices grown on MgO(110). Large transverse MR (14.2%) of Co(1$\bar{1}$00)/Cr(211) superlattices may result from the crystal anisotropy of the Co layers and the spin flip of the Cr layers.

Magnetoresistance in NiFe/Au multilayers and spin-valve structures (abstract)

K. T. Wu and R. J. Gambino
Department of Materials Science and Engineering, State University of New York at Stony Brook, Stony Brook, New York 11794

Permalloy has been widely studied and used in industry for magnetic recording heads and sensors. This article presents a study of the magnetoresistance of $(NiFe/Au)_n$ multilayer films and NiFe/Au/NiFe sandwich structures. Gold is used as the spacer layer because of its low solid solubility in NiFe and the tendency of NiFe and Au to phase separate. Films were grown by dc sputtering with a series of different permalloy and Au thickness. In the multilayer films, the thickness of permalloy varies from 20 to 40 Å and Au varies from 8 to 25 Å. A difference in the sign and magnitude of magnetoresistance for transverse and longitudinal field directions with respect to current indicates the presence of anisotropic magnetoresistance (AMR) effect. The magnitude of $\Delta\rho/\rho$ is small because of shunting by Au layers. In the sandwich structures, the thickness of permalloy layers is different on each side of the Au and varies from 150 to 800 Å. The Au spacer layer varies from 20 to 60 Å. The measurements show mainly anisotropic magnetoresistance. There was a small opposite jump at ~8 Oe on resistivity measurement, which indicates spin valve effect superimposed on the AMR effect. After annealing, the change in magnetoresistance is much more sensitive in low field ~15 Oe, a property which is critical to many applications. © *1996 American Institute of Physics.* [S0021-8979(96)81108-1]

The pinning field H_p (the amount of the shift of the hysteresis loops) and the coercivity H_c of the samples of the form glass/Ta 120 A/(Cu 100 A)/NiFe 75 A/FeMn 150 A/Ta 50 A increase almost linearly with decreasing temperature down to 20 K, below which H_c increases sharply. The observed strong positive correlation between H_p and H_c, seems to be reasonably explained by a combination of a newly developed model in which a directional distribution of the pinning field caused by a random distribution of the crystalline orientations in the antiferromagnetic FeMn layer is taken into account and Hoffmann's ripple theory in which the local anisotropy is assumed to be proportional to H_p, although the sharp increase in H_c at very low temperatures remains to be explained. © *1996 American Institute of Physics.* [S0021-8979(96)24608-7]

I. INTRODUCTION

The "spin valve" is now attracting world wide interest because of its high potential to be applied in the most advanced type of magnetic sensors such as read heads for high density magnetic recording. In a spin valve structure in which an antiferromagnetic (AF) layer is employed for pinning the magnetization of one of the two ferromagnetic (F) layers, which lies facing the other F layer via a nonmagnetic metal layer, it is often observed that the pinned F layer exhibits a substantially higher coercivity than its intrinsic coercivity. Although there have been quite a few investigations about the interaction between ferromagnet and antiferromagnet since the late 1950s,[1–6] it still does not seem to be fully understood. Fulcomer and Charap[2] proposed a model to explain the temperature and frequency dependence of the hysteresis loop displacement, the amount of which is to be called a pinning field H_p hereafter, and the coercivity H_c. In their model, the switching of the spins in the AF layer which is composed of tiny particles is thought to be responsible for the enhancement of H_c. According to this model, the pinning field increases with decreasing temperature, but the coercivity is expected to have a maximum at some temperature and then decreases. This model explained some of the experimental results, e.g., the one on a Co-CoO system,[7] fairly well. Schlenker *et al.*,[3] on the other hand, showed that in a NiFe/FeMn system both H_p and H_c increased monotonically with the decrease of temperature down to 10 K. However, they attributed the enhancement of the coercivity of the NiFe (F) layer in the system to an irreversible rotation of the moments of some parts of the FeMn (AF) layer.

In the course of our investigation on the NiFe/Cu/NiFe/FeMn-type spin valves, the temperature dependence of the pinning field H_p and the coercivity H_c of the NiFe (F) layer coupled with FeMn (AF) layer were examined. The results showed, as was shown by Schlenker *et al.*,[3] that H_p and H_c increased monotonically and almost linearly with decreasing temperature down to 20 K (below which H_c increased drastically), showing a fairly good proportionality between them. It was also observed that H_p and H_c were both enhanced by heating up to 100 °C. These results suggest that there exists some mechanism which gives rise to a strong positive correlation between H_p and H_c. This article presents those experimental results and proposes a mechanism to explain this phenomenon, taking into account a ripple structure generated in the F layer through a distribution of the pinning field direction[5,8] which may be attributed to an expected random distribution of the crystalline axes in the AF layer.

II. EXPERIMENTAL PROCEDURE

The samples were prepared by sputtering on a glass (Corning No. 7059) substrate in a uniform dc field in the form of glass/Ta 120 A/(Cu 100 A)/NiFe 75 A/FeMn 150 A/Ta 50 A [sample-1 (without Cu) and sample-2 (with Cu)]. The sputtering was performed in one continuous process without breaking the vacuum.[9] The crystalline textures were examined by x-ray diffractometry using Cu $K\alpha$ x ray. The hysteresis curves were obtained by means of a vibrating sample magnetometer (VSM) and a SQUID.

III. EXPERIMENTAL RESULTS

Figure 1 shows the x-ray diffraction patterns obtained for sample-1 and sample-2, respectively. It is seen that sample-1 has a little better perpendicular texturing of [111] direction of the NiFe and/or FeMn layers than sample-2, suggesting that a higher pinning field may be obtained for the former than for the latter.[10]

Figure 2 shows an example of the hysteresis loops obtained for sample-1 at room temperature. H_p and H_c were measured as the shift of the center of the hysteresis loop and a half of the loop width as shown in the figure, respectively.

It was observed by VSM that both H_p and H_c of sample-1 changed almost linearly as a function of temperature, both seeming to become zero at the same temperature which is to be regarded as the blocking temperature T_B. In

 0021-8979/96/79(8)/6286/3/$10.00

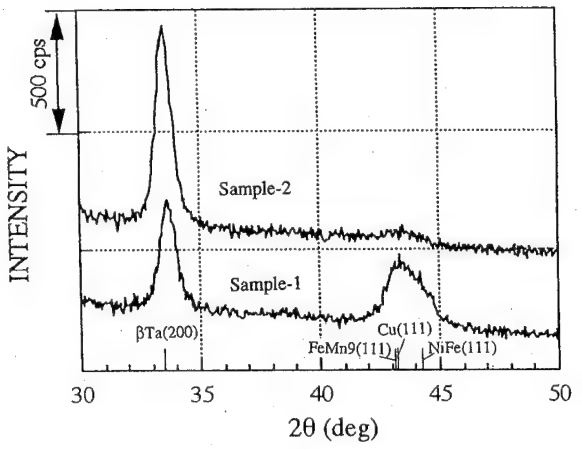

FIG. 1. X-ray diffraction patterns for sample-1 (without Cu) and sample-2 (with Cu) using Cu $K\alpha$.

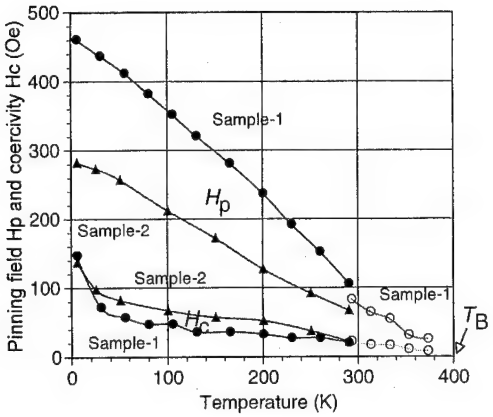

FIG. 3. Temperature dependence of H_p and H_c of sample-1 (circles) and sample-2 (triangles). Solid symbols refer to the data obtained by SQUID. The open circles are the data obtained by VSM for sample-1 by heating from room temperature up to 100 °C (373 K).

order to see to what extent this tendency holds, low-temperature measurement was performed by using a SQUID for both sample-1 and sample-2. Figure 3 shows the results. Solid circles are for sample-1 and triangles, for sample-2. Here, the data obtained for sample-1 which was heated from room temperature up to 373 K are also plotted by open circles. It is seen that both H_p and H_c change almost linearly down to 20 K for both kinds of samples and that below that temperature H_c increases rapidly while H_p is kept almost on the same straight line as at higher temperatures. In Fig. 4, H_c's are plotted as a function of H_p.

IV. DISCUSSION AND CONCLUSION

According to Fulcomer and Charap's model in which the irreversible switching of spins in the AF layer plays a decisive role in enhancing the H_c of the F layer, the H_c should become maximum somewhere around the blocking temperature. Therefore, in order to explain the present results as shown above, some new model seems to be necessary. We have recently proposed a model in which a distribution of the pinning field direction originating from the random distribution of the crystalline orientation of the AF layer is taken into consideration.[11] The model employs an assumption of a checker-board (with a side length L) type distribution of the pinning field orientation making angles of plus (+) and minus (−) ϕ_0 with the average pinning field direction which gives rise to a kind of magnetization ripple structure in the F layer. This assumption is in line with Speriosu *et al.*'s concept of pinning field dispersion[5,7] which was proposed for samples similar to the present ones. According to the model, a substantial enhancement of H_c can be explained by assuming a proper length L and angle ϕ_0 if some switching mechanism of the magnetizations at the center of the ripple walls (the switching of a kind of Néel wall's polarity) is taken into account. In Fig. 5, the maximum H_c which is attainable through the above mechanism is plotted as a function of the local pinning field H_{p0} in each checker block taking L as a parameter. According to this model, the observable pinning field is expressed as

$$H_p = H_{p0} \cos \phi_0 .$$

Although H_c is not proportional to H_{p0} for each L value, because there may be a wide distribution of L in the actual

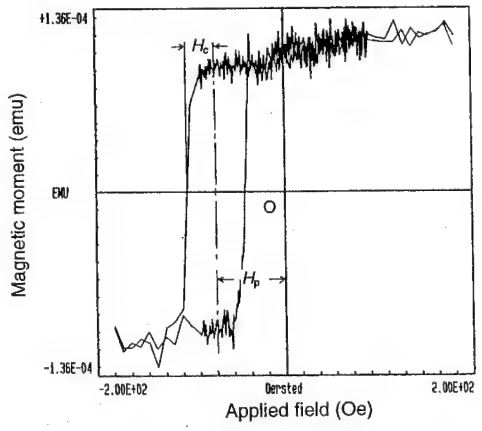

FIG. 2. Hysteresis loop of the as-deposited sample-1 measured at the room temperature by VSM. H_p and H_c were measured as shown in the figure.

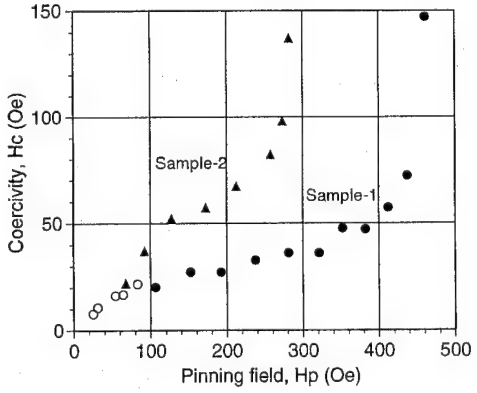

FIG. 4. Coercivity H_c vs pinning field H_p plotted for both sample-1 and sample-2 the data of which are shown in Fig. 3.

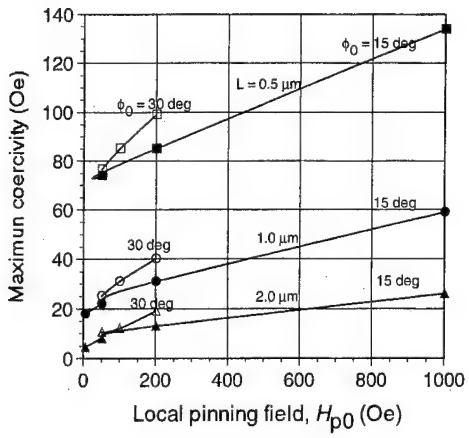

FIG. 5. Calculated maximum coercivity as a function of the local pinning field H_{p0} according to a model proposed recently in which checkerboardlike local distribution of the pinning field direction is taken into consideration (see Ref. 11). L denotes the length of a square of the checker board and ϕ_0 the deflection angle of the local pinning field direction from their mean direction.

samples, the effective L may decrease with increasing H_{p0} giving rise to a faster increase in the maximum H_c than when L is fixed at a single value. As for the mechanism of the switching of the ripple wall polarity, a direct switching mechanism in which Bloch line creation in the wall takes place has been confirmed unfeasible.[11] Therefore, some macroscopic collective magnetization reversal processes, such as a macroscopic domain wall motion or incoherent rotation should be taken into account. Then, the mechanism explained above will act as a magnetization sustaining one when a reverse field is applied until the average magnetization is switched into the reverse direction. About the H_c of the domain wall motion in the films with a ripple structure, Hoffmann[12] showed that H_c should be proportional to the local anisotropy. This theory will also apply to the incoherent rotation mechanism, although the proof may not be straight forward. In our case, the local anisotropy field in the ripple theory is thought to be proportional to $H_{p0} \sin \phi_0$, which directly leads to the explanation of the observed strong correlation between H_c and H_p. The higher coercivity for sample-2 than for sample-1 for the same H_p as is seen in Fig. 4 will be attributed to higher pinning field orientation angle ϕ_0 for the former than for the latter. The steep increase of H_c observed at very low temperatures, however, is still left to be solved.

Magnetic and magnetotransport properties of Ni/Fe multilayers

M. Cai, T. Veres, R. Morel, and R. W. Cochrane
Département de Physique, Université de Montréal, Montréal, Québec, H3C 3J7, Canada

We present a study of sputtered Ni/Fe multilayers in order to examine the effect of interfacial mixing and interdiffusion on the magnetic and transport properties. The multilayer structure has been examined by low-angle x-ray reflectivity, which reveals interface mixing of about two monolayers. The magnetization measurements show differences in the anisotropy of multilayers for which the thickness ratio of nickel to iron is changed from 1:1 to 3:1. With the 1:1 composition, multilayers show high permeability with a longitudinal easy axis, while samples with 3:1 composition show lower permeability and a rotated easy axis. By fitting the resistivity and magnetoresistance thickness variation with a semiclassical model, we have determined an interface contribution to the resistivity and a possible contribution to the magnetoresistance. © *1996 American Institute of Physics.* [S0021-8979(96)24708-3]

I. INTRODUCTION

Since the discovery of new transport and magnetic properties in magnetic/nonmagnetic multilayers, the study of modulated metallic nanostructures has become a very active field of research. On one hand, this interest is driven by the need to design materials with magnetic, magneto-optic and magnetotransport properties suited for high density magnetic recording. On the other hand, these artificially structured materials are also proving to be important for understanding the fundamental physics of interacting magnetic thin films. In multilayers where the individual layers are only a few atomic planes thick, one aspect which needs to be addressed is the nature and the role of the interfaces in the structural, magnetic, and electronic properties of the ensemble. In addition, the structure and properties of individual layers within the multilayers are often different from those of bulk materials, which in turn leads to multilayer properties distinct from those of bulk alloys of the same constituents.

Recently, it has been found that in Ni/Co multilayers this combination of factors produces a relatively large anisotropic magnetoresistance with low saturation fields.[1] Moreover, recent results show oscillations of the magnetoresistance with cobalt and nickel thicknesses, probably due to a superlattice effect.[2] In the case of Ni/Fe multilayers, previous studies have found that for thicknesses below ~20 Å the iron is in an fcc phase,[3] and theoretical calculations predict that this phase may be antiferromagnetic.[4] In the same thickness range, Mössbauer spectroscopy on vacuum deposited Ni/Fe multilayers points to a ferromagnetic fcc iron phase, with an out-of-plane anisotropy.[5] As NiFe alloys are technologically very important due to their magnetoresistive and soft magnetic properties, it is of interest to look at how the magnetic and magnetoresistive properties are influenced by the layering of nickel and iron in a modulated structure.

II. EXPERIMENTAL DETAILS

We present magnetic and magnetoresistance measurements on $(Ni_xFe_y)_n$ multilayers (x and y are the film thicknesses in Å) deposited by rf magnetron sputtering[6] onto glass (Corning 7059) substrates mounted onto a water-cooled support. With a sputtering pressure of 3 mTorr of argon gas (99.999%) and an rf power of 200 W, the deposition rates were 1.2 Å/s for Fe and 2.1 Å/s for Ni and, hence, the residence time of the substrate above the targets was used to control the layer thickness in the range from 12 to 110 Å. The number of periods was chosen so that the total thickness was kept constant at ~1200 Å. Since two films were deposited simultaneously, the first layer is alternatively iron or nickel. A mask over the substrate in the form of strips, 16 mm long and 4 mm wide with sidearms for electrical contacts defined the sample shape. Finally, pure nickel and iron layers of approximately the same thicknesses were deposited for comparison.

Nominal thicknesses were confirmed by DEKTAK and low-angle x-ray-reflectivity measurements. Coercive fields and remanences were measured at room temperature using a vibrating sample magnetometer. However, due to the large nonsymmetric area of the samples, it was not possible to obtain an absolute measurement of the magnetization. Transport properties under magnetic field were also measured at room temperature, using a high-resolution ac bridge. In order to account for the history-dependent zero-field resistivity, the total anisotropic magnetoresistance (AMR) was measured as the difference in resistivity when the sample is rotated in a saturating field.

III. RESULTS AND DISCUSSION

Figure 1 shows low-angle x-ray reflectivity spectra of a $(Ni_{60}Fe_{30})_{11}$ multilayer. The spectra exhibit well-developed Bragg superlattice peaks up to the fifth order (not shown), indicating a sharply defined composition modulation in the film growth direction. Note that, in the figure, the third-order peak is suppressed, as expected for a 2:1 ratio of Ni and Fe. Also, finite size oscillations appears between the Bragg peaks due to the eleven bilayers present in the multilayer, suggesting the smooth nature of the films. In addition, high-angle x-ray data reveal a high degree of fcc (111) and bcc (110) texture.

To estimate the interfacial mixing width, the experimental data are fitted using a standard optical model,[6,7] in which the x-ray reflectivity is calculated using a matrix method. In order to include interfacial mixing, a linear composition profile is assumed at the interface. In addition, the global interface roughness and layer thickness fluctuations are included

 0021-8979/96/79(8)/6289/3/$10.00

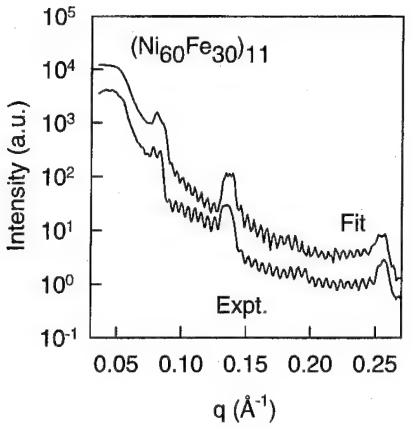

FIG. 1. Low-angle x-ray reflectivity spectra for (Ni 60 Å/Fe 30 Å)$_{11}$. The lower curve is experimental while the upper curve, shifted for clarity, is the fit described in the text.

to simulate a real situation. Further details of the fitting procedure have been described elsewhere.[6] The resulting fitted curve is also presented in Fig. 1 and is clearly in good agreement with the experimental data. An interfacial width of 5 Å is obtained from this fitting, setting an upper limit on the interdiffusion in our samples.

Figure 2 shows magnetization curves for multilayers from two series, measured in longitudinal (along the long axis of the sample) applied field, where the magnetization values are normalized relative to the magnetization of a pure iron layer of equal thickness. On this relative scale, the nickel film gives a saturation magnetization of 0.25 which is slightly less than the ratio of the bulk values for Ni and Fe. Unfortunately, since the absolute values are unknown, it is not possible to determine from these measurements how the Ni and Fe magnetizations depart from their bulk values. Nevertheless, the magnetization of all the multilayers can be fully accounted for using an identical ratio of 0.25 between the magnetizations of the individual Ni and Fe layers. This ratio seems to preclude the possibility of an antiferromagnetic iron phase[4] in our films, even in multilayers with Fe thicknesses below 20 Å.

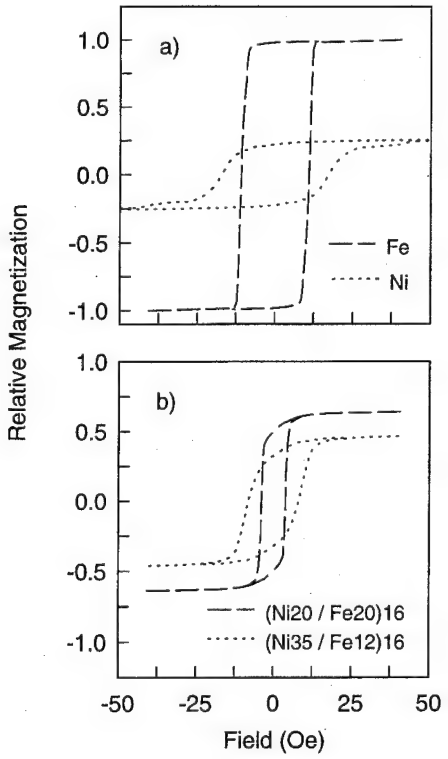

FIG. 2. Magnetization of (a) pure nickel and iron thin films and (b) (Ni 20 Å/Fe 20 Å)$_{16}$ and (Ni 35 Å/Fe 12 Å)$_{16}$ multilayers. In all cases, the applied field is in the longitudinal direction and the magnetizations are normalized relative to that of an iron film of equal thickness.

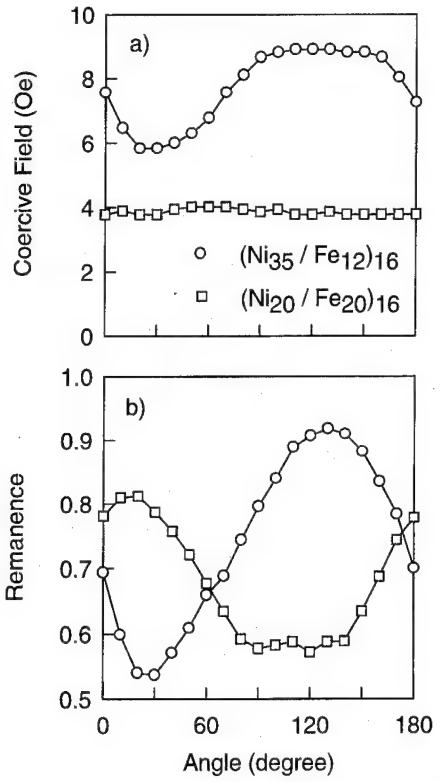

FIG. 3. Coercive field (a) and remanence (b) of (Ni 20 Å/Fe 20 Å)$_{16}$ and (Ni 35 Å/Fe 12 Å)$_{16}$ multilayers as a function of the angle between the applied field and the longitudinal direction of the multilayer strips.

The shape of the magnetization curves of Fig. 2 are reminiscent of those of the pure sputtered films in that the multilayers with greater Ni thicknesses ($x=3y$) have higher coercive fields H_c and reduced remanence M_r than samples with equal Ni and Fe thicknesses ($x=y$). On the other hand, all multilayers show a smaller coercivity and remanence than the elemental films.

In Fig. 3 are presented the angular dependences of H_c and M_r for the multilayers of the previous figure. These curves, representative of all the multilayers within the same series, show that with equal thicknesses of Ni and Fe, the coercive field is almost constant and the remanence is higher when the saturating field is longitudinal, indicating an easy axis in that direction. However, in multilayers where $x=3y$, both H_c and M_r show the presence of an easy axis at some direction varying between 120° and 150° to the sample axis. Since the magnetic field at the substrate position during deposition is only about 1 Oe, this anisotropy is not believed

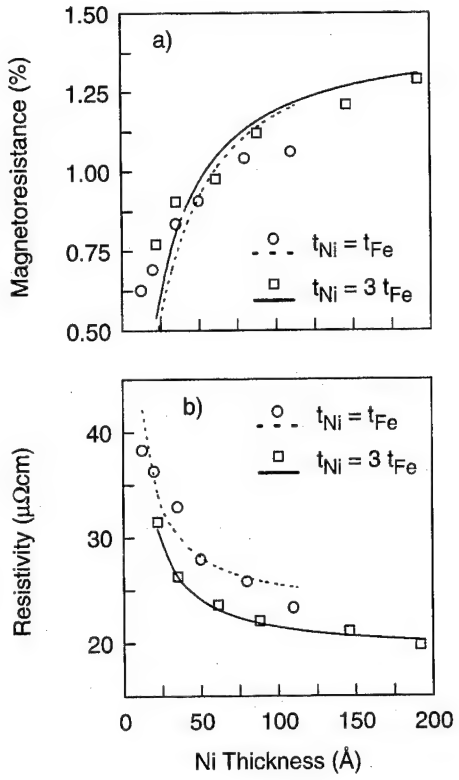

FIG. 4. (a) Anisotropic magnetoresistance (AMR) and (b) resistivity for Ni/Fe multilayers as a function of the nickel layer thickness. The lines have been calculated using the models and parameters described in text.

to be field induced; its precise origin is currently under investigation.

The resistivity and magnetoresistance (AMR) are presented in Fig. 4. The resistance is found to increase and the AMR to decrease as the Ni layer thickness decreases. In single-layer thin films, this behavior is expected when the thickness of the layer becomes of the order of the mean-free path. In multilayers, the thickness variation of the resistivity also depends on the effect of the interface on the conduction electron scattering. To assess this contribution, the results were fitted with a semiclassical model, derived from Carcia and Suna,[8] in which each layer is characterized by its mean-free path λ while the interfaces are represented by an angle-dependent transmission coefficient T (details of the model will be presented elsewhere).[9] The fitted resistivity presented in Fig. 4 are obtained with $\lambda_{Ni}=37.5$ Å, $\lambda_{Fe}=15$ Å, and $T=0.8$; these mean-free paths correspond to bulk resistivities of 16 $\mu\Omega$ cm for nickel and 40 $\mu\Omega$ cm for iron, values very close to those measured for the pure films. Moreover, the fit is quite sensitive to the choice of the transmission parameter, which is indicative of the importance of the interface contribution to the resistivity.

In order to calculate the AMR we introduce an asymmetric mean-free path in the form $\lambda=\lambda_0(1+a\cos^2\theta)$, with a the asymmetry parameter and θ the angle between the electron velocity and the magnetization.[10] Because the bulk magnetoresistance of iron is ten times smaller than that of nickel, we assume that the anisotropy comes solely from the nickel layers. Also, no attempt was made to account for an interface contribution. As can be seen, the fit for AMR obtained with $a=0.05$ in the series with equal thicknesses and $a=0.04$ in the series with $t_{Ni}=3t_{Fe}$ is not as good as that for the resistivity. This observation points to a possible contribution from the interface which could be included in the calculation, for instance by considering for T a dependence on the angle between the electron velocity and the direction of the magnetization.

IV. CONCLUSION

Low-angle x-ray reflectivity indicates that the sputtered Ni/Fe multilayers have good structural properties, with low roughness and an interface mixing of approximately 2 ML. The magnetization is well described by a simple average of the magnetizations of pure nickel and iron thin films; the remanence and coercivity are reduced from those of the bulk materials, due possibly to the finite width of the interface region. The high permeability of these multilayers leads to an enhanced sensitivity of the magnetoresistance to small field changes (0.1%/Oe), comparable to that found in high sensitivity Ni/Co multilayers.[2] Furthermore, the analysis of the thickness dependence of the resistivity and AMR, based upon a semiclassical model, reveals that the increase in resistivity at low thicknesses and the variation in magnetoresistance cannot be explained without an interface contribution.

Studies of Fe/Cr multilayer and trilayer films

E. M. Ho, A. C. Daykin, and A. K. Petford-Long
Department of Materials, University of Oxford, Parks Road, Oxford, OX1 3PH, United Kingdom

Series of sputter-deposited $Fe_{3\ nm}/Cr_x$ multilayer and Fe/Cr/Fe trilayer films have been analyzed. The small magnetoresistance exhibited by the multilayer films is attributed to very rough interfaces and poor Cr layer quality. The hysteresis loop data show the interlayer exchange coupling to be predominantly antiferromagnetic. *In situ* magnetizing of the trilayer films in a Lorentz TEM showed that for a 1.2 nm thick Cr layer the moments of the Fe layers lie approximately parallel at remanence rotating to antiparallel only when the field is increased. The magnetic moments in an $Fe_{12\ nm}/Cr_{0.6\ nm}/Fe_{12\ nm}$ trilayer film were found to be parallel aligned under an applied field whereas the hysteresis loop for the multilayer films with the same Cr thickness suggest the existence of antiferromagnetic interlayer exchange coupling. © *1996 American Institute of Physics.* [S0021-8979(96)24808-0]

I. INTRODUCTION

Factors affecting the giant magnetoresistance (GMR) effect in multilayer films (MLFs)[1] have been studied by many groups, both experimentally[2–4] and theoretically.[5–8] It has been established that the GMR oscillates as a function of spacer layer thickness,[9] because the interlayer exchange coupling oscillates with thickness from ferromagnetic (FM) to antiferromagnetic (AFM). For small changes in the spacer layer thickness the interlayer exchange coupling can vary substantially, and as a result interface roughness and microstructure play an important role in determining GMR.

In this work, series of polycrystalline Fe/Cr MLFs and trilayers with a range of Cr layer thicknesses were grown by sputter deposition, and the correlation between the interlayer exchange coupling, magnetoresistance (MR), and microstructure was studied.

II. EXPERIMENTAL TECHNIQUES

The Fe/Cr layered films were deposited on native-oxide-coated Si(100) wafers using dc (for Fe) and rf (for Cr) magnetron sputter deposition. The base pressure was better than 10^{-5} mbar and the argon pressure was 3×10^{-3} mbar. MR measurements were made using the four-point probe method and the hysteresis loops were obtained using an alternating gradient force magnetometer (AGFM) at Bangor University.

A modified JEOL 4000EX transmission electron microscope (TEM) was used to study the magnetic domain structures of the trilayer films in applied fields up to 400 Oe. The large camera length mode of Lorentz microscopy[10] was used. This mode allows the central region of the electron diffraction pattern (DP) to be observed at high magnification. For thin films with low magnetization, the Lorentz deflection angle is very small, and cannot be observed by conventional techniques.

The periodicity of the MLFs was studied by low-angle x-ray reflectometry (XRR), and the interface morphology and crystallographic structure of the film by high-resolution electron microscopy (HREM).

III. RESULTS AND DISCUSSION

Figure 1 shows MR curves for three $Fe_{3.0\ nm}/Cr_{x\ nm}$, ($0.5<x<1.0$) MLFs measured with the current in-plane and parallel to the applied field. Both the MR and the saturation field H_s increase with decreasing Cr thickness, due to a change in the coupling strength. The magnitude of the MR varies from 0.4% to 1.6%, which is much lower than expected. The hysteresis loops in Fig. 2 for the same films, however, show the presence of a high degree of AFM interlayer exchange coupling, with the characteristic tilting of the curve indicating magnetization rotation rather than domain wall motion. At remanence some of the magnetic moments from the adjacent Fe layers are aligned approximately parallel. They may be pinned in this orientation by microstructural features.

The width of the Bragg peaks visible in the XRR traces (Fig. 3) indicate the presence of some interfacial roughness. For the $(Fe_{3.0\ nm}/Cr_{0.6\ nm})_{55}$ MLF the interference fringes from the top and bottom surfaces of the MLF stack are not visible, suggesting that these surfaces are less well defined than for the other MLFs.

HREM images (Fig. 4) from the $(Fe_{3.0\ nm}/Cr_{0.6\ nm})_{55}$ and $(Fe_{3.0\ nm}/Cr_{0.8\ nm})_{25}$ MLFs confirm both the bilayer spacing and the degree of roughness suggested by the XRR data. In both films the interfaces appear jagged with uneven Cr layer thickness, which is expected to result in nonuniform exchange coupling of the magnetic layers. The MLFs with $x=0.6$ nm show particularly rough interfaces, and the layers

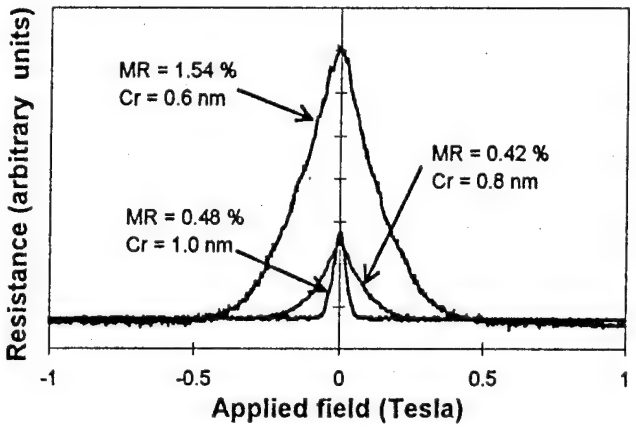

FIG. 1. MR curves for three $Fe_{3.0\ nm}/Cr_{x\ nm}$, ($0.5<x<1.0$) MLFs.

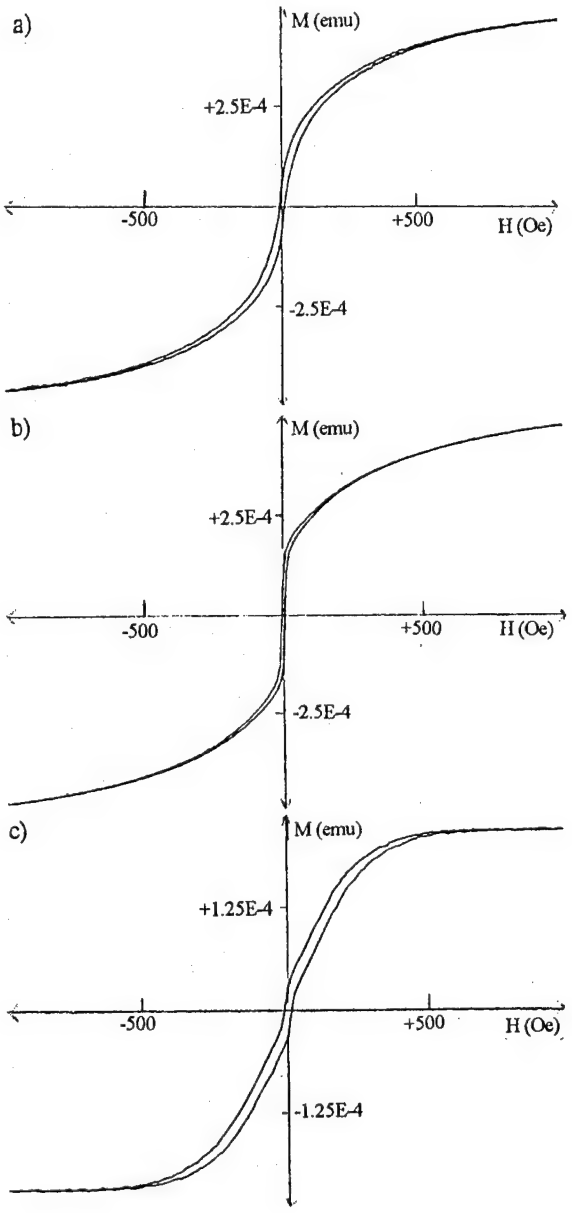

FIG. 2. Hysteresis loops for (a) $(Fe_{3.0\ nm}/Cr_{0.6\ nm})_{55}$ MLFs, (b) $(Fe_{3.0\ nm}/Cr_{0.8\ nm})_{25}$ MLFs, (c) $(Fe_{3.0\ nm}/Cr_{1.0\ nm})_{20}$ MLFs. H is the in-plane applied field and M is the magnetic moments.

appear discontinuous, suggesting that the sputtering conditions used will not allow the growth of continuous Cr layers this thin. In all the MLFs the Cr and Fe layers have a *bcc* structure with strong [100] texture in the growth direction.

The XRR and HREM data suggest that the small MR values obtained may be due to poor layer quality. This will lead to high interfacial scattering which increases the spin independent resistivity of the MLFs. The different layer thicknesses observed suggest that there may be nonuniform coupling throughout the MLF stack.

The trilayer films were chosen for Lorentz microscopy analysis because they contain only two magnetic layers and the domain contrast observed is thus easier to interpret. *In situ* TEM magnetizing experiments were performed on trilayers containing Fe layers of nominal thickness 12 nm

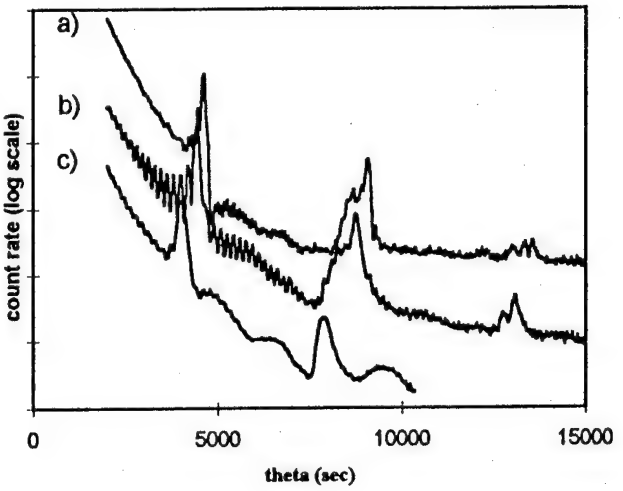

FIG. 3. XRR data for (a) $(Fe_{3.0\ nm}/Cr_{0.6\ nm})_{55}$ MLFs, (b) $(Fe_{3.0\ nm}/Cr_{0.8\ nm})_{25}$, (c) $(Fe_{3.0\ nm}/Cr_{1.0\ nm})_{20}$.

and Cr layers of nominal thickness 1.2 or 0.6 nm. The films were demagnetized *in situ* prior to analysis, and the changes in magnetic structure were monitored around part of the hysteresis cycle starting at remanence. The Lorentz force causes the beam to be deflected if the magnetic moments of the two Fe layers are aligned nearly parallel, whereas the beam is undeflected when the moments of the two Fe layers are aligned antiparallel.

Figure 5 shows an example of an $Fe_{12\ nm}/Cr_{0.6\ nm}/Fe_{12\ nm}$ trilayer which was shown to be FM coupled by *in situ* magnetizing. The magnetic moments in the Fe layers are aligned approximately parallel, and the DP shows a single deflected arc. The presence of an extended arc, as opposed to a sharp spot [Fig. 5(b)] indicates the presence of magnetization ripple, which can be seen in the associated Fresnel mode Lorentz image [Fig. 5(a)]. The saturation field was found to be approximately 55 G. Hysteresis loops from MLFs with a similar Cr layer thickness showed that some AFM interlayer exchange coupling is possible with this thickness of Cr (Fig.

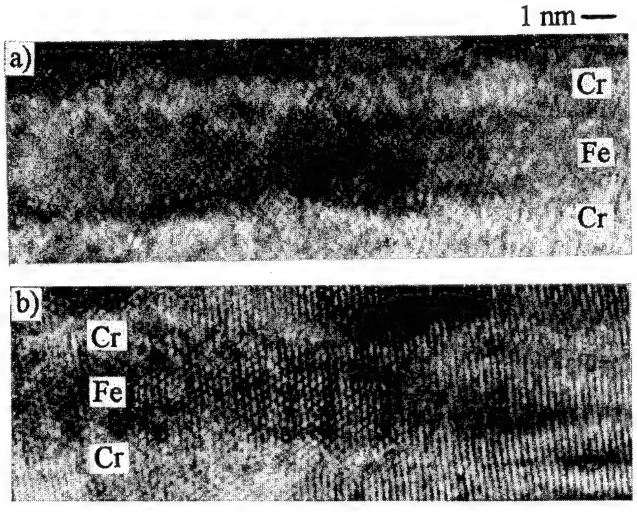

FIG. 4. HREM images of (a) $(Fe_{3.0\ nm}/Cr_{0.8\ nm})_{25}$, (b) $(Fe_{3.0\ nm}/Cr_{0.6\ nm})_{55}$.

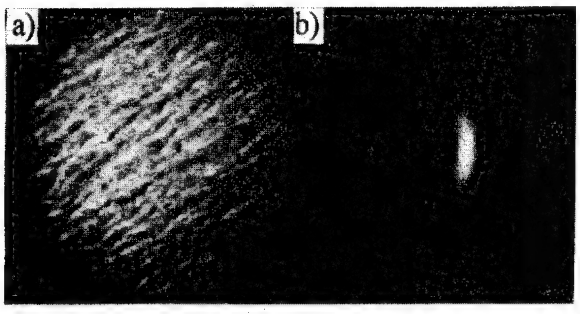

FIG. 5. (a) Fresnel image and (b) DP of an $Fe_{12\ nm}/Cr_{0.6\ nm}/Fe_{12\ nm}$ trilayer film, magnetized at 7.6 G from remanence.

2). The reason why any antiparallel aligned magnetic moments are absent in the trilayers may be that its microstructure affects the interlayer exchange coupling, suggesting the possibility that even with a suitable Cr thickness in a MLF stack some of the magnetic moments can be aligned parallel.

Figure 6 shows a series of DPs and Fresnel Lorentz images of an $Fe_{12\ nm}/Cr_{1.2\ nm}/Fe_{12\ nm}$ film taken during *in situ* magnetizing. At remanence and under a very small applied field most of the magnetic moments are aligned parallel [Fig. 6(a)]. The associated DP shows only a diffuse arc [Fig. 6(b)]. As the applied field increases the magnetic moments begin to align antiparallel, as seen from the changes in the Fresnel image [Fig. 6(c)] and the increase in intensity of the undeflected spot [Fig. 6(d)], until at a field of approximately 72 G

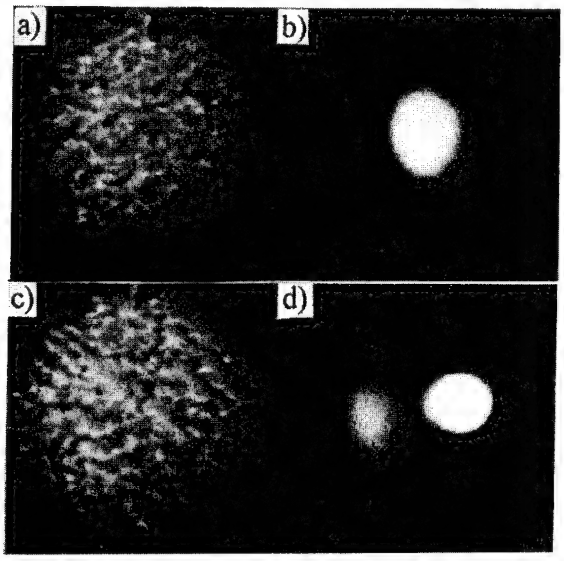

FIG. 6. (a) Fresnel image and (b) DP of an $Fe_{12\ nm}/Cr_{1.2\ nm}/Fe_{12\ nm}$ trilayer film magnetized at 4.2 G. (c) Fresnel image and (d) DP of the same film when magnetized at 23.6 G.

almost all the moments are aligned antiparallel. As the field increases further towards saturation all the magnetic moments align in the direction of the applied field. We believe this to occur because although the coupling is AFM, microstructural features pin the moments in Fe layers in a parallel alignment in zero field. Only on increasing the field slightly is enough energy supplied to allow the moments to relax into an antiparallel state.

XRR data for the two trilayer films shown in Figs. 5 and 6 confirm the nominal layer thicknesses. The FM coupling observed in the $Fe_{12\ nm}/Cr_{0.6\ nm}/Fe_{12\ nm}$ film may be due to the fact that the Cr layer is too thin to be continuous, so that the Fe layers are in direct contact, with no opportunity for their magnetic moments to be aligned antiparallel.

IV. CONCLUSIONS

The GMR effect was observed in sputtered Fe/Cr MLFs, although the value is considerably lower than expected. This is attributed to poor layer quality and microstructural imperfections as shown by HREM and XRR data. The hysteresis loops show the presence of AFM interlayer exchange coupling in all MLFs, whereas *in situ* magnetizing experiment shows that even for trilayers which have magnetic moments aligned antiparallel under an applied field, the moments are mostly parallel aligned at remanence. In addition even with a suitable Cr layer thickness, the interlayer exchange coupling may not be AFM, as the coupling is affected by the microstructure presence of AFM coupling and low GMR in the MLFs shows the important contribution of microstructure, and further analysis of the trilayer films will be used to assess the relative contributions of interfacial quality and AFM coupling.

We have used polarized neutron reflection to determine the layer-dependent spin orientations in an antiferromagnetically coupled 100 Å Cr/50 Å Fe/15 Å Cr/50 Å Fe/Si sandwich structure prepared by sputtering. At low field, the net Fe layer magnetic moments align in an asymmetric canted orientation with a near zero total magnetic moment for the sample. At high fields, a canted state, nearly symmetric with respect to the applied field direction is observed and the magnetization in each layer does not reach the bulk saturation value until the layers are ferromagnetically aligned. The behavior is discussed in the context of current theories of exchange coupling. © *1996 American Institute of Physics.* [S0021-8979(96)24908-6]

Exchange coupling in ultrathin transition metal sandwich structures such as Fe/Cr/Fe has been intensively studied, in part because of the giant magnetoresistance (GMR) behavior which can result.[1–4] In addition to the Heisenberg-like bilinear coupling, an additional biquadratic coupling mechanism, favoring a 90° spin alignment has also been found in several epitaxial systems.[5,6] Theoretical models of biquadratic coupling distinguish between an intrinsic mechanism due to the electronic properties of the perfect structure[7–9] and extrinsic mechanisms which predict a strong dependence on the details of the interface morphology and film structure.[10–12] Neutron scattering studies of biquadratic coupling have been previously performed on both polycrystalline FeNi/Ag[13] and Fe/Cr[14] multilayers. Polarized neutron reflection provides an appropriate tool for probing the spin orientation in polycrystalline single trilayers.

We present in this article the results of a detailed polarized neutron reflection (PNR) study of a polycrystalline Fe/Cr/Fe single-sandwich structure with AF coupling.[15] In an earlier study,[16] we were able to show that the spin orientation for such structures occurring at very low field departed significantly from the purely antiparallel structure expected for pure bilinear coupling. In this article the departure from the antiparallel state is quantified. The 100 Å Cr/50 Å Fe/15 Å Cr/50 Å Fe/Si sandwich structures were prepared by sputtering and the field-dependent magnetoresistance behavior investigated as reported previously.[15] X-ray diffraction studies confirm the polycrystalline structure with a preferred (110) texture. Magnetization measurements obtained using a vibrating sample magnetometer (VSM) indicate the presence of antiferromagnetic coupling with saturation and coercive fields of 1.7 and 0.043 kOe, respectively (solid lines, inset of Fig. 1). The saturation value of the moment agrees with that calculated from the bulk magnetization. Measurements made as a function of the in-plane orientation of the applied field confirm the absence of any significant magnetic anisotropy, as expected for such polycrystalline samples.

PNR measurements[17] were made at 300 K with the sample magnetized in-plane and the total specular reflectivity $R^{\pm}$ was determined as a function of perpendicular wave vector q for incident neutron spin parallel (+) and antiparallel (−) to the applied field direction (z axis). The measurements were made at fixed orientation using the CRISP time of flight reflectometer[17] at the ISIS facility in the UK Rutherford Laboratory. As the field is reduced the magnetic moments of the layers move away from the z axis. Both + and − reflectivities are then dependent upon both of the in-plane compo-

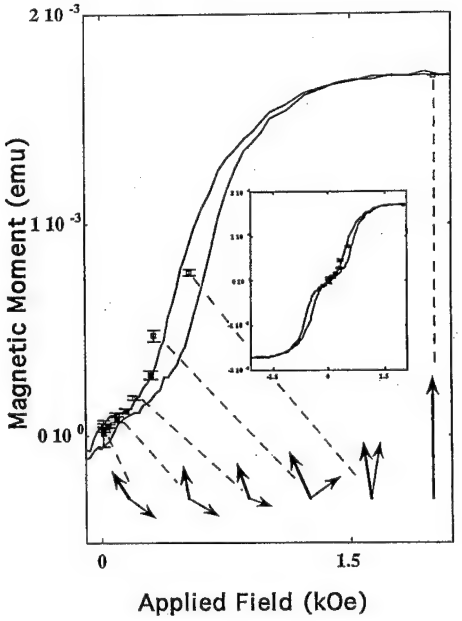

FIG. 1. Magnetization measurements for the positive part of the $M-H$ loop (solid line) for the sputtered 100 Å Cr/50 Å Fe/15 Å Cr/50 Å Fe/Si sample obtained by VSM. The inset shows the full magnetization loop. The net magnetic moment parallel to the applied field deduced from the PNR fits are shown for measurements made upon reducing the applied field from the positive saturation value (open squares) and upon increasing the applied field from the negative saturation value (solid squares). The spin configurations (magnitudes and directions) are drawn to scale as deduced from the coherent multidomain model. The thicker arrow represents the magnetization of the upper Fe layer. The applied field is vertical (z axis).

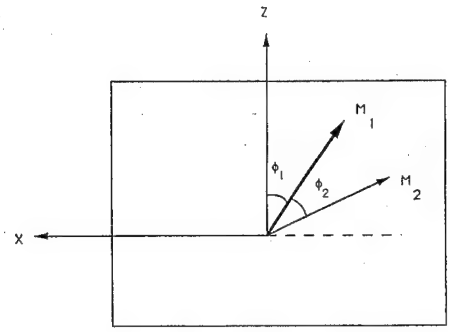

FIG. 2. The sample geometry for a multilayer sample with nonaligned in-plane magnetizations. The first layer magnetization vector $\mathbf{M}_1$ (thick arrow) and the second Fe layer magnetization vector $\mathbf{M}_2$ are constrained to the film plane. The angle ϕ_1 refers to the orientation of $\mathbf{M}_1$ with respect to the applied field direction (vertical z axis) and the angle ϕ_2 defines the angular separation of $\mathbf{M}_1$ and $\mathbf{M}_2$ (narrower arrow), with positive angle corresponding to the anticlockwise sense.

nents of the magnetization vector as described by a reflectivity matrix.[18] A similar description has been given by Felcher *et al.*[19] The magnetic configuration of the sample is shown schematically in Fig. 2. An appropriate spatial averaging procedure is also required since beneath the saturation field magnetic domains can develop.[5] If the domains were larger than the coherence length, then each domain would contribute incoherently to the reflected intensity. The coherence length projected in plane is estimated to be about 100 μm at grazing incidence[17] while Kerr microscopy studies have revealed the existence of an irregular patch domain structure on the scale of a few microns at zero applied field for a trilayer structure with a Cr thickness in the vicinity of the first antiferromagnetic peak (i.e., close to the Cr thickness of our samples) suggesting that coherent averaging applies in our experiment. In a first approximation the net magnetization in each layer then corresponds to the spatial average over the magnetizations of each domain within the coherence area.

The spin asymmetry $S=(R^+-R^-)/(R^-+R^+)$ for $H_a=2$ kOe is consistent with the values calculated for parallel alignment of the two Fe layer moments along the applied field direction.[20] This measurement serves as a check on the experimentally determined layer thicknesses and also on the size of the Fe layer magnetizations which are found to correspond to the bulk value within experimental error. In Fig. 3 we show the spin asymmetry observed evolving as the applied field is reduced from the positive saturation value. The ferromagnetic alignment induces a pronounced peak in the asymmetry at a value of wave vector close to $2.9q_c$ (where q_c is the critical wave vector for the Si substrate). As the applied field is reduced the peak asymmetry at low wave vector diminishes, indicating the expected reduction in the degree of ferromagnetic alignment between the layers, and a second peak close to $6q_c$ increases, as expected from simulations of the spin asymmetry for antiferromagnetic ordering. This peak is related to the antiferromagnetic Bragg diffraction peak that occurs in superlattices,[21,22] although refraction and spin orientation effects must be included in order to accurately fit the position and magnitude of the peak.[18]

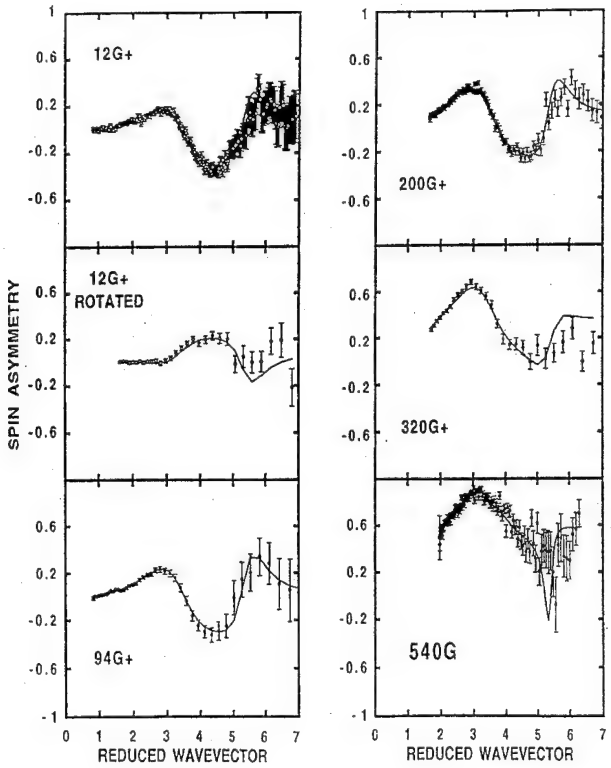

FIG. 3. The spin asymmetry observed for the 100 Å Cr/50 Å Fe/15 Å Cr/50 Å Fe/Si sputtered sandwich structure and the fits (solid lines) predicted by the coherent multidomain model as the applied field is reduced from the positive saturation value to the field strengths indicated. The fit parameters are given in Table I and the resulting spin orientations are shown in Fig. 1.

In fitting the data in the coherent case we relax the requirement that the average magnetization vectors of each layer has the full saturation value $|M_s|$ (corresponding to a single-domain state) and allow both the orientation and size of the magnetization vector in each layer to be determined by the result of a least-squares fit to the asymmetry data. The $S(q)$ curve is computed with the size and orientation of the magnetization vector in each layer treated as independently variable parameters until a close fit (solid line in Fig. 3) is found using a least-squares minimization procedure. This method is found to fit the data very well for the appropriate values of the magnetization vector (magnitude and orientation) in each layer, in contrast to the incoherent averaging method for which no fits could be obtained. The results are summarized in Table I and the resulting spin configurations are shown in Fig. 1. For each configuration shown an alternative symmetry related configuration is also possible corresponding to that obtained by reflecting about the applied field direction. The bold arrow refers to the magnetic moment of the top layer and the thin arrow refers to that of the bottom layer. The resulting component of the magnetization along the applied field ($M_{\|}$ in Table I) fitted using the above procedure is consistent with the magnetometry data on these samples, as shown in Fig. 1. We also find that the angular separation of the magnetic moment vectors is almost exactly preserved under physical rotation of the sample in low-field applied fields (see Table 1 and Fig. 1). This serves as a useful check on our analysis. We see that upon reducing the applied

TABLE I. The result of a least-squares fit to the set of field-dependent spin asymmetry data. The 1st column gives the applied field strength for positive values upon reducing the field from the positive saturation value. The measurement denoted (R) indicates that the sample has been rotated by 90° with respect to the applied field. The angles ϕ_1, ϕ_2 denote the angular position of the top layer magnetization with respect to the applied field and the angular separation of the layer magnetizations. The 4th and 5th columns show the magnitudes of the top and bottom Fe layer moments. The net components of the magnetization parallel and perpendicular to the applied field $M_{\parallel}$ and M_{per} are shown in the final two columns.

H (Oe)	ϕ_1	ϕ_2	M_1/M_s	M_2/M_s	$M_{\parallel}/M_s$	M_{per}/M_s

field from the saturation value, the formation of magnetic domains is inferred (i.e., M_1, M_2 decreases) with, after initial canting away from the applied field direction, the lower Fe layer undergoing a rotation process to attain an overall canted, near AF configuration at low applied fields. Each layer has ~25%–30% of its full saturation magnetization at low fields. We note that from Table I the total magnetic moment of the sample perpendicular to the applied field $|M_{\text{per}}|$ is always zero, within experimental error. This is consistent with the physical requirement that for stability there be no net torque on the layers arising from the applied field since the magnetic anisotropy in the sample is negligible. The magnetization reversal process is clearly inequivalent in the two Fe layers, resulting at low field in an asymmetric magnetic orientation with respect to the applied field direction. This inequivalence may result from the inequivalent interfaces of the two Fe layers (the bottom layer is directly deposited on Si).

The canting observed at low field could suggest that in addition to bilinear coupling favoring antiparallel alignment, biquadratic coupling comparable in strength is also present, since in the absence of anisotropy this configuration would be otherwise unstable. In the fluctuation model[10] biquadratic coupling is expected to occur only for sufficiently large terrace widths and appropriate roughness values. For sputtered structures very sharp interfaces can be achieved on the macroscopic scale but the correlation length is expected to be reduced on a nm scale in comparison with epitaxial structures. On the basis of this model, weaker biquadratic coupling would be expected in sputtered samples in contrast with our findings. Other extrinsic models invoking dipolar coupling[12] and the presence of "loose" spins[11] in the spacer layer are unlikely to result in the large biquadratic coupling strength we observe. It is also possible that the antiferromagnetism of the Cr layer is important in this context. Alternatively, differences between the Fe layers in net moment, pinning sites or local anisotropy variations together with bilinear coupling could explain the canting without invoking biquadratic coupling. This view is supported by the sample rotation results.

In conclusion, the results demonstrate the importance of determining the layer dependent spin orientation in exchange coupled structures, as is possible using PNR.

The interplay between superconductivity (SC) and ferromagnetism (FM) in dilute magnetic alloys and intermetallic compounds attracted considerable attention during the last 30 years. Usually the ferromagnetic state is more stable and therefore tends to suppress SC. On the other hand, the magnetic state can be changed due to a modification of the RKKY interaction in the SC state. Mutual influence of SC and FM may acquire new peculiarities in such artificial systems as FM/SC multilayers. This work is focused on the study of Fe/Nb multilayered system, prepared on $Al_2O_3(11\bar{2}0)$ substrates by rf-sputtering and by molecular beam epitaxy (MBE) techniques. The Nb thickness t_{Nb} was varied from 150 to 500 Å and the Fe thickness t_{Fe} was changed from 5 to 100 Å. The sputtered samples were highly layered with sharp interfaces as revealed by x-ray reflectivity and were textured in the [110] direction. The epitaxial MBE samples showed (110) growth of Nb and Fe with a coherence lengths comprising the total film thickness. Surface and interface roughnesses were very small. The dependence of the ferromagnetic resonance (FMR) spectra parameters on the direction of the dc magnetic field rotating in the plane of the samples show sixfold anisotropic behavior indicating the well known three-domain in-plane structure of Fe layers on sapphire substrates. FMR and SQUID measurements showed that FM of Fe layers survived down to $t_{Fe} = 10$ Å. The out-of-plane FMR measurements also showed that the easy axis of magnetization lies in the plane of the samples down to this thickness. The superconducting transition temperature T_c was determined by measurements of the electrical resistivity and by SQUID measurements. It was established that there is a critical thickness of the Fe layer t_{Fe}^{crit} above which SC was not detected for temperatures down to 1.5 K. This value was dependent on t_{Nb}. Thus, for example, it was found that for $t_{Nb} = 300$ Å the value of $t_{Fe}^{crit} = 30$ Å and for $t_{Nb} = 350$ Å—$t_{Fe}^{crit} = 50$ Å. For constant t_{Fe} with increasing t_{Nb} up to a certain thickness, SC was not detected; then T_c started to increase, and, finally, it approached the constant value of the order of 6 K above a certain t_{Nb} which depended on t_{Fe}. The critical magnetic field H_{C2} obtained from the resistivity measurements, strongly decreased with increasing t_{Fe} or decreasing t_{Nb}. The temperature dependences of H_{C2} were typical for two-dimensional superconductors. For the interpretation of the data obtained, various theories were employed. [S0021-8979(96)44708-8]

A comparison of structure and magnetoresistance in Fe/(Ag–Cu) films (abstract)

S. J. Kwon and S. J. Choi
Department of Materials Science and Engineering, POSTECH, Pohang, 790-784, Korea

Films of 12 Fe/(Ag–Cu) bilayers were prepared to have either granular or multilayer structures on glass substrates with a 50 Å Cu buffer layer. A magnetic Fe layer of 15 Å was deposited by e-beam evaporation, and a nonmagnetic Ag–Cu layer of 20 Å by thermal coevaporation with various Ag/Cu ratio. As the nonmagnetic layer composition changed from Ag to Cu, roughness of the film surface varied from more than 100 Å to less than 10 Å, measured with atomic force microscopy. Regularity of multilayer structure was evident in the Fe/Cu film from a superlattice peak at around 2theta=2.5 deg by Cu $K\alpha$ x-ray diffraction. The peak weakened as the Ag content increased in the nonmagnetic layer, and completely disappeared at Ag/Cu>1, which indicated that granular structure became dominant. Pendelloesung peaks at 2theta=1 to 2 deg had a similar composition dependency. The structural change was confirmed with cross-sectional transmission microscopy, too. The deposited structure is explained in terms of surface tension and wettability of each element. Increasing Cu content decreases the surface tension and increases the wettability of the nonmagnetic layer. Heat treated film structures are explained with identical terms. Change of magnetoresistance is discussed in part by connectivity of the nonmagnetic layer. From the discussion, a reasoning is given to the effect of annealing on the magnetoresistance of the films.

^{59}Co and ^{55}Mn NMR of CoMn alloys and multilayers

T. Thomson and P. C. Riedi
Department of Physics and Astronomy, University of St. Andrews, St. Andrews, Fife KY16 9SS, United Kingdom

Q. Wang and H. Zabe
Ruhr-Universität Bochum, Institut für Experimental Physik IV, 44780 Bochum, Germany

^{59}Co and ^{55}Mn NMR measurements have been made on a range of CoMn materials: dilute powder alloy, thin-film alloys, and multilayers. Our results suggest that in dilute alloys isolated atoms of Mn couple both ferro and antiferromagnetically to the Co host, with the latter producing a reduction in the magnitude of the Co hyperfine field of 17%. This reduction of hyperfine field appears similar for both the fcc and hcp phases of Co. NMR on Co/Mn sputtered multilayers shows large changes in the hyperfine field distribution between a film with Mn layers of 10 Å and Mn layers of 30 Å.
 [S0021-8979(96)35608-2]

I. INTRODUCTION

Mn in its elemental state has both complex structural and magnetic properties.[1–3] A total of four-crystal phases are known, dependent on the temperature, with both antiferromagnetic (AFM) and ferromagnetic (FM) alignment possible for the higher-temperature fcc and bcc phases. The various phases of Mn exhibit a wide range of atomic volumes. Multilayer materials containing Mn are therefore likely to show interesting/novel properties, particularly if the high-temperature phases can be stabilized at room temperature. Hence the CoMn system is currently of interest due to the increasing ease with which high quality multilayer materials can be grown by sputtering or molecular beam epitaxy. These growth techniques offer the possibility of stabilizing exotic crystal phases, for example, the stabilisation of bcc Co in Fe/Co multilayers.[4] CoMn also presents some theoretical challenges as recent work[5] on dilute impurities in $3d$ transition metals continues to be inconclusive regarding the orientation of Mn with respect to Co.

In this work we report NMR measurements of thin-film CoMn alloys, Co/Mn multilayers produced by sputtering, and dilute powdered CoMn alloys. The basic problem in dilute alloys is the magnitude of the moment on the Mn atoms and whether such a moment aligns parallel or antiparallel to the Co host. Theoretical work[5] indicates that the change in the Co hyperfine field, and therefore the frequency, should either be quite small (a few percent) for FM alignment of Mn with Co or rather large (~20%) for AFM alignment of an impurity Mn atom in a Co host. These two magnetic orientations are calculated to have only a small difference in energy.[5] In multilayer materials the situation is further complicated by interfacial effects such as the presence of dead layers of Co immediately adjacent to the Mn and the exact structure of the Co fcc, fct, hcp.

II. EXPERIMENT

The powdered alloy sample was prepared by argon-arc melting Co and Mn. The ingot was filed to a powder and sieved with a 300 mesh sieve to give a $Co_{0.99}Mn_{0.01}$ at. % fine powder. The thin alloy films and the multilayer films were prepared at Bochum by rf sputtering. Base pressures in the sputtering chamber were in the range $1–3\times10^{-7}$ mbar. Sputtering took place at a pressure of 5×10^{-3} mbar in an atmosphere of 99.99% pure Ar gas. The substrates were chemically cleaned in an acetone/ethanol mixture prior to insertion in the chamber, they were then annealed at 500 °C under high vacuum and plasma etched immediately before deposition. Thicknesses were measured *in situ* by a quartz monitor and postdeposition by x-ray reflectivity and x-ray fluorescence.

A total of four thin films were investigated using NMR. Two alloy films with $Co_{0.98}Mn_{0.02}$ were produced simultaneously by cosputtering Mn and Co onto (a) a glass and (b) a MgO substrate. The growth temperature was maintained at 200 °C and the growth rate was 0.12 Å/s. The thickness of the films as measured by the x-ray techniques was 228 Å. Both films were capped with Au=40 Å to inhibit oxidation.

The two multilayer films studied were produced by rotating the MgO(001) substrates between the Co and Mn targets. The growth temperature was 100 °C, and a sputtering rate of 0.1 Å/s was maintained for both Co and Mn. The films were protected by a capping layer of Co=30 Å to inhibit oxidation. The structure of the two multilayers was MgO/[Co 30 Å/Mn 10 Å]$_{\times10}$/Co(30 Å) and MgO/[Co 30 Å/Mn 30 Å]$_{\times10}$/Co(30 Å). Both these films were oriented with the [001] direction normal to the plane of the film.

The NMR spectra were measured in a coherently detected, swept frequency spin echo spectrometer[6,7] using a tuned circuit matched to the 50 Ω line. At each frequency the echo was integrated and measured at phase angles φ and $\varphi+\pi/2$. The phase insensitive quantity $S=\sqrt{S_{\varphi}^2+S_{\varphi+\pi/2}^2}$ was then determined and plotted against frequency. In order to accommodate the wide range of frequencies and large differences in the amplitude some changes were made to the spectrometer configuration, in particular two different coils were used. The first coil covered the frequency range 120–280 MHz while the second covered the range 235–400 MHz. The large overlap region ensured good matching between the two parts of the spectrum. A variable gain receiver was used to extract the maximum signal and again a large overlap region ensured good matching between the various parts of the spectrum. Measurements were taken at two temperatures, $T=4.2$ K and $T=1.3$ K. The lower temperature was used for

 0021-8979/96/79(8)/6300/3/$10.00

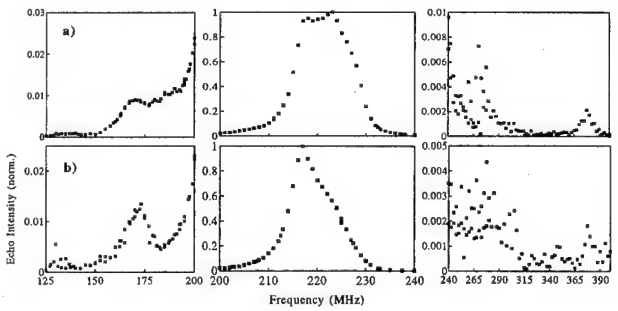

FIG. 1. ^{59}Co and ^{55}Mn NMR spectra of $Co_{0.98}Mn_{0.02}$, 228-Å-thick, sputtered alloy films at $T=4.2$ K. The echo amplitude is normalized to the top of the Co fcc line (~217 MHz). No corrections for frequency or T_2 have been made. The different scales on the x and y axis are used to show the regions of interest. The films were sputtered simultaneously on to: (a) a glass substrate and (b) a MgO substrate.

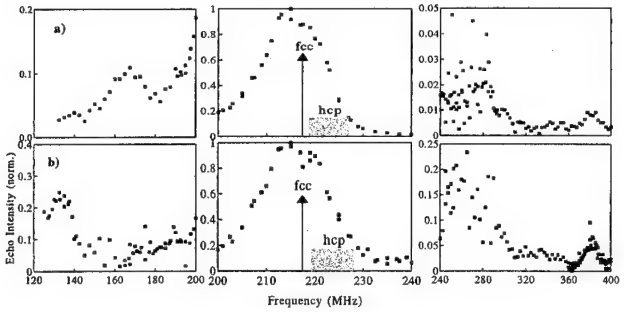

FIG. 2. ^{59}Co and ^{55}Mn NMR spectra of Co/Mn multilayers at $T=4.2$ K. The echo amplitude is normalised to the top of the Co fcc line (~217 MHz), no corrections for frequency or T_2 have been made. The positions of the free Co fcc and hcp lines at $T=4.2$ K are marked for guidance. The composition of the multilayers are: (a) [Co 30 Å/Mn 10 Å]$_{\times 10}$ and (b) [Co 30 Å/Mn 30 Å]$_{\times 10}$.

the parts of the spectrum with the weakest signal, as the signal-to-noise ratio scales with $1/T$. No corrections were made for either the frequency or relaxation time (T_2) dependence of the spectra as these corrections do not alter the positions of the NMR lines and accurate comparison of the relative line intensities was not required for the work undertaken here.

III. RESULTS AND DISCUSSION

The powdered $Co_{0.99}Mn_{0.01}$ at. % alloy was measured from 70 to 400 MHz. Co was found to exist in both the fcc and hcp phases as demonstrated by a sharp ^{59}Co resonance line at 217.4 MHz and a broader line extending from 220 to 228 MHz.[8–10] A feature of all the CoMn materials studied, powdered alloys, thin-film alloys, and multilayers was that a significant fraction of the Co was in the hcp phase. A number of sharp, well-defined satellite lines were also identified between 197 and 212 MHz. These satellite lines must either be associated with grain boundaries or with Co atoms with 11 nearest-neighbor (N.N.) Co and 1×Mn N.N. FM aligned to the Co. As the moment on Mn is similar to that of Co, FM alignment of a Mn impurity produces only a small change in hyperfine field. A ^{55}Mn resonance line was measured at 377.5 MHz, which earlier experimental work[11] ascribes to a single Mn impurity atom FM coupled to 12 surrounding Co atoms.

A line at ~180 MHz was found in all the spectra measured and tentatively identified with the atomic environment where Co is surrounded by 11×Co and 1×Mn N.N. AFM aligned to the Co. This identification is in good agreement with the predictions of Stepanyuk *et al.*[5] for the changes in the Co hyperfine field in the presence of $3d$ impurity atoms. Two much weaker, but still well defined lines were observed at 131 and 114 MHz. The origin of these lines is at present unclear, although the Mn hyperfine field for Mn AFM aligned to 12×Co N.N. is calculated to be about 100 MHz.[5] A paper containing a more comprehensive study of CoMn alloys is currently in preparation.[12]

Figure 1 shows spectra from the two thin-film alloys grown on glass and MgO. The spectra are split into three parts to allow for the difference in amplitude of the various lines. The first point to note is that the film grown on MgO has a significantly smaller fraction of Co in the hcp phase (220–228 MHz) than the film grown on glass. Both alloy films show a clear satellite line at 171 MHz. This line is probably associated with the atomic environment of 11×Co, and 1×Mn AFM aligned N.N., although the frequency of this environment is rather less than that found in the powdered sample (180 MHz). This difference in frequency could be explained in terms of strain, although the reduction in frequency of 9 MHz is rather large compared to the reduction of 0.4 MHz (glass) and 0.8 MHz (MgO) in the Co fcc line from the free-powder value of 217.4 MHz. However as the Mn concentration was double that of the powder it is also possible that Mn in the second nearest-neighbor shell affects the hyperfine field. The Co signal from an environment of 11×Co and 1×Mn FM coupled to Co is contained in the envelope of the main Co line due to the broadening of this line associated with sputtered thin films. Closer inspection of the 180 MHz satellite line reveals that the width and shape of the line are somewhat different between the two samples and that the sample with more hcp Co has a broader line. This indicates that a Mn impurity produces a similar effect in both fcc and hcp Co. A ^{55}Mn line at 377.5 MHz from FM coupled Mn is observed in both spectra although the signal is quite weak. A rather broad and ill defined peak also appears to exist around 270 MHz, but the interpretation of this feature is unclear.

Figure 2 shows spectra for the two Co/Mn multilayers. The main Co line is similar for both spectra and indicates that a fraction of the Co is in the hcp phase for both samples, as shown by the intensity between 220 and 230 MHz. A qualitative inspection of the data suggests a greater fraction of the Co is in the hcp phase for the sample with thicker Mn layers. This is an interesting result as x-ray work on similar materials[13] did not reveal the presence of the hcp phase. It is possible that fct Co could generate a hyperfine field similar to hcp and hence explain this result. The main line in both spectra is shifted to a lower frequency than is expected for a free fcc powder. In Co/Cu multilayers a frequency shift is usually associated with an extensive strain in the plane of the film,[14] although a distortion of the fcc phase to fct might also explain this result, and would be consistent with the x-ray

data. However, it is unlikely that a distortion of the fcc Co lattice to fct could account for both the apparent contribution from hcp Co and the reduction in the frequency of the main peak. We are currently undertaking further work in order to resolve this point.[12]

Ferromagnetic resonance on *e*-beam evaporated Co/Mn grown on Ru(0001)[15,16] showed, that for Mn layers greater than 12 Å, Co was predominately in the hcp phase. In the region outside the main Co line the two spectra are quite dissimilar which is consistent with work[13] which shows that the stability limit of the fcc/fct Mn structure in these multilayers is about 20 Å. Hence the spectrum of Fig. 2(a) for a [Co 30 Å/Mn 10 Å]$_{\times 10}$ multilayer shows only two well-defined satellite lines one at 172 MHz (11×Co and 1×Mn) and one at 377.5 MHz (Mn with 12×Co). The presence of a substantial intensity in the 172 MHz line and a reduced intensity in the 377.5 MHz line indicates that considerable mixing at the interfaces has occurred with a preferred AFM alignment of Mn.

The spectrum in Fig. 2(b) shows a more complicated behavior with a strong line at 131 MHz. A similar, but much weaker, line was observed in the powder alloy. As the Mn layers in this multilayer are thicker than the stability limit for the fcc/fct phase it is reasonable to assume that an increased amount of alloying has taken place, and with the much larger concentration of Mn it is possible that this line is associated with the 10×Co+2×Mn N.N. atomic environment where both Mn are AFM aligned to the Co. However, it is also possible that the previously reported[13] dead Co layer adjacent to Mn could account for this line. Continuing work on powder alloys should resolve this point. The broad, ill-defined feature at ~270 MHz is clearly visible in this spectrum. The ^{55}Mn line at 377.5 MHz has a much greater intensity than in the previous spectrum and this re-enforces the argument that more mixing has occurred in the interfacial region.

IV. CONCLUSIONS

^{59}Co and ^{55}Mn NMR on powder and thin-film CoMn alloys has shown that in the dilute impurity limit (1 or 2 at. %) Mn can exhibit both AFM and FM coupling to its Co nearest neighbors. The AFM alignment of the Mn gives a reduction in the hyperfine field of the N.N. Co atom of 17%. This is in good agreement with the calculations of Stepanyuk *et al.*[5] Thin-film CoMn alloys with different fractions of fcc and hcp Co showed that the substitution of Mn into either of these phases produced a similar reduction in the hyperfine field for this AFM alignment of Mn. In multilayer films the Co hyperfine field associated with both the fcc and hcp phases was observed, although x-ray work on similar samples suggested the absence of hcp Co and the presence of the fct phase. This NMR study confirmed previous work on Co/Mn multilayers which showed that the stability limit for epitaxial growth of Mn on Co is about 20 Å with evidence of substantial interfacial mixing for the [Co 30 Å/Mn 30 Å]$_{\times 10}$ multilayer.

Study of interface structure of Fe/Al multilayers

Ataur R. Chowdhury and Andrea E. Freitag
Physics Department, University of Alaska-Fairbanks, Fairbanks, Alaska 99775-1320

Structural and magnetic ordering of the interfaces determines the physical properties of multilayered structures. Interfaces of Fe/Al multilayers were studied using Mössbauer effect spectroscopy. The samples were fabricated by dc planar magnetron sputtering at room temperature on polyester substrates. The observed spectra indicate that the interfaces have a common structural composition and for thin Fe layers, the whole Fe layer forms mixed phases at the interface. For larger Fe layer thickness, the interface is formed using an about 12-Å-thick Fe layer. Besides the hyperfine field component of bcc Fe, six different magnetic components were identified in all samples (with larger Fe layer thickness). The intensities of the components were determined from the area under the absorption peaks of the Mössbauer spectra of the corresponding phases. The average canting angle of the Fe magnetic moments, as obtained from the spectra, indicate parallel magnetic anisotropy for all phases. © *1996 American Institute of Physics.* [S0021-8979(96)35708-9]

I. INTRODUCTION

There has been a great deal of interest for artificially layered structures for their potential use as new magnetic materials. The fundamental magnetic, electronic, and optical properties of these structures are quite different from their bulk counterparts, and over the last decade, it has been shown that these interesting properties are greatly influenced by the interfaces of the multilayers.[1–3] For a better understanding of the fundamental properties of these multilayers, there is a crucial need for comprehensive studies of the interfaces for their local structures using microscopic techniques.

Multilayers of Fe/Al were chosen for the study of multilayer interfaces using Mössbauer effect spectroscopy. Fe/Al has the potential to be used as thin-film magnetic head for recording media, and it has been shown to possess excellent soft magnetic properties required for such use.[4–6] Structural ordering and magnetic properties of Fe/Al multilayers have been studied in the past.[4–13] Interfacial magnetism of Fe/Al multilayers were studied, in most cases, following either ion beam or thermal mixing of the interfaces using Mössbauer effect spectroscopy.[9–13] Depth selective ion implantation of Al into Fe and Fe into Al was also employed to simulate interfaces of Fe/Al multilayers for studies with Mössbauer effect spectroscopy.[14–16] Results of these Mössbauer investigations clearly reveal a wide variety of magnetic interactions at the interfaces that are characteristic of bcc iron, intermetallic, and nonmagnetic phases. This particular project was initiated to study the structural and magnetic properties of Fe/Al multilayers and correlate these properties with the individual layer thicknesses of Fe and Al.

II. EXPERIMENT

The samples with the form of (X Å) Fe/(Y Å) Al were prepared by dc planar magnetron sputtering at room temperature. The substrate was rotated over the Al and Fe sputtering sources with a constant speed to ensure better uniformity of the samples. The base pressure of the chamber was about 10^{-6} Torr and a constant argon pressure of 5 mTorr was maintained during deposition. Individual layer thicknesses were measured with the help of a calibrated quartz crystal thickness monitor. The substrates are polyester films for transmission Mössbauer measurements, and glass slides for x-ray diffraction and other microprobe analysis.

^{57}Fe Mössbauer spectra were obtained with a conventional constant acceleration-type spectrometer. A 25 mCi source of ^{57}Co in rhodium matrix was used, and the velocity was calibrated with a natural Fe foil. Mössbauer spectra of all samples were least-squares fitted with seven sextets.

III. RESULTS AND DISCUSSION

The room-temperature Mössbauer spectra of four Fe/Al multilayers are shown in Fig. 1. Some of the spectra clearly display the "shoulder" features indicating the presence of more than one magnetic interactions, which, in turn, implies more than one site for ^{57}Fe isotopes. Mössbauer spectra of three samples (B,C,D) with the same Al layer thickness look quite different. This may imply that the interfaces of Fe/Al multilayers sensitively depend on the layer thickness of both constituent elements and the degree of mixing at the inter-

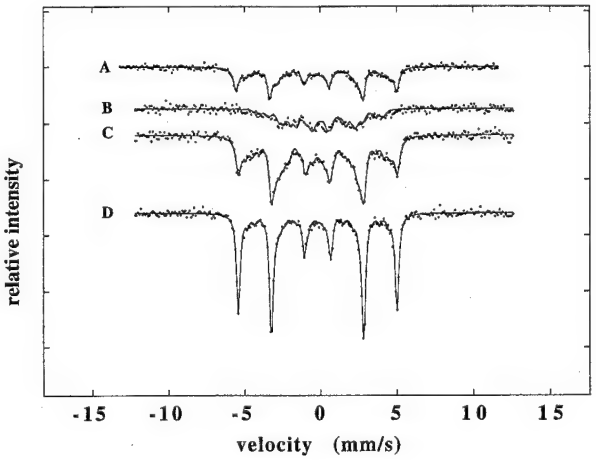

FIG. 1. Room-temperature Mössbauer spectra of Fe/Al multilayer samples: A (19 Å Fe/5 Å Al), B (11 Å Fe/11 Å Al), C (21 Å Fe/11 Å Al), and D (60 Å Fe/11 Å Al).

face. Diffusion of Fe into Al and Al into Fe may lead to formation of stable compounds as well as amorphous phases of Fe-Al alloy. This diffusion process may segregate Fe atoms in Al matrix with fcc symmetry and Al atoms in Fe matrix with bcc symmetry. To identify these different interfacial structures and the extent of the interface, Mössbauer spectra were all fitted with seven sextets corresponding to seven dominant ^{57}Fe sites. Results of these fittings, along with the sample compositions, are provided in Table I. Formation of any Fe clusters in the samples is highly unlikely as none of the spectra show any discernible paramagnetic feature at the center of the spectrum.

As can be seen from Table I, site 1 represents the most dominant Fe phase for samples A, C, and D. Hyperfine field of site 1 of sample D is 329 kG and is typical of bcc Fe, and for samples A and C it is 325 and 321 kG, respectively. This slightly smaller field for site 1 for samples A and C directly scales with the unmixed Fe layer thickness of the respective samples. The size of the interface of the samples studied is about 12 Å, as will be shown later, and hence the thicknesses of unmixed Fe layers for samples A and C are about 7 and 9 Å, respectively. A reduction of hyperfine field compared to bulk bcc Fe is expected for such thicknesses due to the finite size effect. For interpretation of our results, site 1 will be considered as bcc Fe like, and will not be considered as part of the interface. Site 1 is completely absent in sample B, and, therefore, the multilayered structure for this sample is not conserved, and all Fe atoms belong to the interface.

The second sextet, corresponding to site 2, with a hyperfine field of 292 kG is due to stable Fe_3Al phase,[9] and is common for samples A, C, and D. This site is also absent in sample B. The first major site for sample B is the site 3 with a hyperfine field of 252 kG, which is representative of a stable phase of random alloy of the form $Fe_{55}Al_{45}$ with bcc symmetry. Site 3 for samples A, C, D is different from that of sample B, and has an average hyperfine field of 262 kG, which is close to the predicted hyperfine field of a homogeneous Fe-Al alloy having a Fe site with three Al atoms as nearest neighbors.[17] Hyperfine fields of site 4 of all samples are close together with an average field of 226 kG, and this field is close to the predicted hyperfine field of a homogeneous Fe-Al alloy having a Fe site with four Al atoms as nearest neighbors.[17] Although site 4 is small for samples A, C, D; it is quite significant for sample B.

Aside from the four iron-rich phases that were described above, three aluminum-rich phases were also detected. First one of this is the site 5 with an average hyperfine field of 175 kG. This field is close to the predicted hyperfine field of an aluminum-rich Fe-Al alloy having a Fe site with six Al atoms as nearest neighbors.[9] This site is the most dominant site for sample B. Site 5 is very small for all samples, and has an average field of 122 kG. It has been predicted to be the field of a aluminum-rich Fe-Al alloy with Fe site having eight near-neighbor Al with fcc symmetry.[9] Site 7 is quite small for samples A, C, and D, but significant for sample B with 20% of the Fe atoms belonging to this site. The hyperfine field for this weak magnetic site for samples B and D is about 48 kG, which is close to the predicted field of a metastable homogeneous Fe-Al alloy having a Fe site with eleven Al atoms with fcc symmetry as nearest neighbors.[9] The hyperfine field for site 7 for samples A and C is about 30 kG, and the corresponding Fe site is probably very unstable and not easy to predict.

From the above discussion it is quite clear that the interface of Fe/Al multilayers is composed of a few distinctly identifiable stable and metastable phases, and most of these phases are common to all the samples. This fact indicates that the underlying mechanism for the formation and nucleation of the interfaces of the samples under study is the same. The results show that despite increasing Fe layer thickness the interface is formed by roughly the same number of Fe atoms corresponding to a Fe layer thickness of about 12 Å. It is also clear from above discussion that the diffusion of Fe and Al atoms is greatly influenced by the individual layer thicknesses. When the individual Fe layer thickness is greater than the Al layer thickness, diffusion results in mostly Fe-rich phases, whereas for sample B, for which the Fe and Al layer thicknesses are the same, it results in mostly Al-rich phases.

We find it useful to define an average hyperfine field which is the weighted sum of all hyperfine components. The average hyperfine field of all samples, is listed in Table I, and plotted in Fig. 2 as a function of Fe layer thickness. The average hyperfine field of the three samples (B,C,D) with the

same Al layer thickness decreases with Fe layer thickness. The smaller the Fe layer thickness the larger the fraction of the Fe atoms that belong to the interface where they form stable alloy phases with hyperfine fields less than the bcc Fe phase. This decrease of hyperfine field with Fe layer thickness is very similar to what has been observed in homogeneous Fe_xAl_{1-x} alloys.[18] The decrease of the average hyperfine field of sample A is, however, not consistent with the corresponding decrease of that for samples B, C, D. This is a clear indication that the average hyperfine field sensitively depends on the thickness of both Fe and Al layers. The intensity ratios of the Mössbauer lines (roughly 3:4:1) imply that the average direction of magnetization lies in the plane of the sample, as expected.

IV. CONCLUSIONS

Results of our Mössbauer experiment with a limited number of samples show that all the interfaces of Fe/Al multilayers are unique and are composed of distinct stable and metastable phases. Seven such phases were detected and identified. Only two of these phases (site 1 and site 2) were previously detected in a similar sample of Fe/Al multilayer.[15] Results establish that the average thickness of the interface is about 12 Å, and the diffusion of Fe and Al atoms depends on the individual layer thicknesses of both elements. The average hyperfine field of the samples with constant Al layer thickness decreases with Fe layer thickness. The observed Mössbauer line intensities indicate an inplane magnetic anisotropy at room temperature for all samples.

Effect of ion beam mixing on microstructure and magnetic properties of Gd-Co multilayer films

G. Choe[a] and R. M. Walser
I/UCR Center for Magnetics, The University of Texas at Austin, Austin, Texas 78712

This work investigated the effect of ion beam mixing on the magnetic and structural characteristics of Gd-Co multilayer films. Multilayer films with bilayer periods (BP) from 10 to 300 Å were mixed by 150 to 300 keV Ar^+ ion doses of 10^{16} cm^{-2}. The magnetizations of the as-deposited multilayers were dominated by oxidation, and by the asymmetric redistribution of Co atoms. Ion beam mixing eliminated much of these effects, but the degree was strongly dependent on the layer thickness. The small BP films were completely mixed, with amorphous nanoparticles, but the large BP films contained small, microcrystals in an amorphous matrix due to incomplete mixing. The magnetic moment of ion beam mixed films were strongly dependent on the ion beam energy and the layer thickness. © *1996 American Institute of Physics.* [S0021-8979(96)25008-0]

I. INTRODUCTION

Ion beam mixing of layered thin films often results in nonequilibrium amorphous alloys that cannot be obtained by common techniques such as liquid quenching, vapor deposition, and solid state reaction. Ion beam mixing of magnetic multilayers can produce materials with scientifically interesting nonequilibrium structures, and potentially useful magnetic properties.

There has been considerable previous research on ion beam mixing of magnetic multilayers in which the correlation between the microstructure of ion beam mixed films and their magnetic properties has been reported for a wide variety of alloys.[1] In our previous study, ion beam mixed Co-B multilayers were shown to be hetero-amorphous, soft magnetic films, that were ferromagnetic with significantly larger boron concentrations than alloy films.[2] This work investigated the effect of ion beam mixing on the microstructure and magnetic characteristics of Gd-Co multilayers. We report the correlations in the ion induced changes in magnetic properties, and the nanostructural morphological features, as a function of layer thicknesses of the Gd-Co multilayer films, and the ion beam energy.

II. EXPERIMENTS

Multilayered Gd-Co films with bilayer periods ($BP=T_{Gd}+T_{Co}$, $T_{Gd}/T_{Co}\approx 1$) from 10 to 300 Å were deposited by alternately sputtering Gd and Co in a multitarget, rf diode sputtering system. A background pressure of 5×10^{-7} Torr and argon sputter gas pressure of 10 mTorr were used. The ion mixing of ≈800–900-Å-thick multilayer films was carried out in an ion implanter using Ar^+ ions with energies in the range of 150–300 keV, and a dose of 10^{16} ions/cm^2. The projected ranges and deviations calculated from Lindhard, Scharff, and Schiøtt (LSS) range statistics for these beam parameters (Table I) were selected to ensure that the ions were fully stopped in the films. The substrates of the multilayered films were held at liquid nitrogen temperature during ion beam mixing. The changes in the compositional, structural, and magnetic properties of the ion beam mixed Gd-Co multilayer films were characterized, respectively, by AES (Auger electron spectroscopy) depth profiling, x-ray diffraction, TEM (transmission electron microscopy), Lorentz microscopy, and B-H hysteresisgraph.

III. RESULTS AND DISCUSSION

A. As-deposited Gd-Co multilayer films

The compositional modulation of Gd and Co layers in Gd-Co multilayer films was observed as a function of layer thickness. The AES depth profiles of the as-deposited Gd-Co multilayer films in Fig. 1 shows the periodic distributions of Gd and Co atoms, and oxygen peaks in the Gd layers. Due to the higher affinity of Gd for oxygen, the Gd layers are selectively oxidized. An asymmetric distribution of Co atoms was also observed, possibly due to a greater diffusion of Co atoms into the Gd layer, compared to the diffusion of Gd atoms into the Co layer.

Cross-sectional TEM micrographs of the multilayered films showed that the growth of Gd and Co grains was limited to within each atomic layer. The Co grains were columnar and grew perpendicular to the film plane. Since Gd-Co alloys readily form amorphous phases, the polycrystalline grain size of Gd-Co multilayer films was strongly dependent on the layer thickness. The change in the grain size of the various Gd-Co multilayer films was determined from the Debye Sherrer equation[3] using the line broadening of the two principal x-ray peaks for hcp Gd(10.0) and Co(00.2). The measured grain sizes agreed well with those obtained from TEM micrographs. As shown in Fig. 2, in all of the films, the grain sizes of Gd and Co were found to be smaller than the Gd and Co layer thickness, suggesting that their growth was

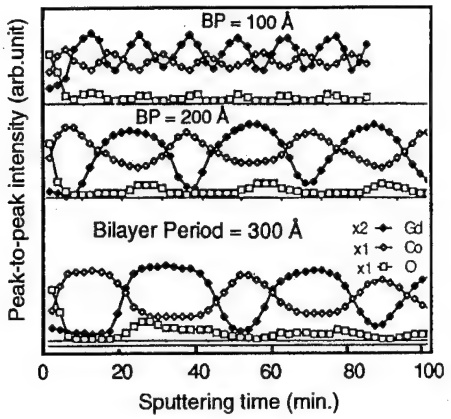

FIG. 1. Auger depth profiles of as-deposited Gd-Co multilayer films as a function of bilayer period.

limited by neighboring different atomic layers. The Co grain growth increased linearly with layer thickness, but the Gd growth increased more slowly, possibly due to the asymmetric diffusion of Co.

The in-plane magnetizations of Gd-Co multilayer films were measured with a thin film hysteresis loop tracer with an applied field of 100 Oe. As shown in Fig. 3, the magnetizations of the Gd-Co multilayer films increased with the BP, and their coercivities were less than 50 Oe. Using their measured total magnetization, we estimated the average magnetic moment per Co atom (μ_β) in each film. As the BP increased, the estimated value of the Co magnetic moment increased due to the large magnetic moment of isolated Co grains in films with larger BP. The values of μ_β in Gd-Co multilayer films were lower than those of Co atoms ($\approx$1.7 μ_β), possibly due to an antiferromagnetic (AF) coupling at the Gd/Co interfaces. The reduced magnetic moment per Co atom of the small BP films, compared to those of the larger BP films, was ascribed to an enhancement of AF coupling at Gd/Co interfaces.

B. Ion beam mixed Gd-Co multilayer films

The degree of ion beam mixing was strongly dependent on the layer thickness of multilayer films. As shown in the AES depth profiles of the films mixed with 200 keV Ar^+ ions

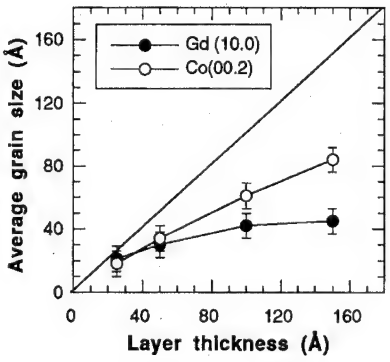

FIG. 2. Change in grain size of Gd-Co multilayer films with layer thickness ($T_{Co}/T_{Gd}\approx1$).

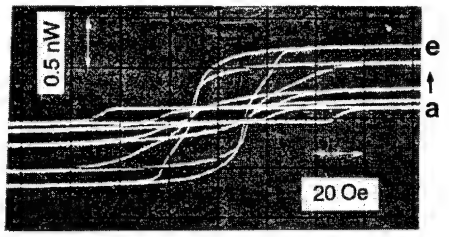

FIG. 3. *B-H* loops of Gd-Co multilayer films as a function of bilayer period: (a) 10, (b) 50, (c) 100, (d) 200, and (e) 300 Å.

(Fig. 4), the small BP film ($\leq$100 Å) was completely mixed throughout the film thickness, but some compositional modulation was observed in the large BP film ($\geq$200 Å) indicating that the ion mixing was incomplete. The principal x-ray diffraction (XRD) peaks observed in the small BP multilayer films (BP$\leq$100 Å) were no longer detected due to the amorphization by ion beam mixing, and the peak intensity of large BP films was also sharply reduced by intermixing of Gd and Co layers.

The morphologies observed in the ion beam mixed films varied with the layer thickness in the multilayer films, and with the beam energy. As shown in Fig. 5, films with a 10 Å BP had a hetero-amorphous morphology with spherical, nanoscale (70 Å) features when mixed by a 150 keV beam, but those mixed at 300 keV had a morphology with a uniform distribution of, amorphous, chainlike features. The change in morphology with ion beam energy is likely associated with the difference in the ballistic displacements of Gd and Co atoms during mixing. The spherical morphologies of the ion-mixed, small BP films was similar to that observed in completely mixed Co-B multilayer films.[2] As the layer thickness increased, the ion beam mixing was incomplete, and the films contained microcrystals embedded in an amorphous matrix. However, the microcrystals of ion beam mixed films were much smaller than those of as-deposited films due to the destruction of microcrystals by the implanted ions. The uniform amorphous matrix seen in the TEM micrographs of Figs. 5(b), 5(c) of large BP (300 Å) multilayers mixed at higher ion energies (300 keV), is similar to the morphology

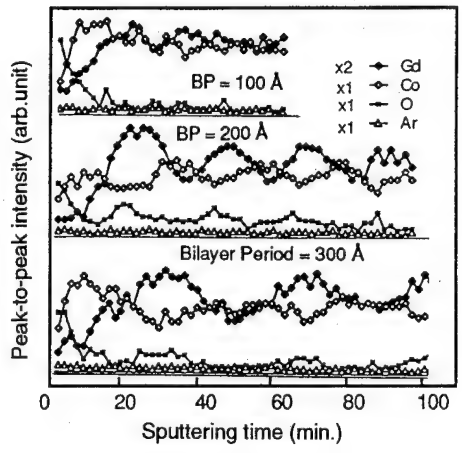

FIG. 4. Auger depth profiles of Gd-Co multilayer films mixed with 200 keV Ar^+ ions.

of the as-deposited multilayer. These layers were incompletely mixed because the penetration depth (projected range ≈1240 Å) for the 300 keV ions was comparable to the film thickness.

The domain patterns observed by Lorentz microscopy (Fig. 6) in multilayers with a 300 Å BP, show that the strong ripple pattern associated with the crystalline Co layers in the as-deposited films, was not observed in the ion beam mixed

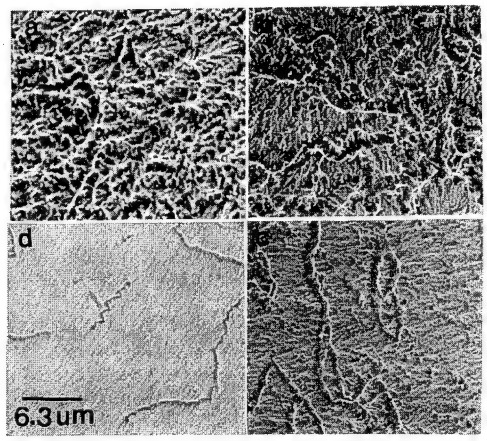

FIG. 6. Lorentz micrographs showing the changes in the magnetization distribution and domain structure of (a) the as-deposited (BP=300 Å) film, and ($b \rightarrow d$) after ion-mixing with increasing dosage of a 200 keV Ar^+ beam.

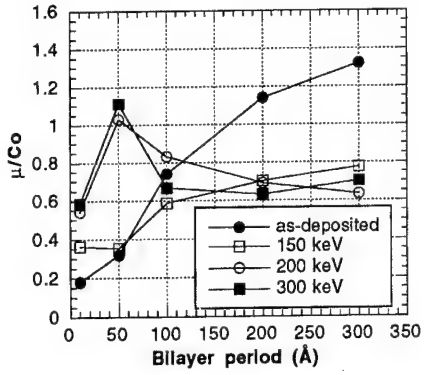

FIG. 7. Change in magnetic moment per Co atom of as-deposited, and ion beam mixed Gd-Co multilayer films with bilayer period.

film. After ion mixing, the irregular submicron domain structure of the as-deposited films was replaced by a single domain with a weak magnetization ripple. Intermediate ion mixing produced domains with a 360° wall structure, and coupled domain walls, similar to those observed in 100 Å BP multilayer films.

The changes in magnetic moments of the ion beam mixed films with ion beam energy are shown in Fig. 7 as a function of BP. After ion beam mixing, the magnetic moments of the larger BP films were greatly decreased due to the destruction of crystalline Co grains and the enhanced AF coupling of Gd/Co pairs, but those of small BP films changed only slightly. When the Ar^+ ion energy was increased from 150 to 200 or 300 keV, the magnetic moment of the small BP films was increased but that of large BP films did not change. Since the layered structure of films with large BP was not completely mixed by ion beam energies of 150 or 300 keV, their magnetic moment was nearly independent of ion beam energy. However, the magnetic moment of films with a small BP increased with the ion energy, indicating a change in the nearest-neighbor atomic exchange with ion energy. The energy dependent increase in the magnetic moment of the small BP films is ascribed to the enhancement of interfacial exchange in the hetero-amorphous state. This enhancement is evident in the 2D→3D transition in the TEM morphology (Fig. 5) of the ion-mixed film (10 Å BP).

Nonlinear dynamics in microwave driven coupled magnetic multilayer systems

S. M. Rezende and F. M. de Aguiar
Departamento de Física, Universidade Federal de Pernambuco, 50670-901 Recife-PE, Brasil

Conventional microwave ferromagnetic resonance (FMR) techniques have proven very useful in the investigation of coupled magnetic multilayer systems. Here we show theoretically that with sufficiently high powers, a microwave magnetic field applied either parallel or perpendicular to the dc field, can drive nonlinear effects. The Landau–Lifschitz equation is used to obtain the nonlinear equations of motion for the two normal modes of a coupled two-layer system. In the usual FMR configuration, only the acoustic mode is coupled to the driving field. However, for driving fields above a critical value, energy can be transferred to the optic mode, in a process similar to the subsidiary resonance observed in spin-wave systems. At higher driving the system may display well-known transitions to chaos. © *1996 American Institute of Physics.* [S0021-8979(96)27208-7]

The interlayer exchange coupling between two ferromagnetic films provided by a metallic nonmagnetic spacer gives rise to a variety of phenomena which have attracted considerable interest in recent years.[1–3] The dynamic magnetic excitations in trilayer "sandwich" structures have been studied by ferromagnetic resonance (FMR) and Brillouin scattering techniques.[4] All investigations so far have been restricted to the linear regime of the excitations. However, the equations of motion of the magnetizations in the two coupled films are highly nonlinear. In this article we investigate the conditions under which nonlinear phenomena can be manifest in these systems.

We consider two ferromagnetic layers with uniform magnetizations $\mathbf{M}_1$ and $\mathbf{M}_2$ in a static external field $\hat{z}\,H_0$, applied in the film plane. We assume that the two layers have the same thickness t and are made of the same material, so that they have the same g value and the same saturation magnetization, $M_1=M_2=M$. The exchange energy per unit area is $E=-A_{12}\mathbf{M}_1\cdot\mathbf{M}_2/M_1M_2$, where the interaction constant A_{12} can be positive (ferromagnetic) or negative (antiferromagnetic). In the latter case we assume that $H_0>2|H_{\rm exc}|\equiv 2|A_{12}|/tM$ so that in equilibrium the two magnetizations are parallel to each other. The motion of the magnetization is driven by a microwave oscillating field $h\cos\omega t$, applied either perpendicular to the static field (along $\hat{x}$, in the film plane), as in a FMR experiment, or parallel to the field ($\hat{z}$ direction). The motion of each magnetization is described by the Landau–Lifschitz equation,

$$\frac{d\mathbf{M}_i}{dt}=\gamma\mathbf{M}_i\times\mathbf{H}_i, \tag{1}$$

where the effective field $\mathbf{H}_i$ acting on $\mathbf{M}_i$ is related to the free-energy E_i per unit volume through $\mathbf{H}_i=-\partial E_i/\partial\mathbf{M}_i$ and γ is the gyromagnetic ratio (2.8 g/2 GHz/kOe). The damping is introduced by a phenomenological term with relaxation rate η.

Note that the dynamic demagnetizing energy introduces a uniaxial field perpendicular to the film plane, in the form $H_i^y=-4\pi M_i^y$. As a result the precession of the magnetization has an ellipticity given by

$$e=[(H_0+4\pi M)/H_0]^{1/2}. \tag{2}$$

The linearized equations of motion, obtained with M_i^x, $M_i^y\ll M_i^z\simeq M$, yield two normal modes. In the acoustic, or symmetric (S) mode, the magnetizations precess parallel to one another with frequency $\omega_S=\omega_0=\gamma[H_0(H_0+4\pi M)]^{1/2}$. In the optic, or antisymmetric (A) mode, the two precessions are out of phase and the frequency is $\omega_A=\omega_0+\gamma 2H_{\rm exc}$. In the perpendicular pumping configuration the symmetric mode is linearly coupled to the driving field whereas the antisymmetric mode is not coupled to the driving.

The nonlinearity in the equations of motion arises from the fact that M_i^z is related to the transverse components of $\mathbf{M}$ by higher order terms,

$$M_i^z=[M^2-(M_i^{x2}+M_i^{y2})]^{1/2}\simeq M-(M_i^{x2}+M_i^{y2})/2M. \tag{3}$$

This leads to terms in the equations of motion involving products of three transverse components. In order to obtain the working equations from (1) we proceed with the following steps: (i) elliptically polarized variables are introduced by $M_i^{\pm}=M_i^x\pm ieM_i^y$, where the ellipticity e is defined in Eq. (2); (ii) these variables are then replaced by slowly varying amplitudes in a frame rotating with frequency ω, $\tilde{M}_i=M_i^+\exp(i\omega t)$; (iii) normal mode variables in the rotating frame are introduced through the transformations,

$$\alpha_S=(\tilde{M}_1+\tilde{M}_2)/\sqrt{2}M,\quad \alpha_A=(\tilde{M}_1-\tilde{M}_2)/\sqrt{2}M. \tag{4}$$

The resulting equations of motion for the normal mode variables in the perpendicular pumping configuration are,

$$\frac{d\alpha_S}{dt}=-(\eta+i\Delta\omega_S)\alpha_S+\gamma h(1+e)/\sqrt{2}-iI_1(\alpha_S\alpha_S\alpha_S^*+\alpha_A\alpha_A\alpha_S^*+2\alpha_S\alpha_A\alpha_A^*), \tag{5}$$

$$\frac{d\alpha_A}{dt}=-(\eta+i\Delta\omega_A)\alpha_A-iQ_1\alpha_A\alpha_A\alpha_A^*-iQ_2\alpha_S\alpha_S\alpha_A^*-iQ_3\alpha_S\alpha_S^*\alpha_A, \tag{6}$$

where $\Delta\omega_S=\omega_S-\omega$ and $\Delta\omega_A=\omega_A-\omega$ are the detunings and the nonlinear parameters are

$$Q_1=T_1+2T_2+4T_3,\quad Q_2=T_1+2T_2-4T_3,\quad Q_3=2T_1-4T_2, \tag{7}$$

 0021-8979/96/79(8)/6309/3/$10.00

where

$$T_1=\frac{\gamma 4\pi M}{32e}(1+3/e^2),\quad T_2=-\frac{\gamma H_{\rm exc}}{32}(1-1/e^2)^2,$$
$$T_3=\frac{-\gamma H_{\rm exc}}{32}(1+1/e^2)^2. \tag{8}$$

Note that Eqs. (5) and (6) resemble those describing the nonlinearities in spin wave perpendicular pumping in the two-mode approximation.[5–7] However, whereas the derivation of the spin wave equations involve transformations from spin to magnon operators and lengthy algebraic treatment of the magnon Hamiltonian,[5] here the equations follow in a straightforward manner from the Landau–Lifschitz equation. One also sees in Eqs. (5) and (6) that while the S mode is driven linearly by the oscillating field, the A mode does not couple to the external field. However, the A mode can be excited indirectly by the S mode via the last two nonlinear terms in Eq. (6). This excitation is characterized by an exponential growth of the amplitude α_A when the driving field exceeds some threshold value h_c,

$$h_c\sim[(\eta^2+\Delta\omega_S^2)(\eta^2+\Delta\omega_A^2)^{1/2}/\gamma^3|H_{\rm exc}|]^{1/2}. \tag{9}$$

Through this process an absorption peak will appear at the frequency of the A mode at sufficiently high power, similarly to the subsidiary resonance observed in FMR experiments.[7,8] In good crystalline metallic films, such as Fe, Ni, or Co, the FMR linewidths are on the order of 20–40 Oe, as compared to 10^{-1} Oe in yttrium iron garnet (YIG). As a result the critical fields in metallic films are at least 10^3 larger than in YIG films in which nonlinear effects have been widely studied. The detunings also contribute to increase the values of h_c. Thus, in order to bring h_c to more reasonable values one should work with sandwiches with large antiferromagnetic exchange coupling near the region where the dispersion relations of the two modes cross[9] [the actual normal modes in the spin-flop configuration yield equations similar to Eqs. (5) and (6)]. As the h field increases further above h_c, the A mode reacts back on the S mode through the last two nonlinear terms in Eq. (5). As a result, at some critical value h_c' there is a new bifurcation whereby the fixed point becomes unstable and the system starts to oscillate. The amplitude of the spin precession grows in one mode at the expense of the other, resulting in a dynamic alternating energy shuffling between the two modes. The frequency of this self-oscillation is on the order of η. In order to study this further one must resort to numerical solutions of Eqs. (5) and (6).

The numerical results presented here were obtained with the following parameters: $\Delta\omega_s/\eta=0.4$, $\Delta\omega_A/\eta=-0.4$, $T_1/\eta=T_2/\eta=1.0$, and $T_3/\eta=3.2$. These are approximately valid for a Ni/Ag/Ni sandwich with AF coupling near the mode-crossing frequency with parameters: $4\pi M\sim 4$ kOe, $H\sim 1.5$ kOe, $\Delta H\sim 30$ Oe, and $H_{\rm exc}\sim -50$ Oe. Figure 1 shows the time record of $|\alpha_A(t)|$ and the phase portrait $|\alpha_A(t)|$ vs $|\alpha_S(t)|$ as the control parameter $R=\gamma h(1+e)/\sqrt{2}\eta$ increases from 0.875 to 0.898. The initial conditions at $t=0$ have been chosen so that the transient response to the limit cycles is negligible. For $R=0.875$ the response is periodic and the frequency in this case is $f\sim 0.3\eta$. Similar to the high-power ferromagnetic resonance in bulk samples, this frequency increases with increasing R. Period doubling is shown for $R=0.888$ and a period-4 oscillation is shown for $R=0.893$. Higher-order bifurcations are observed as the driving field is further increased, accumulating at a critical value $R_c=0.8942\ldots$. The lower panel in Fig. 1 shows the strange attractor for $R=0.898$. The overall period-doubling scenario is shown in the bifurcation diagram of Fig. 2, obtained from the local maxima of $|\alpha_A(t)|$ as a function of R. There are many periodic windows in the chaotic region ($R>R_c$), the period-3 one being the largest, bearing close resemblance to the behavior of the standard logistic map.[10]

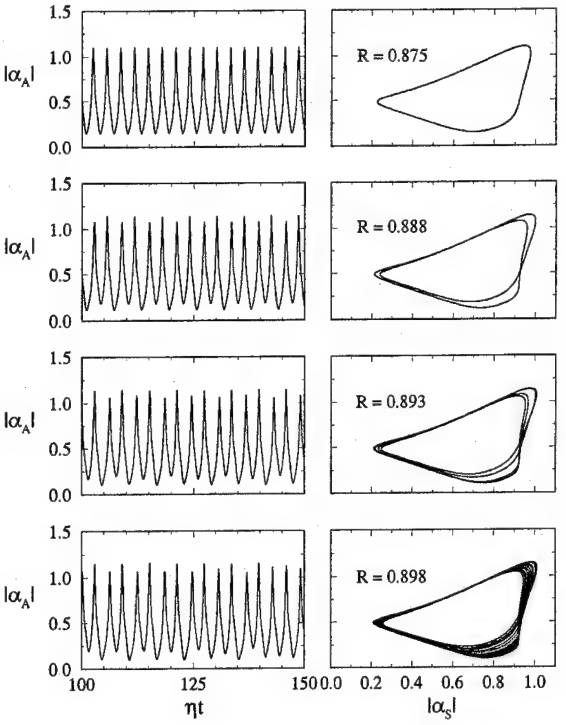

FIG. 1. Time series of $|\alpha_A|$ (left panels) and phase portraits $|\alpha_A(t)|$ vs $|\alpha_S(t)|$ (right panels) in the period-doubling region. Parameters are given in the text.

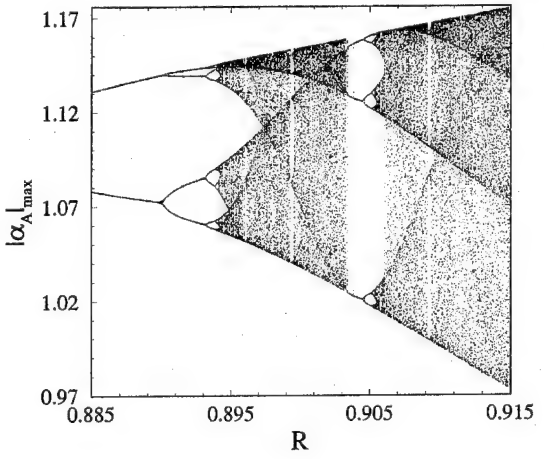

FIG. 2. Bifurcation diagram obtained from the local maxima of $|\alpha_A(t)|$. Parameters are given.

In the case where the driving field is applied parallel to the static field, both modes are driven nonlinearly with a term of the type $h\alpha_\lambda$, where $\lambda=S,A$. In this case each mode grows unstable only when the driving exceeds its critical value. Depending on the parameter values, auto-oscillations, and chaos develop at higher drivings, similar to the perpendicular pumping case.

Several samples of enhanced-remanence nanocrystalline $Sm_{15}Fe_{19}Co_{66}$ were prepared by mechanical alloying of the elementary powders followed by heat treatments. Sample A had a remanence ratio $\eta=\sigma_r/\sigma_s=0.68$ and $H_c=7.1$ kOe, while, for B, $\eta=0.58$ and $H_c=10.4$ kOe, and, for C, $\eta=0.57$ and $H_c=12.6$ kOe. The isothermal remanent magnetization $M_r(H)$, obtained for different initial demagnetized states (ac, dc^+, dc^-), and the demagnetization remanence $M_d(-H)$, obtained for an initially saturated state, were determined. The ac-demagnetization Henkel plot showed both magnetizing and demagnetizing interactions as observed in other nanocrystalline magnets. A comparison with the moving Preisach model indicates the importance of both mean-field and random interactions. © *1996 American Institute of Physics.* [S0021-8979(96)34408-8]

I. INTRODUCTION

Nanocrystalline materials consisting of a hard magnetic rare earth-based intermetallic, exchange coupled to a soft magnetic phase have been the subject of much recent interest. This is due to the possibility of these materials presenting enhanced remanence and large energy products in magnets containing large volume fractions of a soft magnetic phase. Several examples of this phenomenon are known for which the hard magnetic phase is $Nd_2Fe_{14}B$.[1,2] On the other hand, Ding *et al.*[3] reported large energy products in a material consisting of $Sm_2Fe_{17}N_x+\alpha$-Fe, produced by mechanical alloying. Recently Ding *et al.*[4] and Smith *et al.*[5] investigated remanence enhancement in alloys of the SmFeCo system where high-moment α-(Fe,Co) is encountered.

Modeling of these exchange-coupled systems by Kneller and Hawig[6] and by Schrefl *et al.*[7] has emphasized the ultrafine-grained microstructure necessary to achieve these "exchange-spring" magnets. However, it is also interesting to study magnetic interactions via remanence measurements using Henkel plots and the Preisach model.[8,9] In this case, an elegant mathematical apparatus can be brought to bear on the problem. The latter approach is adopted here to study magnetic interactions in three SmFeCo alloys presenting different degrees of remanence enhancement. Since the isothermal remanence $M_r(H)$ depends strongly upon the initial demagnetized state, it was obtained for different initial demagnetized states (ac, dc^+, dc^-). These results were compared to the demagnetization remanence $M_d(-H)$, obtained for an initially saturated state, to determine Henkel plots. The Henkel plot obtained for the ac demagnetization showed both magnetizing and demagnetizing interactions as observed in other nanocrystalline magnets.[2,10] The results were compared with the moving Preisach model.

II. EXPERIMENT

The starting materials for the samples were high-purity elementary powders: Fe (99.99%, particle size <40 μm), Co (99.99%, particle size <40 μm), Sm (99.99%, particle size <100 μm). The initial composition of the alloys considered here was $Sm_{16}Fe_{10}Co_{74}$. Mechanical alloying was carried out for 30 h with hardened steel balls in a hardened steel vial using a Fritsch Pulverisette-7 mill. The mass of the balls was approximately 25 times the mass of the precursor powders. All powder handling and milling were carried out under a high-purity (99.99%) Ar atmosphere. After milling, the sample compositions were determined by energy dispersive x-ray analysis in a Cambridge Stereoscan 240 SEM. We obtained $Sm_{15}Fe_{19}Co_{66}$, reflecting increased Fe due to milling. As-milled powders were cold pressed into 3-mm-diam cylinders, wrapped in Ta foil, and heated under a 10^{-5} mbar vacuum for 15 min at (A) 640 °C, (B) 730 °C, or (C) 750 °C. For this temperature range, Ding *et al.*[4] reported the observation of disordered $Sm(Co,Fe)_7$ with the $TbCu_7$ structure. Our x-ray diffraction, DSC, and Mössbauer measurements will be reported at a later time. Finally, after annealing, the oxygen and nitrogen levels of the samples were measured with a Leco analyzer. Oxygen levels around 5500 ppm and nitrogen levels of 200 ppm were encountered. These levels are comparable to those found in $SmCo_5$ magnets produced in our laboratory.

Sample demagnetizations as well as magnetization measurements were made at room temperature using a vibrating sample magnetometer (VSM) mounted in a 90 kOe superconducting solenoid. Internal magnetic fields were calculated using the demagnetization factors appropriate for the cylindrical geometry of the sample. The dc^- demagnetized state was obtained by saturating the sample to 50 kOe in the positive direction, after which H was decreased to a negative remanent coercive field. Upon increasing H to zero, the specific magnetization σ was less than 1% of σ_r. For the dc^+ demagnetization, the sample was first saturated to 50 kOe in the negative direction, after which H was increased to a positive remanent coercive field. Upon decreasing H to zero, $\sigma<0.01\sigma_r$. Finally, the ac demagnetization was carried out

 0021-8979/96/79(8)/6312/3/$10.00

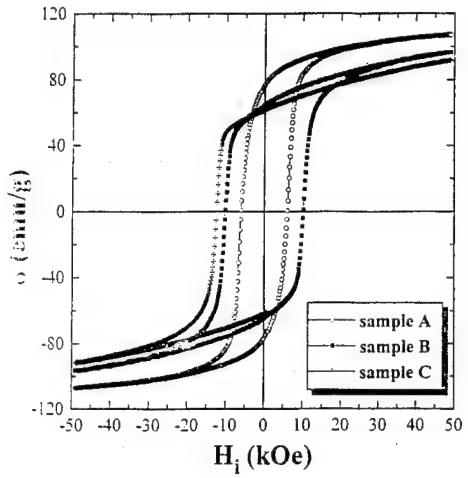

FIG. 1. Specific magnetization σ vs internal magnetic field H_i for samples A, B, and C.

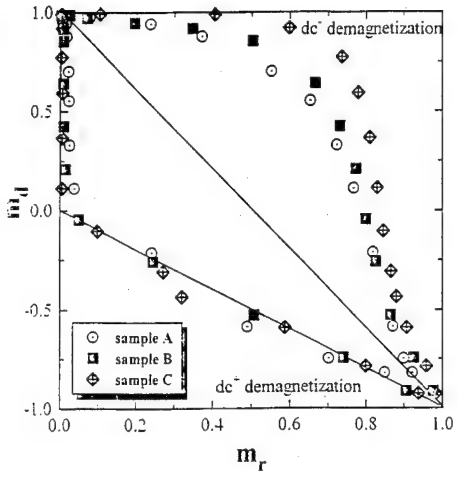

FIG. 2. Normalized demagnetization remanence m_d vs normalized isothermal remanent magnetization m_r for dc^+ and dc^- demagnetizations.

by first saturating the sample to 50 kOe, followed by saturation at -50 kOe, then to 49 kOe, followed by -49 kOe, etc., until $\sigma<0.01\sigma_r$.

III. RESULTS AND DISCUSSION

In Fig. 1 we show hysteresis curves for samples A, B, and C. The curves did not saturate at the highest fields used (90 kOe), but followed a general trend of higher coercivity values being associated with lower values of σ_s. The saturation value σ_s was calculated by extrapolating the experimental curves to infinite fields using the expression $\sigma=\sigma_s(1-a/H)$. The coercive field H_c was determined from the maximum value of the irreversible susceptibility. We obtained $\sigma_s=114$ emu/g, $\sigma_r=77$ emu/g, and $H_c=7.1$ kOe for sample A, giving a remanence ratio $\eta=\sigma_r/\sigma_s=0.68$. For sample B we obtained $\sigma_s=112$ emu/g, $\sigma_r=65$ emu/g, and $H_c=10.4$ kOe, giving a remanence ratio $\eta=\sigma_r/\sigma_s=0.58$. For sample C we obtained $\sigma_s=109$ emu/g, $\sigma_r=62$ emu/g, and $H_c=12.6$ kOe, giving a remanence ratio $\eta=\sigma_r/\sigma_s=0.57$. Thus, for all three samples we found σ_s values which are essentially the same, considering our experimental uncertainty of 2%. Our σ_s values are also in excellent agreement with those of Smith *et al.*[5]

For all three samples we observed remanence enhancement above the value $\eta=0.5$ expected for an isotropic magnet. As noted in Ref. 5, the remanence enhancement is lower in samples treated at higher temperatures and this may be due to the increased grain size of the exchange-coupled phases. Furthermore, as reported in Ref. 6 for an "exchange spring" magnet, second quadrant recoil curves show elevated susceptibility. Consistent with the η values obtained, it was found that the reversible susceptibility was largest for sample A and smallest for C. Finally, the energy products were calculated for these three materials using the measured densities. Using a density of 6.1 g/cm^3, we obtained $(BH)_{max}=6.4$, 5.6, and 5.2 MG Oe for samples A, B, and C, respectively. If these materials had had their full densities (8.5 g/cm^3), $(BH)_{max}=10$–12 MG Oe would have been obtained.

Henkel plots were obtained for the three samples by plotting the normalized demagnetization remanence $m_d(-H)=M_d(-H)/M_r(90\text{ kOe})$ as a function of the normalized isothermal remanent magnetization $m_r(H)=M_r(H)/M_r(90\text{ kOe})$. We show the Henkel plots in Fig. 2 for the dc^+ and dc^- demagnetizations. Also shown is the line $m_d=1-2m_r$ corresponding to noninteracting, single-domain particles[11] or domain walls in continuous media moving through a fixed distribution of pinning sites. For the dc^+ demagnetized state, the Henkel plots for samples A, B, and C are all closely coincident with the curves $m_r=0$ (when $m_d>0$) and $m_d=-m_r$ (when $m_d<0$). This result is predicted theoretically when there is no dispersion in local coercivities.[9] The dc^+ demagnetization thus effectively narrows the switching field distributions and allows their representation by some narrow function.

On the other hand, the differences in the switching field distributions have been emphasized by the dc^- demagnetization. In Fig. 2, we see that, for the dc^- demagnetization, the experimental points fall above the Wohlfarth line $m_d=1-2m_r$. In this case, the interactions are said to be magnetizing. In Fig. 2, the points corresponding to sample A are closest to this line, while those of sample C are farthest. Thus, the magnetizing interactions appear to be strongest for sample C, which possesses the highest coercive field $H_c=12.6$ kOe and the lowest remanence ratio $\eta=0.57$. In fact, the Henkel plot measures a combination of effects, and not simply the interaction with neighboring grains.[9] Thus it may be more helpful to consider the results for ac demagnetization.

In Fig. 3, we present m_d vs m_r for samples A and C after these had been subjected to an ac demagnetization. The experimental data for both A and C are close to the Wohlfarth line $m_d=1-2m_r$, being above it (magnetizing) for low fields and below it (demagnetizing) for high fields. This same kind of behavior was observed previously for nanocrystalline $Nd_9Fe_{85}B_6$ (α-Fe+$Nd_2Fe_{14}B$) by Liu *et al.*[2] In that case, the dependence of the magnetic properties on applied field was determined for three nanocrystalline NdFeB alloys of very different Nd/Fe ratios. The deviation from the Wohlfarth line

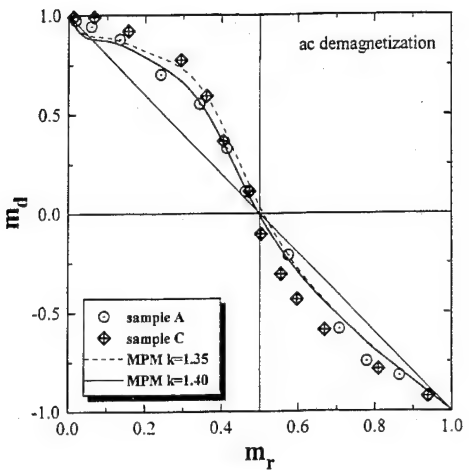

FIG. 3. m_d vs m_r for ac demagnetization of samples A and C. Dashed and solid curves were obtained from the moving Preisach model.

was largest (magnetizing) for the high Nd alloy where the grains were decoupled by the paramagnetic Nd-rich phase. On the other hand, the deviation was small and oscillatory, as we have observed here, for the low Nd alloy where there is believed to be substantial exchange coupling. An oscillatory Henkel plot was observed for thermally demagnetized nanocrystalline $Nd_4Fe_{78}B_{18}$ by Altoé *et al.*[10] This behavior was contrasted to that of MQII which showed strong magnetizing interactions. Thus, an oscillatory Henkel plot has been observed for high remanence materials belonging to the three major systems.

Several authors[8,9] have recently attempted to interpret Henkel plots using variations of the Preisach model. It has been shown using the moving Preisach model (MPM)[8] that Henkel plots exhibiting both magnetizing-like and demagnetizing-like deviations from the line $m_d=1-2m_r$ are an indication of the presence of random interactions and magnetizing-like mean-field effects. We have tried to compare the data of Fig. 3 to the MPM using a probability distribution $p(h_c,h_u)$ such as that of Eq. (14) of Ref. 8:

$$p(h_c,h_u)=\frac{1}{4\pi h_c\sigma_u\sigma_c}\exp\left[-\frac{(\log h_c)^2}{2\sigma_c^2}\right]\exp\left(-\frac{h_u^2}{2\sigma_u^2}\right). \tag{1}$$

The coercive fields have a log normal distribution of width σ_c and interaction fields follow a Gaussian distribution of width σ_u. The MPM differs from the Preisach model in that the field $h=H/H_c$ acting on any elementary loop is

$$h=h_a+ki(h), \tag{2}$$

where h_a is the external field, $ki(h)$ is the mean-field contribution, assumed proportional to the magnetization $i(h)$, and k is the moving parameter. The curves of Fig. 3 represent the predictions of the MPM with $\sigma_c=1$, $\sigma_u=1$, and with the mean-field parameter k assuming the values 1.35 and 1.40. There is general agreement with the shape of the experimental curve, the calculated curves presenting both magnetizing and demagnetizing regions. We have not yet optimized the values of σ_c, σ_u, and k. However, both the mean-field interactions and random interactions seem to be important in the case of these nanocrystalline materials, as suggested previously.

IV. CONCLUSIONS

Three samples of nanocrystalline SmFeCo with different degrees of remanence enhancement have been produced. Henkel plots for an ac demagnetization show both magnetizing and demagnetizing regions, as was observed previously in $Nd_9Fe_{85}B_6(\alpha\text{-}Fe+Nd_2Fe_{14}B)$[2] and $Nd_4Fe_{78}B_{18}$.[10] The data were compared to the moving Preisach model. Preliminary calculations indicate the necessity to consider both mean-field and random interactions. It is not yet clear whether this model can account for the different degrees of remanence enhancement observed in our samples.

Neutron diffraction studies of $Nd_nFe_{m-x-y}V_xAl_y$ [$(n,m)=(1,12)$, (2,17), (3,29)]

Z. Hu and W. B. Yelon
Research Reactor Center, University of Missouri-Columbia, Columbia, Missouri 65211

W. J. James
Graduate Center for Materials Research, University of Missouri-Rolla, Rolla, Missouri 65401

Several $Nd_nFe_{m-x-y}V_xAl_y$ [$(n,m)=(1,12)$, (2,17), (3,29)] samples were prepared and analyzed using neutron powder diffraction. Rietveld analysis of the neutron diffraction data indicates that the V and Al substituents take those sites with similar environments in all three phases, as observed in our previous study of Ti-substituted compounds. It was confirmed that the diffraction data of the 3:29 compound can be better refined using the $A2/m$ space group than using the $P2_1/c$ space group. The SQUID measurements show that all samples have Curie temperatures well above room temperature. The neutron diffraction results show that the easy direction is along the a axis for the 3:29 compounds, along the c axis for the 1:12 compounds and in the a-b plane for 2:17 compounds, respectively. The average site magnetic moments, the metal–metal bond lengths and the unit cell parameters of these compounds are compared with those of the Ti-substituted compounds. [S0021-8979(96)34508-4]

I. INTRODUCTION

Because the number of known rare-earth-iron phases with high iron/rare-earth ratios is very limited, improving the magnetic properties of the known phases, especially the 2:17, 1:12 and the newly discovered 3:29 phases, to make them practically useful is a focus for research. Addition of some other elements into these phases, such as the interstitial atoms (C or N)[1–5] or substitutional atoms (Al,Ga,Si),[6–14] results in a dramatic enhancement in magnetic properties.

The unit cell of the rare-earth-iron compounds can expand upon the addition of substitutional atoms (Ga,Al)[6–8] or contract upon the addition of Si.[9–14] In both cases the magnetic properties can be enhanced significantly. It is believed that in the expansion case, like the Al-substituted 2:17 compounds, the lattice expansion is sufficient to decrease the antiferromagnetic exchange and to enhance the ferromagnetic exchange.[7] In the contraction case, the enhancement of magnetic properties with Si substitution may be related to the expansion of the bond lengths around the $6c$ and $18f$ sites.[14] However, it appears that the increase in the iron–iron bond lengths is not the only mechanism to improve the magnetic properties of these compounds.[15]

Our previous studies showed that Al and Si have similar site affinities at low Al or Si content and it was found that a combined substitution of Fe by Si and Al (both are nontransition metal atoms), at the appropriate levels, could lead to greater enhancement of the magnetic properties than the singly substituted compounds.[16] It is obviously interesting to study doubly substituted compounds using two substituents of different site affinities. Our previous studies showed that while Al prefers the $18h$ site at low Al contents in 2:17 compounds,[6,7] V atoms strongly prefer the $6c$ sites.[17] Here we report studies of Al+V (a nontransition atom plus a transition atom of different site affinity) substitution compounds, $Nd_nFe_{m-x-y}V_xAl_y$ [$(n,m)=(1,12)$, (2,17), (3,29)].

II. EXPERIMENT

Samples used in this research were synthesized by rf induction melting of the constituent elements (purity 99.9% or better) in a water-cooled copper boat under a flowing argon atmosphere at the Graduate Center for Materials Research of the University of Missouri-Rolla. The ingots were annealed under vacuum at temperatures of 980 °C for one week. The annealed ingots were then crushed and ground in an acetone bath for neutron diffraction and other studies. Neutron diffraction data were collected using the position sensitive detector (PSD) diffractometer at the University of Missouri Research Reactor. Data collection times for each sample where typically 24 h on about 2 g of the powdered samples in a 3-mm-diam vanadium can at a wavelength of 1.4783 Å.

Neutron diffraction data were analyzed using the program FULLPROF, a program for Rietveld analysis of neutron (nuclear and magnetic scattering) or x-ray powder diffraction data collected at constant steps in the scattering angle 2θ on a conventional instrument. The Curie temperatures T_c were measured using a Quantum Design MPMS system.

III. RESULTS AND DISCUSSION

It was suggested[18] recently that the structure of the 3:29 phase can be described more accurately by using the space group $A2/m$, a minimal nonisomorphic supergroup of type II of $P2_1/c$ space group which was initially used for solving the structure of this phase.[19–21] Thus, the neutron diffraction data of the 3:29 compounds were refined in both space groups ($P2_1/c$ and $A2/m$). It was found that the fitting factors were only slightly better when the space group $P2_1/c$ was used, in which as many as 91 parameters were refined, compared to 57 parameters refined for the space group $A2/m$. The R-factor ratio[22] test leads to the conclusion that the model based on the space group $A2/m$ is more reliable, which confirms the conclusion of Kalogirou *et al.*[18]

Samples with V and Al content ratio changing in a limited range were prepared but only one of each type with the

TABLE I. Refinement results for $NdFe_{10.05}V_{1.38}Al_{0.57}$.

Space group: $I4/mmm$			Unit cell volume=351.443 Å^3

best phase purity are reported in this paper and the refinement results are given in Tables I, II, and III. Previous work shows that Al and V atoms introduced into Nd_2Fe_{17} compounds will expand the cell of the compounds by 1.44 Å^3/V atom[17] and 8.49 Å^3/Al atom.[7] The lattice parameters of the V+Al double substituted 2:17 compound are linear combinations of the corresponding singly substituted compounds (Table II). For 1:12 and 3:29 compounds, no data for Al or V single-substitution compounds are available and thus no comparison can be made.

It is not possible to determine the site distributions of the substituents in doubly substituted compounds directly from the neutron diffraction techniques. We use some assumptions based on our previous work to determine the locations of the substituents, as was done for $Nd_2Fe_{17-x-y}Al_xSi_y$.[16] It is found that the V atoms will mostly occupy the 6c sites, which have the fewest rare-earth neighbors and the most transition metal neighbors in $Nd_2Fe_{17-x}V_x$,[17] and it is assumed that the V atoms will occupy the same sites in the $Nd_2Fe_{17-x-y}V_xAl_y$ compound. It was also found that the Ti atoms will occupy sites with similar environments in all 1:12, 2:17, and 3:29 phases.[21] In fact, because the structures of all three compounds are derived from the same parent structure of RT_5 with differing degrees of Fe–Fe dumbbell replacement for the rare-earth atoms, it is assumed that a given substituent will occupy those sites with similar environments in all 1:12, 2:17, and 3:29 compounds. Thus, we assume that the V atoms will occupy those sites with the fewest rare-earth neighbors and most transition metal neighbors, while Al atoms will prefer those sites with the most rare-earth neighbors and the fewest transition metal neighbors in all V+Al double-substituted 1:12, 2:17, and 3:29 compounds. Thus, the V atoms occupy the three dumbbell sites in the 3:29 phase, the 6c sites in the 2:17 and the 8i sites in the 1:12 phase, while the substituents found in any other sites are Al atoms. In fact, the neutron data show a strong decrease of the effective scattering length in those sites with the fewest rare-earth neighbors, which indicates substitution of V atoms at those sites because V has a very small scattering length. By using these assumptions, the site occupancies of V and Al in Tables I, II, and III are obtained.

The refined site magnetic moments are also given in Tables I, II, and III. The easy direction is found along the a axis for the 3:29 compounds, along the c axis for the 1:12 compounds and in the a-b plane for the 2:17 compounds, respectively. The 1:12 compound has the biggest site moments whereas the 3:29 compound has the smallest site moments. The average Fe site moments are 2.2, 1.81, and 1.5μ_B for the 1:12, 2:17, and 3:29 compounds, respectively. Compared to the average site moment of $Nd_2Fe_{16.03}Ti_{0.97}$, 1.95μ_B,[21] the average site moment of $Nd_2Fe_{15.66}V_{1.06}Al_{0.28}$ is a little lower, very possibly due to the higher substituent content in the V+Al double-substituted compound. Similarly, the average site moment of $NdFe_{10.05}V_{1.38}Al_{0.57}$, 2.2$\mu_B$, is lower than that of the $Nd_2Fe_{10.9}Ti_{1.1}$ compound, 2.36μ_B.[21] For the 3:29 compounds, the refined average site moment of $Nd_3Fe_{26.97}V_{1.83}Al_{0.20}$, 1.11$\mu_B$, is a little higher than that of the $Nd_3Fe_{27.76}Ti_{1.24}$ compound (1.05μ_B) in spite of the higher substituent content in $Nd_3Fe_{26.97}V_{1.83}Al_{0.20}$. The SQUID measurements give Curie temperatures of 600, 395, and 385 K for the 1:12, 2:17, and 3:29 compounds, respectively. Because the Curie temperatures of the corresponding Al or V single-substitution compounds are not available at present, no comparison between single- and double-substituted compounds can be made. The high T_c and large site magnetic moment of the 1:12 compound suggests that it can be of economic interest even without nitriding or carbiding. Since the substituents and their content ratio can be adjusted in a wide range for doubly substituted compounds, it will not be surprising if doubly substituted compounds with even better properties are discovered.

IV. CONCLUSIONS

It was confirmed that the diffraction data of the 3:29 compound can be better refined using the $A2/m$ space group than using the $P2_1/c$ space group. All samples have Curie temperatures well above room temperature. The easy direction is along the a axis for the 3:29 compounds, along the c axis for the 1:12 compounds and in the a-b plane for the 2:17 compounds. The average site magnetic moments are similar to those of the Ti-substituted compounds.

Six samples of $Ce_2Fe_{17-x}Ga_x$ with nominal Ga content x equal to 0, 0.3, 0.5, 0.7, 1.0, 2.0 have been studied by powder neutron diffraction at room temperature. Both crystalline and magnetic refinements have been carried out. All six samples adopt the Th_2Zn_{17}-type rhombohedral structure. The only additional phase found is α-iron. Gallium atoms are found to have high affinity for the iron 18*h* site, and are absent from the 9*d* and 18*f* sites. The Ga substitution for Fe leads to an expansion of both the *a* and *c* axes. The Curie temperature increases from 238 K for Ce_2Fe_{17} to 406 K for $Ce_2Fe_{15}Ga_2$. Magnetic refinements on the samples with $x=0.3$, 0.5, 0.7, 1.0, and 2.0 reveal that the magnetic moments of the four Fe sites are in the basal plane and that their values increase with increasing Ga content. © *1996 American Institute of Physics.* [S0021-8979(96)34608-0]

I. INTRODUCTION

The studies of high-performance hard magnetic materials consisting of rare-earth (R)-3*d* transition metals have been reinvigorated after the discovery of the ternary $Nd_2Fe_{14}B$ compound[1,2] and the carbided, hydrided, and nitrided compounds based on the R_2Fe_{17} and RFe_{12} phases.[3,4] It is believed that the lengthened Fe–Fe bonds, with enhanced ferromagnetic exchange, play an important role in the increase of Curie temperature (T_c). It has been found that some iron site substitutional atoms, such as Al, Si, Ti, and Ga, can also enhance the Curie temperature significantly.[8] Thus, it is of interest to look into the influence of the substitutional atom(s) on the crystallographic structure and the intrinsic magnetic properties of these compounds. Recent studies[7,9,10] of $Tb_2Fe_{17-x}Ga_x$, $Nd_2Fe_{17-x}Ga_x$, and $Tb_2Fe_{17-x}Al_x$ reveal that an increase in unit cell volume and Curie temperature can be achieved through the substitution of gallium or aluminum for iron. For the Tb series, the Curie temperature reaches a maximum between $x=3$ and 4 and the easy magnetization direction changes from planar to axial with increasing Ga concentration. In this article, we report a neutron diffraction structural study of $Ce_2Fe_{17-x}Ga_x$ with gallium nominal composition x up to 2.0. Since Ce is expected to be nonmagnetic, the effect of R-Fe exchange may be ignored.

II. EXPERIMENT

$Ce_2Fe_{17-x}Ga_x$ samples with nominal gallium contents of $x=0$, 0.3, 0.5, 0.7, 1.0, and 2.0 were prepared by radio-frequency induction melting of the constituent elements of purity 99.9–99.95%. The samples were wrapped in tantalum foil and annealed in argon atmosphere at 950 °C for one week. They were then crushed and ground for later measurements. Neutron diffraction data were collected at the University of Missouri Research Reactor using the high-resolution linear position-sensitive detector diffractometer at room temperature. The neutron wavelength was 1.4783 Å. Approximately 1 g samples were contained in thin wall (0.1 mm) vanadium holders. The data were accumulated in five settings of the detector in 24 h with 2θ values ranging from 5° to 105° in 0.05° steps. The neutron diffraction powder patterns were analyzed by the Rietveld method[11] using the FULLPROF program[12] for multiphase refinement, including magnetic structure refinement.

III. RESULTS AND DISCUSSION

From the powder neutron diffraction data refinement, all six samples were confirmed to adopt the Th_2Zn_{17}-type rhombohedral structure with the R-3*M* space group. The refinement results are given in Table I. Both the *a* and *c* lattice parameters increase as the gallium content increases, approximately 0.45% per substituted Ga for *a* and 0.55% for *c*, as is shown in Fig. 1. The compositional dependence of the unit cell volume is also shown in Fig. 1. The unit cell volume expands from ~775 Å^3 for Ce_2Fe_{17} to ~799 Å^3 for $Ce_2Fe_{15}Ga_2$. The corresponding Curie temperature rises from 238 K for the parent binary phase to 406 K for $Ce_2Fe_{15}Ga_2$. The compositional dependence of the *c*/*a* ratio is weak; only a very slight rise is observed. α-Fe was observed in all samples with a maximum of almost 12% in volume.

Gallium is found to have high affinity for the iron 18*h* site, which is filled by 35% Ga for $x=2$. Some Ga is also found in the iron 6*c* site with less than 10% for the sample with the highest Ga content. However, no gallium is found on either the 9*d* or the 18*f* site. The compositional dependence of the gallium site occupancy is shown in Fig. 2. The 6*c* gallium site occupancy appears to be close to saturation at ~10% for $x>1$. In Ce_2Fe_{17}, the iron 6*c* site has the largest Wigner–Seitz cell volume[7] followed by the 18*h* site, while the 9*d* site is the smallest. Gallium's high affinity for the 18*h* site is because this site has the most near-neighbor rare-earth atoms in the coordination shell. The effect of Ga having high

affinity for rare-earth atoms surpasses that of the site volume, as is also the case[5,13,14] for Si- and Al-doped samples.

The bond lengths and the site average bond lengths are listed in Table II. Almost all bond lengths increase with increasing Ga concentration, as do the average bond lengths for all four Fe sites. However, two exceptions were observed for $18f-18h$ and $6c-6c$ bond lengths. The $6c-6c$ dumbbell, which is often thought to be responsible for the low Curie temperature of the R_2Fe_{17} compounds, decreases slightly with Ga content despite the increase in the c axis. From this, one would predict a decrease in Curie temperature, which is in contrast with the observations. This phenomenon has also been observed in some other investigations.[13–15] This suggests that it is unlikely that the changes in T_c arise from the changes of the $6c-6c$ bond, but rather, the increase is more likely related to the average bond lengths.

Magnetic refinement has been carried out on samples with $x=0.3$, 0.5, 0.7, 1.0, and 2.0. Ce_2Fe_{17} is not magnetically ordered at room temperature and in all cases cerium is treated as nonmagnetic. The refinement results indicate that the magnetic moments of all four Fe sites lie in the basal plane and the average values of these moments tend to increase with increasing gallium content. The magnetic moments at low gallium contents have been constrained to be equal rather than being refined independently because their moments are too small to give reliable individual values. The refinement results for $x=1$ and 2 samples show that the moments of the $6c$ and $18h$ sites are larger than those of the $9d$ and $18f$ sites, especially that of the $6c$ site. The overall in-

crease in site moments is the result of the increase in Curie temperature and the larger degree of magnetic order at room temperature.

IV. CONCLUSIONS

Both the *a* and *c* lattice parameters show a similar dependence on Ga content in the $Ce_2Fe_{17-x}Ga_x$ solid solutions. The gallium atoms have a high affinity for the iron 18*h* site. The easy magnetization direction is in the basal plane.

Magnetic properties of $DyCo_{10-x}Ni_xSi_2$ compounds

Z. G. Zhao, N. Tang, E. Brück, K. H. J. Buschow, and F. R. de Boer
Van der Waals-Zeeman Institute, University of Amsterdam, Valckenierstraat 65, 1018 XE Amsterdam, The Netherlands

The temperature dependence of the magnetization of $DyCo_{10-x}Ni_xSi_2$ compounds with $x=0$, 2, 4, and 6 was measured in fields up to 5.0 T and in the temperature range from 4.2 to 300 K in a SQUID magnetometer. Compensation temperatures were observed for the compounds with $x=4$ and 6. The values of the R-T exchange interaction obtained by fitting the M-T curves on the basis of two-sublattice molecular-field theory are compared with the values obtained from high-field magnetization measurements on powder particles free to be oriented by the applied field. In all four compounds magnetic transitions are found in the ac-susceptibility measurements which were carried out between 4.2 K and room temperature. The types of magnetic anisotropy were investigated by magnetization measurements on samples that were magnetically aligned at room temperature.
 [S0021-8979(96)34708-7]

I. INTRODUCTION

$RT_{10}Si_2$ compounds (R=rare earth, T=Fe, Co, Ni) form in the tetragonal $ThMn_{12}$-type structure. Like in many other Fe-rich rare-earth intermetallic compounds, the Curie temperature can be strongly increased by partially substituting Co for Fe. This substitution can also be accompanied by changes of the magnetic anisotropy and magnetization of the T sublattices. In $RT_{10}Si_2$ systems, the Fe sublattice, according to the results on $YFe_{10}Si_2$, has an easy-axis magnetic anisotropy,[1,2] and the Co sublattice, according to results on $YCo_{10}Si_2$, has an easy-plane magnetic anisotropy.[3,4] The Curie temperature of $YCo_{10}Si_2$ is about 300 K higher than that of $YFe_{10}Si_2$.[4] To study the influence of the Co sublattice on the magnetic properties of 1:12 compounds, we have investigated the magnetic properties of the series $DyCo_{10-x}Ni_xSi_2$ compounds with $x=0$, 2, 4, and 6.

II. EXPERIMENTS

$DyCo_{10-x}Ni_xSi_2$ compounds with $x=0$, 2, 4, and 6 were prepared in the same way as the $DyCo_{10-x}Ni_xSi_2$ compounds reported on in Ref. 5. The temperature dependence of the magnetization of samples consisting of powder particles free to be oriented by the applied field was measured from 4.2 K to room temperature in external fields of 2 T.

In order to gather information on the type of magnetic anisotropy of the compounds at room temperature, x-ray-diffraction experiments were carried out both on magnetically aligned samples and on samples consisting of randomly oriented powder particles. Bulk samples were used in ac-susceptibility measurements which were done in the temperature range from 4.2 to 300 K. To study the easy-magnetization direction at different temperatures, the magnetization was measured in a SQUID magnetometer as a function of the angle between the alignment direction of the sample and the applied field of 1.0 T.

III. RESULTS

The temperature dependence of the magnetization of $DyCo_4Ni_6Si_2$ in a field of 2 T is shown in Fig. 1. A temperature-independent ferromagnetic impurity contribution of $0.53\mu_B$/f.u. has been subtracted in accordance with our former results.[5] From the results on $DyCo_4Ni_6Si_2$, where we were able to study the magnetization fully up to the Curie temperature, we can derive the molecular-field coefficients, n_{TT}, n_{DyT}, and n_{DyDy} by fitting the curve to the temperature dependence of the magnetization obtained in a two-sublattice molecular-field model. The following relations were used:

$$\mathbf{B}_{Dy}(T)=\mathbf{B}+n_{DyDy}\mathbf{M}_{Dy}(T)+n_{DyT}\mathbf{M}_T(T),$$

$$\mathbf{B}_T(T)=\mathbf{B}+n_{TT}\mathbf{M}_T(T)+n_{DyT}\mathbf{M}_{Dy}(T).$$

The temperature dependence of each sublattice moment is determined by the Brillouin function $B_J(x)$:

$$M_{Dy}(T)=M_{Dy}(0)B_{J_{Dy}}[\mu_{Dy}B_{Dy}(T)/k_BT],$$

$$M_T(T)=M_T(0)B_{J_T}[\mu_TB_T(T)/k_BT].$$

Because the magnetization of the Dy sublattice decreases faster with increasing temperature than does the T-sublattice magnetization, there will be a compensation temperature at which the difference between the two sublattice moments, and therefore also the critical field for breaking the antiparallel configuration, both approach zero.

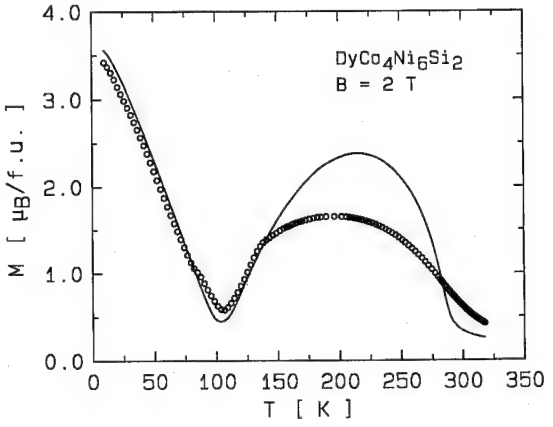

FIG. 1. Temperature dependence of the magnetization of $DyCo_4Ni_6Si_2$ in 2 T. The circles represent the experimental results and the full curve corresponds to the calculated magnetization.

 0021-8979/96/79(8)/6321/3/$10.00

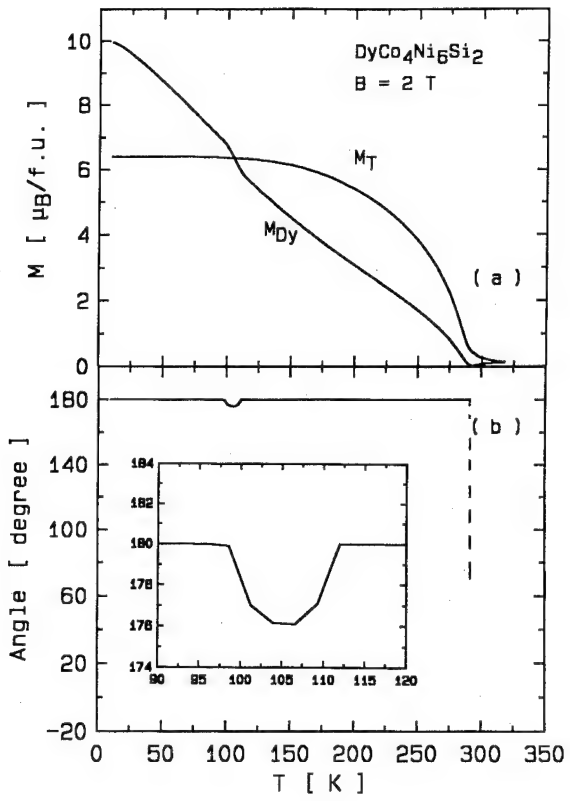

FIG. 2. (a) Calculated temperature dependence of the Dy- and T-sublattice moments in $DyCo_4Ni_6Si_2$. (b) Calculated temperature dependence of the angle between the Dy- and T-sublattice moments in $DyCo_4Ni_6Si_2$.

Therefore, in our calculation the temperature dependence of the angle between the two-sublattice moments has been taken into account. This angle, which determines the value of the magnetization, is found by minimizing the free energy:

$$F(T)=n_{\mathrm{DyT}}M_{\mathrm{Dy}}(T)M_{\mathrm{T}}(T)\cos\,\alpha - B\sqrt{M_{\mathrm{Dy}}^2(T)+M_{\mathrm{T}}^2(T)+2M_{\mathrm{Dy}}(T)M_{\mathrm{T}}(T)\cos\,\alpha}.$$

The fit to the experimental magnetization curve is shown in Fig. 1 as a solid line. The molecular-field coefficients used in the fitting procedure are $n_{\mathrm{DyDy}}=1.1\times10^{23}$ Tf.u./J, $n_{\mathrm{DyT}}=4.9\times10^{23}$ Tf.u./J, and $n_{\mathrm{TT}}=7.8\times10^{24}$ Tf.u./J. The value for n_{DyT} has been taken equal to the value derived previously from high-field magnetization measurements.[5] One can see in Fig. 1 that the magnetization above 130 K is not fitted very well. This may be due to the change of the magnetic anisotropy around this temperature which will be discussed below and/or to the crystallographic disorder of the T sublattice which may give rise to an inhomogeneous magnetization. In particular, the broadening of the magnetization around T_C may be attributed to this disorder.

The temperature dependences of the Dy- and T-sublattice moments and of the angle between M_{Dy} and M_{T} are shown in Fig. 2(b). Around the compensation temperature, the antiparallel configuration between M_{Dy} and M_{T} is broken, albeit only slightly [see insert of Fig. 2(b)]. At higher temperatures, the two sublattice moments remain antiparallel until the Curie temperature is reached.

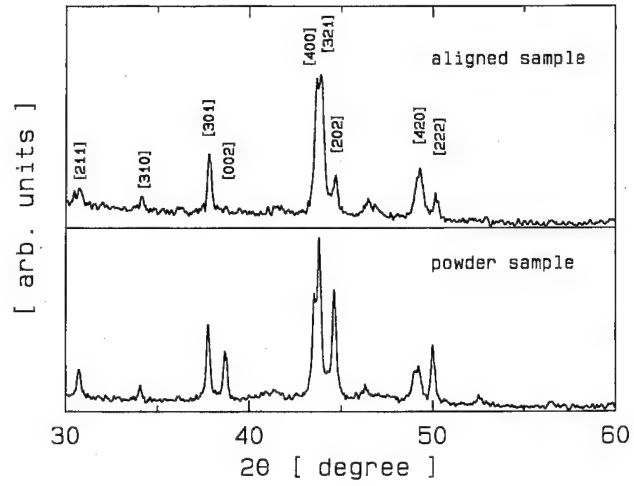

FIG. 3. X-ray diffraction patterns at room temperature on a magnetically aligned $YCo_{10}Si_2$ sample (top) and a randomly oriented powder sample.

The magnetic anisotropy of the Co sublattice is of the easy-plane type. This is demonstrated in Fig. 3 which shows x-ray-diffraction patterns taken on a magnetically aligned $YCo_{10}Si_2$ sample with the alignment direction perpendicular to the surface and on a sample consisting of randomly oriented powder. One can see that for the aligned sample, the [002] reflection has disappeared whereas the [400] reflection is strongly enhanced.

Figure 4 shows the temperature dependence of the ac susceptibility measured on bulk samples between 4.2 and 300 K. All four compounds have clear magnetic transitions. The transition at about 270 K in $DyCo_4Ni_6Si_2$ is related to the Curie temperature which is consistent with the M-T measurements. The second transition in this compound is visible as a clear kink but is rather broad in the other compounds. The small anomaly in $DyCo_4Ni_6Si_2$ at low temperatures is probably due to a second phase.

To interpret the ac-susceptibility results, the magnetization of aligned samples was measured as a function of angle between the alignment direction and the direction of the ex-

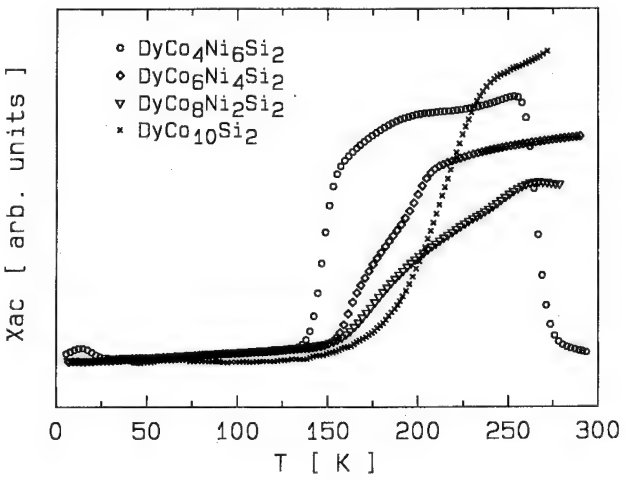

FIG. 4. Temperature dependence of the ac susceptibility of $DyCo_{10-x}Ni_xSi_2$ compounds.

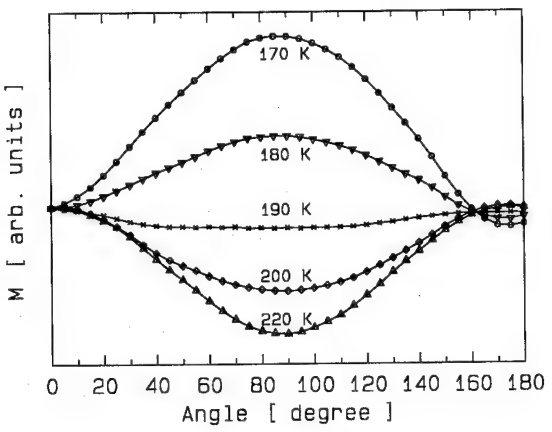

FIG. 5. Dependence of the magnetization of $DyCo_{10}Si_2$ on the angle between the alignment direction and the direction of the external field.

ternal field. The sample was mounted in such a way that the external field is along the direction in which the sample was aligned at room temperature. Therefore, at a certain temperature, the magnetization measured along the external field will get its maximum value when the easy-magnetization direction is in the field direction. The magnetization measured along the external field will get its minimum value when the hard-magnetization direction is in the field direction.

Figure 5 shows the experimental results for $DyCo_{10}Si_2$ measured at 220, 200, 190, 180, and 170 K. The curves have been normalized to the zero-angle magnetization values. The easy-magnetization direction of $DyCo_{10}Si_2$ can be seen to change at 190 K from easy plane above this temperature (established in the x-ray experiment) to easy axis below this temperature. At low temperatures, the magnetic anisotropy of the compound is dominated by the Dy-sublattice anisotropy. At high temperatures, the $3d$-sublattice anisotropy (easy-plane type) becomes most important. Between about 150 and 250 K the two sublattice anisotropies are comparable. The competition between the two sublattices can clearly be seen in Fig. 5. At 190 K, the magnetization is nearly independent of the direction of the external field, indicating that the anisotropy has become very weak.

IV. DISCUSSION AND CONCLUSIONS

It is shown that Ni substitution for Co in $DyCo_{10}Si_2$ strongly influences the magnetic anisotropy. The ac susceptibility results show that the spin-reorientation temperature decreases with increasing Ni content (see Fig. 4). This may either be due to an increase of the T-sublattice anisotropy upon Ni substitution or to a decrease of the Dy-sublattice anisotropy upon Ni substitution or to both effects. This point will be the subject of further studies.

The molecular-field analysis of the magnetization shows that the Dy-Dy exchange interaction is almost zero in $DyCo_4Ni_6Si_2$ and that n_{DyT} is about one order of magnitude smaller than n_{TT}.

The analysis of the temperature dependence of the magnetization presented in this article shows that, in systems with a compensation temperature, when the external field is not very low, the angle between the two sublattice moments has to be taken into account.

High-field magnetization measurements have been performed on both free-powder samples and magnetically aligned samples of $R(Fe,Mn)_{11}Ti$ (R=Y, Nd, Sm, Gd, Er) compounds at 4.2 K in a step field up to 28 T. The temperature dependence of ac susceptibilities of $R(Fe,Mn)_{11}Ti$ has been measured in a temperature range from 4.2 to 800 K. It has been found that both the magnetic moment of the transition-metal sublattice and the Curie temperature of $RFe_{11-x}Mn_xTi$ compounds decrease with increasing x. Spin reorientations occur in $ErFe_{11-x}Mn_xTi$ compounds as the result of competition between the uniaxial anisotropy of the transition-metal sublattice and the planar or conical anisotropy of the Er sublattice. The intersublattice exchange constants n_{RT} of $ErFe_{11-x}Mn_xTi$ compounds have been deduced by the high-field free-powder method. The effect of the substitution of Fe by Mn on the magnetic anisotropies of $R(Fe,Mn)_{11}Ti$ with R=Y, Nd, Sm has been investigated. First-order magnetization processes take place in $SmFe_{11-x}Mn_xTi$ compounds when the external field is applied perpendicular to the alignment direction. © *1996 American Institute of Physics.* [S0021-8979(96)34808-3]

I. INTRODUCTION

In the early 1980s, many efforts have been made to produce iron-rich compounds with the $ThMn_{12}$ structure by substituting Mn by Fe in RMn_{12} compounds.[1] However, since the solid solubility of Fe in $YMn_{12-x}Fe_x$ limits to $x=8$, this substitution cannot lead to an Fe-rich compound. Recently, the Fe-rich $R(Fe,M)_{12}$ compounds with the $ThMn_{12}$ structure have been obtained by adding a small amount of a third element, such as Ti, V, Cr, Mo, W, and Al.[2] So it is possible to study the effect of Mn substitution on the magnetic properties of Fe-rich rare-earth transition-metal compounds with the $ThMn_{12}$-type structure, in which the Mn is added as a fourth element to substitute part of the iron. In the present work, we have chosen $RFe_{11}Ti$ as the starting compound, and prepared the $RFe_{11-x}Mn_xTi$ compounds with $x=0$, 1, 2, 3, 4. The magnetic properties of these compounds have been investigated by high-field magnetization measurements up to 21 T at 4.2 K and ac-susceptibility measurements from 4.2 to 800 K.

II. SAMPLE PREPARATION

Polycrystalline $RFe_{11-x}Mn_xTi$ ingots with R=Y, Nd, Sm, Gd, and Er and $x=0$, 1, 2, 3, 4 have been prepared by induction-melting appropriate amounts of pure materials of a purity of at least of 99.99 wt %. The ingots were remelted two times to achieve homogeneity. Weight losses during the melting due to evaporation of the rare-earth element and Mn were compensated for by starting with an excess of 3 wt % R (with respect to the R content) and 5 wt % Mn (with respect to the Mn content). The as-cast ingots were wrapped in Ta foil and sealed in a pre-evacuated and then argon-gas-filled quartz tube, followed by annealing at 1273 K for three weeks and then water-quenched to avoid possible metallographic phase transitions during the cooling process.

The crystal structures of the samples were checked by x-ray diffraction. It was found most of the samples have the $ThMn_{12}$-type tetragonal structure and a small amount of α-Fe exists as a second phase.

III. RESULTS AND DISCUSSION

The high-field measurements at 4.2 K were performed on free-powder samples of $RFe_{11-x}Mn_xTi$ compounds to study saturation magnetization and exchange interaction. For the high-field free-powder (HFFP) measurements,[3,4] fine-powder (<40 μm) samples were loosely loaded into the sample holders. These particles can be considered as monocrystalline and are free to rotate in the external field so that the total magnetic moment of the samples is always parallel to the external field direction. The values for the saturation magnetization obtained in this way are tabulated in Table I. One can see that, for $RFe_{11-x}Mn_xTi$ (R=Y, Nd, Sm) compounds, the saturation magnetization in these compounds decreases upon Mn substitution. In the $YFe_{11-x}Mn_xTi$ compounds, since Y is nonmagnetic, the magnetic moment of the transition-metal sublattice is equal to the saturation magnetization. In $NdFe_{11-x}Mn_xTi$ and $SmFe_{11-x}Mn_xTi$, if we assume that the $4f$ electrons of rare-earth element are well localized, the moment of the transition-metal sublattice (M_T) can be obtained by subtracting the free-ion moment of the rare-earth element (M_R) from the saturation magnetization (M_s). The obtained M_T values are listed in Table II. In $GdFe_{11-x}Mn_xTi$ and $ErFe_{11-x}Mn_xTi$ compounds, M_s first

$x=4$	4.2	3.6	4.0	4.3	4.4

decreases upon the Mn substitution from $x=0$ to $x=3$, and then increases. This behavior is due to the antiparallel configuration of the moments of the transition-metal sublattice and the heavy-rare-earth sublattice. In $ErFe_{11}Ti$ and $GdFe_{11}Ti$, the magnetic moment of the Fe sublattice is much larger than that of the rare-earth sublattice so that the total magnetic moment equals to M_T-M_R. When Fe is substituted by Mn, the moment of the transition-metal sublattice decreases and causes a decrease of the saturation magnetization. If the moment of the transition-metal sublattice becomes smaller than that of the rare earth upon the Mn substitution, the total magnetic moment, which is now M_R-M_T, will increase (the case of $x=4$) with decreasing M_T. The values of the moments of the transition-metal sublattice are obtained by $M_T=M_R\pm M_s$ accordingly (see Table II).

For all investigated $RFe_{11-x}Mn_xTi$ compounds, M_T decreases monotonically with increasing x. If the mean Fe moment were not affected by substitution and the Mn ion were nonmagnetic, M_T would decrease linearly by $M_T(x)=M_T(0)(11-x)/11$, where $M_T(x)$ and $M_T(0)$ are the saturation magnetizations of $RFe_{11-x}Mn_x$ and $RFe_{11}Ti$, respectively. The experimental results obviously deviate from this line, which is similar to the case of $R(Co,Mn)_{11}Ti$ compounds.[5] One possible interpretation for the relatively fast decrease of M_T could be that the magnetic moment of iron is affected by the surrounding of Mn atoms which might be coupled antiferromagnetically with the Fe moment.[1] Another possible reason for this is that the Mn atom which is larger than Fe prefers to substitute the Fe atom on the $8i$ site where Fe has the largest moment in $RFe_{11}Ti$.[1]

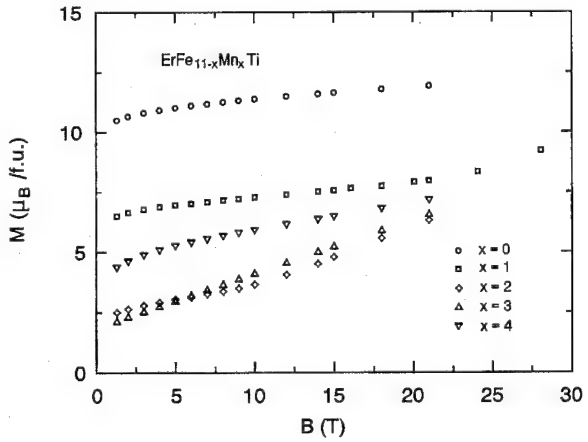

FIG. 1. Magnetic isotherms at 4.2 K of $ErFe_{11-x}Mn_xTi$ compounds measured on powder particles that are free to rotate in the sample holder.

HFFP measurements are usually used to get information about the intersublattice interaction in heavy-rare-earth transition-metal compounds.[3,4] If the external field is so high that the collinear configuration of the magnetic moments of the rare-earth and transition-metal sublattices is broken, the coupling constant n_{RT} can be obtained from the slope of the bending process if the anisotropy of at least one of the sublattices is negligible. In external fields up to 28 T, the bending process can be observed in $ErFe_{11-x}Mn_xTi$ compounds with $x=1$, 2, and 3 (see Fig. 1). Hurley[6] has measured the free-powder magnetization process of $ErFe_{11}Ti$ and its first critical field is 35 T. In the present work, the first critical fields have been determined to be 23, 10.5, and 0 T for $x=1$, 2, and 3, respectively. The coupling constants deduced from the slope in the bending section are 4.5, 4.0, and 4.5 T f.u./μ_B for $x=1$, 2, and 3, respectively. It seems that Mn substitution has no significant influence on n_{RT}. However, no bending process is found in $GdFe_{11-x}Mn_xTi$ compounds. This may be due to the relatively large n_{RT} in Gd compounds.

To investigate the effects of Mn substitution on the anisotropy of $R(Fe,Mn)_{11}Ti$ (R=Sm, Nd, Y) compounds. The high-field magnetization was measured on aligned samples with the magnetic field parallel and perpendicular to the alignment direction. In $YFe_{11-x}Mn_xTi$ compounds, the anisotropy field B_a decreases upon Mn substitution. The values obtained for B_a are 4, 3.5, and 2.5 T for $x=0$, 1, 2, respectively. The Curie temperature for compounds with $x>2$ is

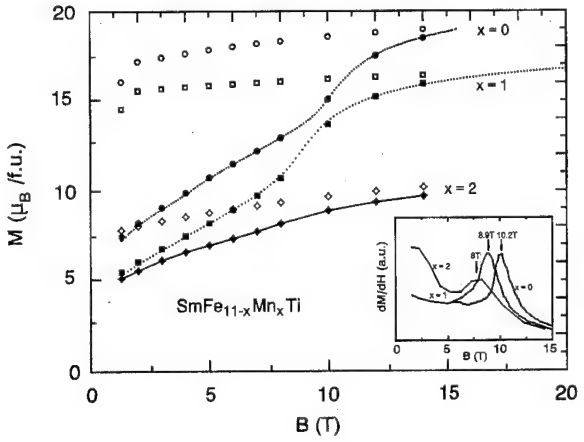

FIG. 2. Magnetic isotherms at 4.2 K of $SmFe_{11-x}Mn_xTi$ compounds measured on magnetically aligned powders. Open marks correspond to the field parallel to the alignment direction and filled marks to the field perpendicular to the alignment direction. The dots correspond to the measurements in a continuously varying field. The solid lines are guides to the eye.

TABLE III. Curie temperatures of $RFe_{11-x}Mn_xTi$ compounds.

T_c (K)	Y	Nd	Sm	Er	Gd
$x=0$	530	550	595	515	605
$x=1$	455	465	510	425	530
$x=2$	370	405	460	305	430
$x=3$	200	285	115	210	330
$x=4$	105	215	85	90	...

lower than room temperature, so we cannot prepare well-aligned samples of these compounds at room temperature. For $NdFe_{11}Ti$, the magnetization along the alignment direction is smaller than that perpendicular to the alignment direction. A possible interpretation for this may be that the weak easy-axis anisotropy of $NdFe_{11}Ti$ at room temperature[7] changes to an easy-cone anisotropy with a cone angle larger than 45° at 4.2 K. With increasing x, the magnetization parallel to the orientation direction becomes relatively large indicating that Mn substitution decreases the cone angle at low temperature or causes an easy-cone anisotropy at room temperature. Of more interest are the $SmFe_{11-x}Mn_xTi$ compounds in which first-order magnetization process (FOMP)-like anomalies appear in the magnetization curves measured along the direction perpendicular to the orientation direction (Fig. 2). These anomalies are similar to the one found by Hu *et al.*[7] in $SmFe_{11}Ti$. The critical field, corresponding to the maximum of the first derivative of the magnetization curve, decreases upon Mn substitution. The critical fields in $SmFe_{11}Ti$ and $SmFe_{10}MnTi$ are 10.2 and 8.9 T, respectively. In $SmFe_9Mn_2Ti$, the anomaly becomes hard to distinguish because of the poor alignment of the powder at room temperature, and the critical field decreases to about 8 T. These anomalies may be due to field-induced first-order transitions or quasi-FOMPs.[8]

The ac susceptibilities of $RFe_{11-x}Mn_xTi$ compounds were measured in the temperature range from 4.2 to 800 K. The obtained T_c values are listed in Table III. T_c decreases monotonically with increasing x. This is similar to the concentration dependence of M_T. Spin reorientations from easy axis at high temperature to easy cone or easy plane at low temperature were found in $ErFe_{11-x}Mn_xTi$ compounds. At T_{SR} and above, the uniaxial iron anisotropy usually determines the magnetization direction but at lower temperatures the rare-earth anisotropy may be dominant. The T_{SR} corresponds to the minimum of $d\chi'/dT$. The T_{SR} for compounds with $x=0$, 1, 2, 3 are 48, 50.5, 99.4, and 171.4 K, respectively. The decrease of T_{SR} with increasing x may imply that the uniaxial anisotropy of the transition-metal sublattice decreases upon Mn substitution.

In conclusion, both the magnetic moments of the transition-metal sublattice and the Curie temperatures of the $RFe_{11-x}Mn_xTi$ ($x=0$, 1, 2, 3, 4) compounds decrease with increasing x. The introduction of Mn atoms, which are nonmagnetic or possess a magnetic moment antiparallel to the Fe moments, gives rise to a decrease of the mean Fe moment. In $RFe_{11-x}Mn_xTi$, the transition-metal sublattice possesses uniaxial anisotropy which decreases upon Mn substitution. In $RFe_{11-x}Mn_xTi$ (R=Nd, Er), there exists competition between the uniaxial anisotropy of the transition-metal sublattice and the planar or conical anisotropy of the rare-earth sublattice, which gives rise to spin reorientations in the $ErFe_{11-x}Mn_xTi$ compounds. FOMP-like anomalies found in $SmFe_{11-x}Mn_xTi$ compounds indicate that the high-order anisotropies play an important role in the magnetization processes of these compounds.

Temperature and field-induced spin reorientations in $NdFe_{10-x}Co_xMo_2$ single crystals

W. A. Mendoza and S. A. Shaheen
Department of Physics and Center for Materials Research and Technology (MARTECH), Florida State University, Tallahassee, Florida 32306

Single crystals of the $NdFe_{10-x}Co_xMo_2$ alloy system ($x=0,1,3,5,7,10$) have been prepared by the Czochralski technique and studied by x-ray and magnetometry techniques. All of the compounds in this series crystallize in the tetragonal $ThMn_{12}$-type structure. The single-crystal data support the previous findings on polycrystalline samples, namely, that (1) with increasing Co content, the easy direction of magnetization at 300 K appears to deviate from the c axis for $x \leqslant 3$, and becomes axial for $x \geqslant 5$; (2) temperature-induced spin reorientations are observed for $x<3$; and (3) for $x \geqslant 5$, no temperature-induced but field-induced spin reorientations are observed. Single-crystal data also clarify the anomalies observed in the temperature-dependent magnetization data on polycrystalline samples. © *1996 American Institute of Physics.* [S0021-8979(96)34908-X]

I. INTRODUCTION

Rare-earth-3d transition metal compounds are a fertile area for searching for new materials for permanent magnet applications. In recent years, the attention has been focused on iron-rich ternary compounds of the form $RFe_{12-x}M_x$ (R=rare-earth element, M=Ti, V, Cr, Si, Mo; $x=1$ or 2).[1–7] These compounds crystallize in the $ThMn_{12}$-type structure. The binary RFe_{12} alloys are unstable and 1–2 M atoms are needed to stabilize this structure. The Fe and M atoms occupy the three nonequivalent transition metal sites in this structure. In these compounds, those rare earths with a positive second-order Stevens factor ($\alpha>0$) (e.g., Sm, Er, Tm, Yb) prefer magnetization along the c axis, and so does the Fe. On the other hand, rare earths with $\alpha<0$ (e.g., Nd, Tb, Dy, Ho) prefer magnetization in the basal plane. Nitrogen can be introduced at the interstitial sites in an amount up to one atom per formula unit and causes a lattice expansion. Adding N atoms to the structure enhances the magnetic ordering temperature and changes the easy direction of magnetization (EDM).

The effect of Co substitution on structure and magnetic anisotropy has been studied on a number of systems with the $ThMn_{12}$-type structure, e.g., $RFe_{11-x}Co_xTi$,[8–10] $RFe_{10-x}Co_xV_2$,[11–13] and $RFe_{10-x}Co_xMo_2$.[14–18] From these studies, it has been established that the Curie temperature and magnetic moment initially increase and the EDM goes through a complex cycle of changes, as Fe is gradually substituted by Co in these compounds. In the $RFe_{10-x}Co_xMo_2$ series, temperature and field-induced spin reorientations are observed.[14–18] In this series, the compounds containing R elements with $\alpha<0$ have their EDM (at room temperature) initially slightly deviating from the axial direction (c axis). The EDM turns to the basal direction at the intermediate Co concentrations, and finally returns back to the axial direction at higher Co concentrations. On the other hand, for compounds containing R elements with $\alpha>0$, the EDM (at room temperature) is along the c axis at the Fe-rich end and it starts becoming nonaxial as Fe is substituted by Co and is along the basal direction for Co-rich alloys. Previous studies on polycrystalline samples across the $NdFe_{10-x}Co_xMo_2$ series[16,19] suggested the possibilities of preferential substitution of Co at three nonequivalent sites available for the occupation of 3d metal elements in this lattice structure and canting of the spins. To gain further insight into this system, single-crystal samples have been prepared across the $NdFe_{10-x}Co_xMo_2$ series.

II. EXPERIMENT

$NdFe_{10-x}Co_xMo_2$ alloys ($x=0$, 1, 3, 5, 7, 10) were prepared by melting together metals of high purity (99.9% or higher) in a water-cooled triarc furnace in a flowing argon gas atmosphere. The alloys were melted several times to ensure homogeneity. The crystals were then pulled from the arc-melted alloys by the Czochralski method. The crystals are typically 2–3 mm in diameter and 10–15 mm in length. The crystals were cut approximately perpendicular to the growth direction and then the cut surface was smoothed for x-ray diffraction studies. A Siemens diffractometer (D500) and Cu $K\alpha$ radiation were used for x-ray examination. Only one line was observed for each sample. For $x=0$, 1, 7, the (101) line was observed, and for $x=3$, 5, 10, the (002) line was observed. The magnetic anisotropy measurements on the samples which showed (002) reflections on x-ray examination showed results identical to those obtained on the aligned powder samples, which in turn confirmed the crystallographic ordering of the crystals and anticipated growth along the c axis. However, these observations do not fully confirm the single-crystal nature of our samples, and the possibility of growth of multiple seeds with axial orientation along the growth direction is not ruled out.

A Quantum Design SQUID magnetometer with external fields up to 55 kOe was used for the measurements of the saturation magnetization (M_s). For measurements in fields up to 70 kOe, a Quantum Design SQUID magnetometer at the National High Magnetic Field Laboratory was used. The samples used for magnetic measurement were 2–3 mm in diameter and 5–8 mm in length.

III. RESULTS AND DISCUSSION

The spin reorientations, described as a change of the EDM from one crystallographic direction to another with

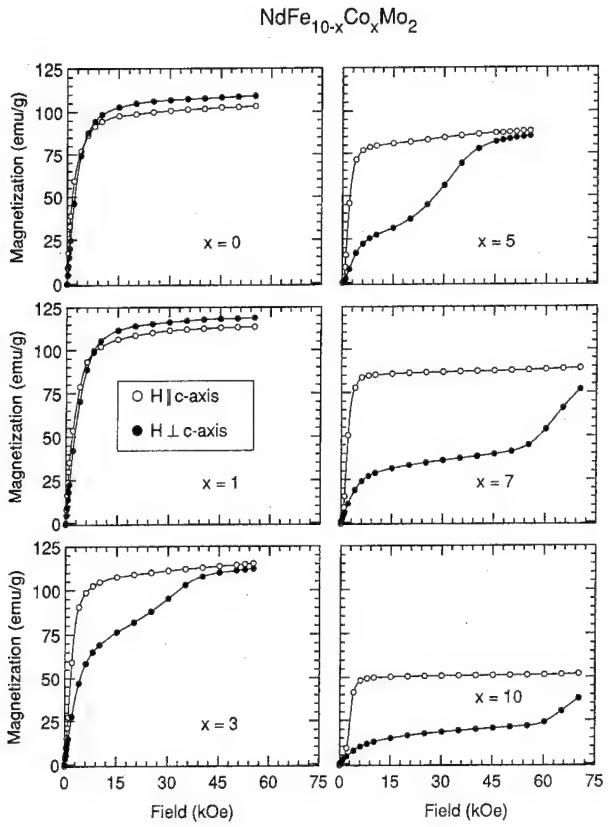

FIG. 1. Magnetization as a function of applied field for the crystals across the $NdFe_{10-x}Co_xMo_2$ series at 5.0 K.

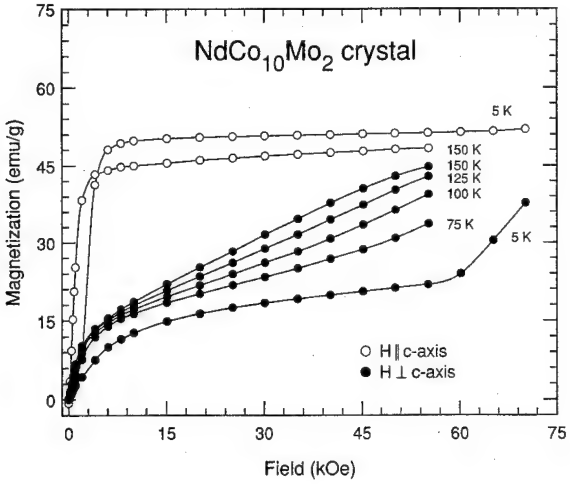

FIG. 2. Magnetization as a function of applied field for the $NdCo_{10}Mo_2$ crystal at different temperatures.

varying temperature, were detected in the ac susceptibility and dc magnetization measurements for $x=0$, and 1 in the $NdFe_{10-x}Co_xMo_2$ series. The observed spin reorientation temperatures of 180 K (for $x=0$) and 190 K (for $x=1$) are in agreement with the published data.[16,20] These spin reorientations appear to be planar to cone type transitions with increasing temperature.

The results of the magnetization versus magnetic field measurements across the $NdFe_{10-x}Co_xMo_2$ series at $T=5$ K in fields up to 70 kOe are displayed in Fig. 1. The samples with small Co content have very little magnetic anisotropy, and measurements with H parallel to the c axis and with H perpendicular to the c axis are nearly identical. On the other hand, for $x=3$, 5, 7, 10, there is a marked difference in magnetization when H is parallel to the c axis and when H is perpendicular to the c axis. For $x=5$, 7, and 10, the magnetization along the hard direction ($H\perp c$ axis) initially increases as a function of field but unlike the spontaneous rise for magnetization along the easy axis, the magnetization along the hard axis does not shoot to its saturation value at low fields. At intermediate field values, the magnetization shows a plateau at a value which is less than half of the saturation magnetization (saturation along the easy axis). At higher field values, there is a spontaneous jump in magnetization and the magnetization value eventually tends to approach the saturation value. These jumps in magnetization along the hard axis occur at about 30, 60, and 65 kOe for $x=5$, 7, and 10, respectively, and are associated with reorientation of spins due to the shift in the EDM from one crystallographic direction to another under the influence of the magnetic field. Therefore, they are referred to as field-induced spin reorientations. They are sometimes also called first-order magnetization processes. There is also some indication of a first-order magnetization process for $x=3$ (see Fig. 1). These data on single-crystal samples are in excellent agreement with measurements on aligned polycrystalline samples in our laboratory[16] and elsewhere.[21]

Figure 2 shows the magnetization versus field data at various temperatures for $x=10$. It is apparent that the field at which the magnetization jump occurs is dependent on the temperature and decreases as the temperature is increased.

During the studies on polycrystalline $NdFe_{10-x}Co_xMo_2$ samples, some observations were made which could not be fully understood and prompted the need for single-crystal samples. One of the observations which was not understood at that time was the unusual temperature dependence of the magnetization at the Co-rich end of the series. The saturation magnetization (in 50 kOe) on randomly oriented chunk samples showed an initial increase on cooling, as expected. However, when cooled below a certain temperature (~200 K), the magnetization started decreasing. Since Nd and Fe (and or Co) spins are expected to align parallel to each other, a decrease in the magnetization at low temperature is not expected. The measurements on single-crystalline samples shed some light on this aspect. Figure 3 shows the temperature dependence of magnetization (in 50 kOe) on various single-crystal samples across the $NdFe_{10-x}Co_xMo_2$ series. For all samples, the magnetization along the easy axis increases monotonically from its room temperature value to 5 K. The noteworthy features are the strong decrease of magnetization for the field along the direction perpendicular to the easy axis for $x=7$ and $x=10$. This decrease in magnetization can be understood in terms of the magnetic anisotropy and field-induced spin reorientations in these samples. The decrease in the magnetization along the hard axis for $x=7$ and 10 is consistent with the corresponding low value of magnetization along the hard axis in magnetization versus field data at 5 K in Fig. 1. It may be noted that for $x=5$, the magnetization in both directions is monotonically increasing

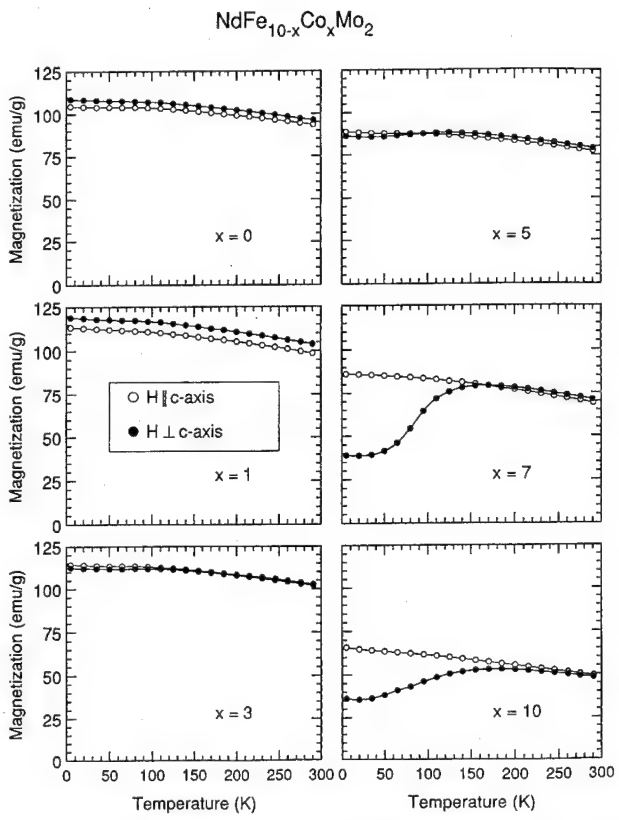

FIG. 3. Temperature dependence of the magnetization in a field of 50 kOe for the $NdFe_{10-x}Co_xMo_2$ crystals.

with the decreasing temperature, even though like $x=7$ and 10, first-order magnetization processes are observed at this composition. The difference lies in the fact that magnetization measurements in Fig. 3 were made in a 50 kOe field that is well above the 30 kOe field at which the spin reorientations for $x=5$ occur and is lower than the field (60–65 kOe) needed to induce the spin reorientations for $x=7$ and 10.

N. V. Kudrevatykh and P. E. Markin
Institute of Physics and Applied Mathematics, Ural State University, 620083 Ekaterinburg, Russia

Very large discrepancies exist with regard to the spin reorientation transition in $TbFe_{11}Ti$ (see Ref. 1 for a summary of the different results). In this work, this transition is studied by measuring the angular dependence of the parallel ($M_{\parallel}$) and perpendicular ($M_{\perp}$) components of the magnetization to the applied magnetic field in the temperature range of 4.2–330 K and applied magnetic fields ranging from 2 to 15 kOe. This method allows an accurate determination of the easy magnetization direction to be made, i.e., the maximum value of $M_{\parallel}$ and the zero value of $M_{\perp}$. The experimental results have undoubtedly established that the compound is easy plane below 260 K and easy axis above 320 K. Within this intermediate range of temperature the easy magnetization direction lies along a nonmajor symmetry direction making an angle θ with the c axis. This angle depends on the applied magnetic field and the magnetic history of the sample. This fact can be understood on the basis of the existence of a first-order spin reorientation transition at $T_{SR} \approx 320$ K from easy axis to easy plane. Within the temperature region 206–320 K both phases (axial and planar) coexist with relative volumes depending on the applied magnetic field and the magnetic history. This gives rise to a macroscopic conical structure. Such behavior has already been observed in $DyFe_{11}Ti$.[2] [S0021-8979(96)65308-4]

Magnetic and structural characteristics of $LaCo_{9+\delta}Si_4$ and $LaCo_{8.5+\delta}Si_{4.5}$ alloys (δ=0–4)

M. Q. Huang, Jason Wolf, and W. E. Wallace
Department of Materials Science and Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213

$LaCo_{9+\delta}Si_4$ and $LaCo_{8.5+\delta}Si_{4.5}$ alloys with δ=0 to 4 have been synthesized and characterized. The stoichiometric alloys (δ=0) have low T_c and small moments, whereas the alloys with $\delta \neq 0$ have larger T_c and magnetization. © *1996 American Institute of Physics.* [S0021-8979(96)35008-4]

I. INTRODUCTION

The $RCo_{13-x}Si_x$ systems have recently been receiving considerable attention in this and other laboratories as potential high-energy magnet materials.[1–7] Si doping is being extensively employed to generate uniaxial symmetry of the alloys. With extensive Si doping, the cubic symmetry is degraded to tetragonal, allowing the possibility of significant anisotropy. However, T_c and magnetization sharply decrease. In the present study, efforts are made to prepare and characterize alloys that will crystallize in the tetragonal form but will not lose the desirable T_c and B_{sat}. Ukranian workers Fedna *et al.*[8] formed about ten years ago a tetragonal phase $Pr_{0.69}(Co,Ge)_{13}$. It can be viewed as a nonstoichiometric (Co,Ge)-rich $Pr(Co,Ge)_{13}$ phase. The work by Fedna *et al.* suggested that the Si counterpart of the Fedna alloy warranted attention. Accordingly, several nonstoichiometric $LaCo_{9+\delta}Si_4$ and $LaCo_{8.5+\delta}Si_{4.5}$ alloys were prepared and studied with δ ranging from 0 to 4.

II. EXPERIMENTAL DETAILS

The alloys were prepared by induction melting under high-purity argon, after which they were heat treated at 1273 K for about one week. X-ray diffraction (XRD) with Cu radiation was used to determine the crystal structure, lattice parameters, and phase present. The Hot Stage XRD was performed at temperatures ranging from room temperature to 1023 K under vacuums to determine the structure at high temperature. The relative amount of bct and fcc phases present were established by quantitative XRD measurements. The Jandel Scientific "Peak Fit" and "Desktop Microscopist" computer programs were employed to perform XRD deconvolution and structure factors calculations, respectively. The magnetic properties (M and T_c) were measured by vibrating sample magnetometers (VSM) at temperatures ranging from 10 to 1173 K and fields ranging from 100 Oe to 17 kOe. The TMA measurements were made in such a manner—low applied field (500 Oe) and variable heating rate—to provide the most reliable information about phases present and the values of T_c.

TABLE I. Phases present and crystal structures of $LaCo_{9+\delta}Si_4$ and $LaCo_{8.5+\delta}Si_{4.5}$ (δ=0–4).

III. RESULTS AND DISCUSSION

A. Phases formed and structural information

The relative amounts of the bct and fcc phases present were established by quantitative XRD measurements;[9] the

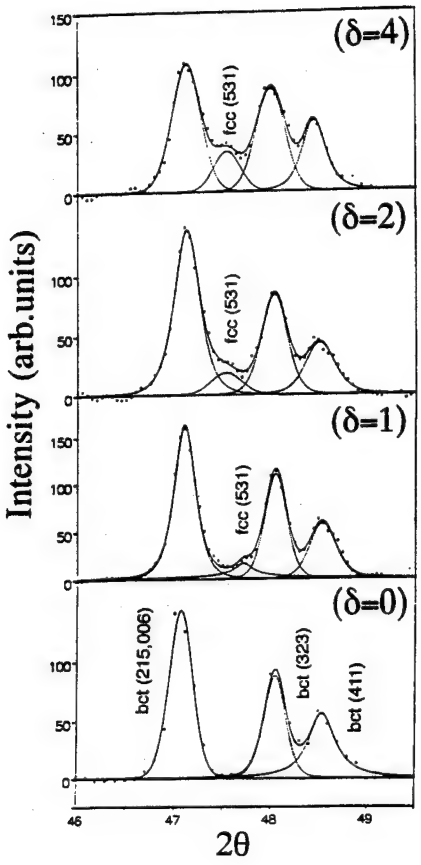

FIG. 2. XRD for $LaCo_{9+\delta}Si_4$ alloys. The lower portion is for a single-phase material (bct). The upper portion is for the two-phase system. As d increases, the fcc phase increases.

m_{bct}-mass factor for the bct phase are listed in Table I. Structural information is summarized in Table I. The tabulated results are derived from the data in Figs. 1 and 2. $LaCo_9Si_4$ and $LaCo_{8.5}Si_{4.5}$ may be regarded as the base alloys to which extra Co, δ is added. The base alloys form in the bct $Ce_2Ni_{17}Si_9$ structure. It is interesting to attempt to ascertain where the extra Co's go. There are at least two possibilities: (1) They may precipitate out as a pure Co phase or (2) they may enter the bct lattice, substituting for La and Si atoms. This issue will be considered shortly.

The similarity of the XRD patterns (Fig. 1) indicates that the main phase for all the alloys ($\delta \neq 0$) has the same structure as the stoichiometric alloys ($\delta=0$). The ratio c/a decrease as d increases, a point that will be returned to later. A minor phase was observed and was found to form in the fcc $NaZn_{13}$ structure. A small amount of Co_2Si was detected in some alloys, as shown in Fig. 1. TMA results, to be discussed below, were consistent with the XRD findings. An important result of the TMAs was that there was no evidence of elemental Co in any of the alloys. This was also indicated by the XRD patterns obtained. The lack of Co lines in the XRD patterns is not unexpected since XRD is less sensitive than TMA.

The location of the extra Co atoms is a matter of considerable interest. The site occupancies in $Ce_2Ni_{17}Si_9$ are as follows: 4 Ce in $4a$; 2 Si+2 Ni in $4d$; 16 Ni in $16k$; 16 Ni in $16l_1$; 16 Si in $16l_2$. The extra Co in the nonstoichiometric alloys is assumed to reside in the $4a$ and $16l_2$ sites. (The $4d$ sites are excluded because they are so much fewer in number than the $16l_2$ sites.) The composition of the main phase of the example alloy $LaCo_{11}Si_4$ accords with site occupancies as follows: $4a$ {3.5 La+0.5 Co}; $4d$ {2 Co+2 Si}; $16k$ {16 Co}; $16l_1$ {16 Co}; $16l_2$ {4 Co+12 Si}. Using $LaCo_{11}Si_4$ as an example, the fraction of the La or Si sites which are occupied by Co is 0.125 and 0.25, respectively. The fraction of the $4a$ sites occupied by Co ranges from 0.067 for $\delta=1$ to 0.223 for $\delta=4$.

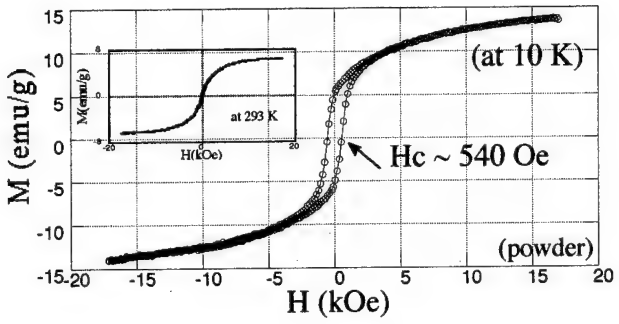

FIG. 3. Hysteresis loop of loose powder for $LaCo_{10}Si_4$ at 10 K.

The site occupancies cited in the preceding paragraph may be substantially overestimated. The surplus Co has been allocated to a portion of the $4a$ and $16l_2$ sites, assuming that one Co atom replaces one La atom. One would expect a decrease in c and c/a, since La atom, which located along c axis ($4a$ sites) was replaced by Co atom, the latter is much smaller than the former. Actually, there might exist the situation such as in R_2Co_{17} in which the 2:17 structure is formed by Co pairs (often called dumbbells) replacing R in the RCo_5 structure. If R is replaced by pairs of Co, the fraction of the sites not occupied by rare earths will be reduced by about 50% in the nonstoichiometric 1:13 system. If dumbbell Co's are indeed involved, this might also account for the tetragonal structure of the system. If the dumbbell axis lies along the a axis, one would expect expansion of a and a decrease

[a]T_c cannot be detected at 10 K.

in the axial ratio. This is in accord with experiment. Although it is tempting to relate the decrease in axial ratio to the substitution of La by Co pairs, other factors are undoubtedly involved. If there is a 1 for 1 Co for La substitution, one should write $LaCo_{11}Si_4$ as $(La_{3.5}Co_{0.5})(Co_{38}Si_{14})$ to emphasize the observance of the 1:13 structure.

The replacement of nonmagnetic La with magnetic Co should profoundly affect the magnetism of the alloy, raising T_c, for example.

B. Magnetic properties

The magnetic properties T_c, M, and H_c are given in Figs. 3–4 and in Table II.

From the results presented, it is to be noted that the stoichiometric alloys with δ=0, which are bct, have a low moment and low T_c. The isostructural La-poor nonstoichiometric alloys with $\delta\neq0$, which are in bct and fcc two-phase mixture, show a higher moment and two Curie temperatures T_c. The fcc phase has a T_c above room temperature, up to 1103 K. The bct phase has a lower T_c down to temperature <40 K.

As expected, with increasing Co content, the T_c for both phases increased. In the $LaCo_{9+\delta}Si_4$ case, the bct phase has a T_c ranging from 40 K (δ=0) to 125 K (δ=4), and in the fcc phases T_c is increased from 1023 K (δ=1) to 1103 K (δ=4). In the $LaCo_{8.5+\delta}Si_{4.5}$ case, the T_c of the bct phase with δ=0 cannot detected even at 10 K, but for $\delta\neq0$, T_c increased from 50 K (δ=1) to 75 K (δ=3).

The magnetization observed M_{ex} at 10 K, is contributed by both the weakly magnetic bct phase and the strongly fcc phase. One can estimate the bct main phase's moment, M_{cal}(bct), by making use of quantitative XRD measurement,[9] employing "Peak Fit" and "Desktop Microscopist" computer programs to estimate the phases present. As listed in Table II, M_{cal} (bct) increases with increasing Co content δ. In the $LaCo_{9+\delta}Si_4$ case, M_{cal}(bct) for $\delta\neq0$ is fourfold to sixfold higher than that of the δ=0 alloy. In the $LaCo_{8.5+\delta}Si_{4.5}$ case, even higher, up to tenfold increases, is observed.

A coercive force of ~540 Oe was observed in loose powder samples of $LaCo_{10}Si_4$ at 10 K (see Fig. 4). Similar behavior was observed in other samples (see Table II). The origin of this behavior may be due to a change in anisotropy or exchange hardening. The latter may occur in a fine mixture of hard and soft phases. It appears to be a consequence of the extra cobalt. Figure 5 shows the M vs T about 293 K in a chunk sample of $LaCo_{13}Si_4$ alloy. The heating curve shows an increase of M with increasing T. A puzzling sharp drop in M occurs at $T\sim853$ K during cooling. The XRD patterns before and after this cycle show the main structure did not change. However, Hot Stage XRD patterns show that the intensity for some lines changed when cooling to 773 K, but then returned to normal upon cooling to 373 K. This behavior may be related to some type of order-disorder transformation which affects the Co-Co magnetic interaction. A surprising feature is that the drop is not in powder samples (see insert in Fig. 5). A similar situation was found in other alloys of $LaCo_{9+\delta}Si_4$ ($\delta\neq0$). Further investigation about this unusual behavior and also the odd coercivity behavior cited above is in process.

In connection with a previous work,[1] magnetic and crystallographic properties of the off-stoichiometric compounds $R_2Fe_{14}Si_2$ of the R_2Fe_{17}-type are studied. Magnetization curves at T=5 K are observed in a high magnetic field up to 15 T for loose powders as well as for field-aligned powders of the samples expressed in the title. Temperature dependencies of the spontaneous magnetizations are also determined in the temperature region from 5 K to the respective Curie temperature. Detailed x-ray analysis is carried out for $Y_2Fe_{14}Si_2$. Conclusions are as follows: (1) the Si substitution brings about significant displacements of the 12j-site Fe as well as the dumbell-site Fe from their original positions, which is discussed in connection with other present experimental data such as the remarkable enhancement of the Curie temperature caused by the Si substitution; (2) averaged Fe moment reduction is strictly determined for the present samples; (3) all the samples have a planer anisotropy at room temperature, taking this fact the magnetization curves for the field-aligned samples are analyzed; (4) exchange interaction between R sublattice and Fe sublattice has been determined for all the samples. Effect of Fe and/or Cu contents on the intrinsic coercivity of Sm_2Co_{17}-type coercive powders for the bonded magnet application

W. L. Liu, Y. L. Liang, D. W. Scott, B. M. Ma, and C. O. Bounds
Rhône-Poulenc, Rhône-Poulenc Rare Earths and Gallium, CN 7500, Cranbury, New Jersey 08512

The microstructure of conventionally cast $Sm(Co_{bal}Fe_{0.28}Cu_vZr_{0.022})_{8.0}$ alloys, where $v=0.043$–0.092, were examined by optical microscopy and scanning electron microscope with energy dispersed analytical x ray in the as-cast state. In addition to the regular 2:17 matrix phase, the Sm-rich grain boundary phase and the needle-like Zr-rich phases are present in most commercial $Sm(Co,Fe,Cu,Zr)_z$ alloys. A grayish Sm- and Cu-rich grain boundary phase was found in alloys with $v \geqslant 0.07$. Attention was focused on the impact of increasing Cu content to the microstructure and process parameters required to produce coercive powder for bonded magnets. An increase of the Cu content from the v value from 0.043 to 0.092 shifts the liquid+2:17→$TbCu_7$-type transformation temperature from slightly above 1180 to approximately 1140 °C. The H_{ci} of optimally prepared magnet was found to increase significantly while the B_r remained relative constant when the Cu content is increased. When the Cu content was increased to beyond $v=0.07$, a slight decrease in the BH_{max} was noticed. A magnetizing field of 15 kOe and more than 50 kOe were determined to be necessary to charge magnets with a H_{ci} of 12 and 25 kOe, respectively, to about 90% of their full potential. For a composition of $Sm(Co_{bal}Fe_uCu_{0.07}Zr_{0.022})_{8.0}$, a slight increase in Fe concentration from $u=0.22$ to 0.28 was found to increase the B_r of an optimally prepared magnet from 8.07 to 8.28 kG and decrease the H_{ci} from 11.8 to 9.7 kOe. A BH_{max} of 15 MGOe was obtained on a bonded magnet with a composition of $Sm(Co_{bal}Fe_{0.28}Cu_{0.07}Zr_{0.022})_{8.0}$ when the data are normalized to a specific density of 7.0 g/cm^3. © *1996 American Institute of Physics.* [S0021-8979(96)35108-0]

I. INTRODUCTION

Although NdFeB-type permanent magnets have gained most of the attention in the magnet industry in the past decade, outstanding thermal stability and high-energy product (BH_{max}) at elevated temperatures make $Sm(Co,Fe,Cu,Zr)_z$ magnets attractive for advanced applications.[1,2] The near net-shape production of $Sm(Co,Fe,Cu,Zr)_z$ bonded magnets make them potentially superior to any magnets made by the sintering route.

In our previous work,[3] we have generally identified the three major phases, namely, the 2:17 matrix phase, the Sm-rich grain boundary phase, and the Zr-rich phases embedded in the grain boundary region, present in the as-cast alloy. The influence of Zr on the solidus curves of liquid+2:17 →$TbCu_7$-type structure transformation, their impact on the selection of processing parameters and, consequently, the H_{ci} of the powders were also discussed.[4] In this article, we discuss the effect of Cu to Fe ratio on the H_{ci} obtained on the coercive powders. We will also try to establish a relationship between the H_{ci} obtained and the magnetizing field required to achieve full potential properties.

II. EXPERIMENT

An alloy series with the composition of $Sm(Co_{1-u-v-w}Fe_uCu_vZr_w)_z$, where $u=0.22$–0.28, $v=0.043$–0.092, and $w=0.02$–0.029, and z varied from 7.9 to 8.3, was prepared by vacuum induction melting and conventional mold casting. An isothermal anneal in the temperature range of 1130–1210 °C was applied to cast ingots in order to homogenize the microstructure. At the end of homogenization, ingots were quenched to 200 °C under an argon atmosphere. A precipitation hardening treatment (step aging) was then applied to the homogenized ingots to develop their H_{ci}. Alloy ingots were pulverized by a hammer mill to less than 40 μm. Cylindrical bonded magnets were produced by mixing the alloy powder with a 2 wt % epoxy resin, aligning with a 60 kOe pulse magnetic field and pressing isostatically. After curing, the magnets were demagnetized then sliced to about 10 mm in length for magnetic property measurements. The bonded magnets included in this work all exhibited a specific density of more than 6.1 g/cm^3. Samples were then pulse magnetized in a field of 60 kOe prior to magnetic measurement. The magnetic properties, namely, the B_r, H_{ci}, and BH_{max}, were measured by a Walker Hysteresisgraph System model MH-50. The B_r and BH_{max} values reported are normalized to a specific density of 7.0 g/cc, which is the density of most commercial $Sm(Co,Fe,Cu,Zr)_z$ bonded magnets.

The microstructure of alloy ingots at various processing stages was examined by an Olympus PMG-3 microscope under normal mode. A scanning electron microscope (SEM) with energy dispersed analytical x ray (EDAX) was utilized to determine the Cu distribution in the grain boundary region of treated samples.

III. RESULTS AND DISCUSSION

Shown in Fig. 1 are optical micrographs of cast ingots with a nominal composition of $Sm(Co_{bal}Fe_{0.28}Cu_vZr_{0.022})_{8.0}$, where $v=0.043$, 0.056, and 0.092. As in most of the commercially cast $Sm(Co,Fe,Cu,Zr)_z$ alloy, three major phases, namely, the Sm_2Co_{17} matrix phase, the Sm-rich grain boundary phase, and the needle-like Zr-rich phase embedded in the grain boundary phase region, are present in all cast alloys. A grayish phase in the grain boundary region was also detected in alloys of high Cu concentration ($v \geqslant 0.07$). SEM EDAX

FIG. 1. Optical micrographs of $Sm(Co_{bal}Fe_{0.28}Cu_vZr_{0.022})_{8.0}$, where $v=$(a) 0.043, (b) 0.056, and (c) 0.092, ingots in the as-cast state.

analyses, shown in Fig. 2, reveal significant enhancements on both the Sm/Co and Cu/Co intensity ratios when the Cu content was increased from 0.043 to 0.092. This suggested that the solubility of Sm in the grain boundary region increases with increasing Cu content in the cast alloy. A slight suppression of the Zr peak was also noticed when the Cu

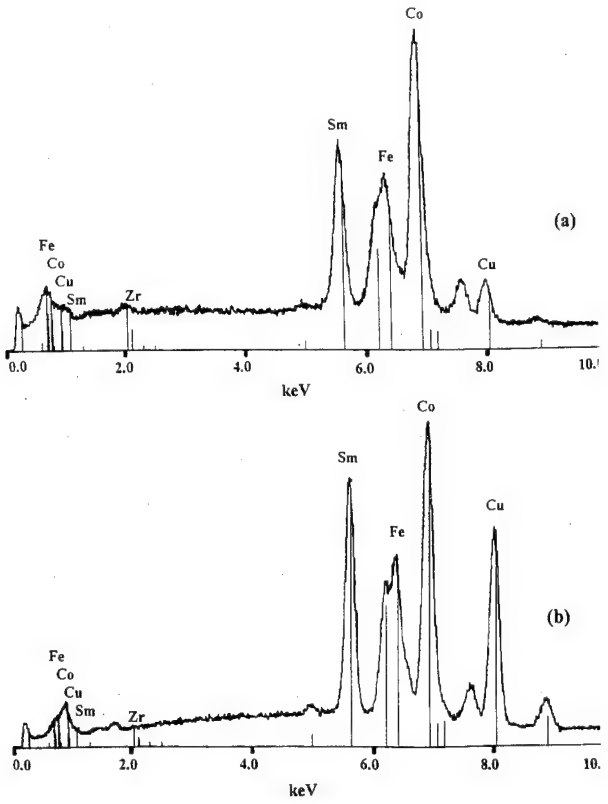

FIG. 2. SEM EDAX analyses of $Sm(Co_{bal}Fe_{0.28}Cu_vZr_{0.022})_{8.0}$, where $v=$(a) 0.043 and (b) 0.092, ingots in the as-cast state.

content (v value in the formula expression) was increased from 0.043 to 0.092. These changes in the Sm, Cu, and Zr distribution in the grain boundary region may also change the position of the solidus line for the liquid+2:17→$TbCu_7$ phase transformation and, consequently, the solid solution treatment temperature required and the magnetic proprieties obtained.

Shown in Figs. 3(a), 3(b), and 3(c) are optical micrographs of three ingots with a nominal composition of $Sm(Co_{bal}Fe_{0.28}Cu_vZr_{0.022})_{8.0}$, where $v=0.043$, 0.056, and 0.092, respectively, after an isothermal annealing at a temperature of 1180 °C. For $v=0.043$ [shown in Fig. 3(a)], the microstructure exhibited a nearly single-phase material with the exception of a few Zr-rich spots scattered in the matrix phase. This relatively uniform microstructure suggests the ingot was annealed at a temperature below the solidus curve.[3] With a slight increase in Cu content [$v=0.056$ shown in Fig. 3(b)], a band-like liquid phase can vaguely be observed around the grain boundary region indicating the ingot was heat treated at a temperature slightly above the solidus curve. When the Cu content was further increased to $v=0.092$ [shown in Fig. 3(c)], the presence of the liquid phase became very pronounced indicating the ingot was treated at a temperature well above the solidus curve. Employing the same technique to a series of alloys, the liquid+2:17→$TbCu_7$ phase transformation temperature was determined to decrease linearly from a temperature slightly above 1180 to approximately 1140 °C when the Cu content v was increased from 0.043 to 0.092. This decrease of the liquid+2:17→$TbCu_7$ phase transformation temperature sug-

FIG. 3. Optical micrographs of $Sm(Co_{bal}Fe_{0.28}Cu_vZr_{0.022})_{8.0}$, where $v=$(a) 0.043, (b) 0.056, and (c) 0.092, ingots after an isothermal annealing at a temperature of 1180 °C for 6 h.

gests that it is necessary to adjust the solid solution treatment for each Cu concentration to obtain the optimum structure and magnetic properties, particularly the H_{ci}, desired.

Shown in Fig. 4 are the relationships of the B_r, H_{ci}, and BH_{max} of bonded magnets to the Cu content for a magnet

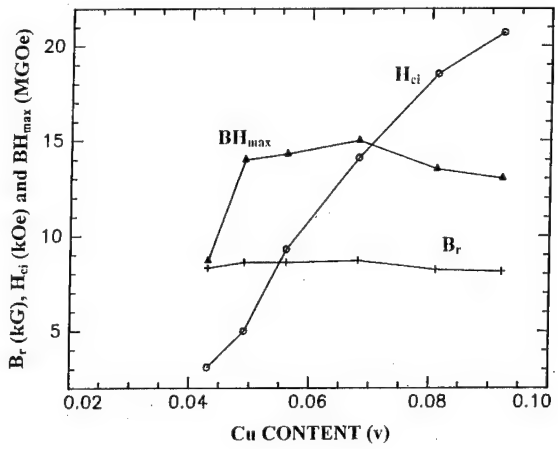

FIG. 4. The variation of B_r, H_{ci} and BH_{max} with the Cu content for an alloy series with a nominal composition of $Sm(Co_{bal}Fe_{0.28}Cu_vZr_{0.022})_{8.0}$, where $0.043 \leq v \leq 0.092$.

series with a compositions of $Sm(Co_{bal}Fe_{0.28}Cu_uZr_{0.022})_{8.0}$, where v ranged from 0.043 to 0.092, when optimized with an appropriate solid solution treatment and the corresponding precipitation hardening treatment. The H_{ci} increases sharply while the B_r remains relatively constant with the increasing Cu content. Unlike the B_r, the BH_{max} value showed a wide variation with the Cu content. Because of the low H_{ci}, a relatively low BH_{max} was obtained at low Cu concentration ($v=0.043$). With a slight increase in H_{ci}, a drastic increase in BH_{max} can be observed when the Cu content (the u value in the formula expression) was raised from 0.043 to above 0.05. When the Cu content was increased to above $v=0.07$, a slight decrease in BH_{max} can be observed. This decrease in BH_{max} may be attributed to the fact that either an excessive amount of the nonmagnetic phase is present or a reduction of the magnetization of the 2:17 phase in the final magnet has occurred which would require further investigation.

IV. CONCLUSIONS

The microstructure of $Sm(Co_{bal}Fe_{0.28}Cu_vZr_{0.022})_{8.0}$, where $v=0.043-0.092$, cast alloys have been examined in the as-cast state. A Sm- and Cu-rich grain boundary phase was found in alloys with $v \geq 0.07$ using SEM EDAX analysis. The liquid+2:17$\rightarrow TbCu_7$ transformation temperature was found to decrease from slightly above 1180 to approximately 1140 °C when the Cu content (i.e., the v value) was increased from 0.043 to 0.092. The H_{ci} of optimally prepared magnets was found to increase significantly while the B_r remained relatively constant with the increasing Cu content.

$CoFe_2O_4$ thin films grown on (100) MgO substrates using pulsed laser deposition

P. C. Dorsey,[a] P. Lubitz, D. B. Chrisey, and J. S. Horwitz
Naval Research Laboratory, Washington, DC 20375

Thin films ($\approx$0.4 μm) of cobalt ferrite ($CoFe_2O_4$) have been grown on single-crystal (100) MgO substrates using pulsed laser deposition (PLD). The phase, orientation, and microstructure of the as-deposited films were investigated as a function of substrate temperature (i.e., 200–800 °C) at a constant oxygen deposition pressure of 30 mTorr. The as-deposited films were found to be single phase, well oriented, and approximately matching the stoichiometry of the target, but the cubic lattice constant of the films depended on the substrate temperature indicating that the films were strained. The greatest effect of the substrate temperature was on the magnetic properties of the as-deposited films. At 800 °C, $4\pi M_s$ was measured to be 5370 G which is approximately the accepted bulk value for cobalt ferrite. In addition, PLD cobalt ferrite films grown at substrate temperatures of 600 and 800 °C exhibited a uniaxial magnetic anisotropy with an easy direction normal to the film plane. Films grown at 200 and 400 °C also exhibited a uniaxial magnetic anisotropy but possessed a planar easy direction.

I. INTRODUCTION

In this study, the potential for growing high quality single-crystal films of Co-ferrite ($CoFe_2O_4$) on (100) magnesium oxide (MgO) substrates using pulsed laser deposition (PLD) was investigated. MgO substrates are a very good lattice match with spinel ferrites and previous success at growing epitaxial MnZn-ferrite films on (100) MgO has already been demonstrated at relatively low substrate temperatures.[1] Most practical applications of Co-ferrite such as magnetic recording and magneto-optic recording require low-temperature processes so PLD may be an attractive alternative to some of the other deposition techniques which have been used to grow Co-ferrite.[2–6] The growth of high quality single-crystal films of Co-ferrite is important since many intrinsic magnetic properties can be investigated using single crystals. The information obtained from the PLD growth of single-crystal films can then be used to understand the PLD processing of Co-ferrite films on amorphous or polycrystalline substrates for more practical applications.

II. EXPERIMENT

Thin films were pulsed laser deposited from a 5-cm-diam phase-pure polycrystalline $CoFe_2O_4$ target onto 1 cm×1 cm single-crystal (100) MgO substrates. The PLD system was operated for 5000 shots at a laser repetition rate of 5 Hz and an energy density of 2.5 J/cm^2. The PLD films were grown at substrate temperatures of 200, 400, 600, and 800 °C in a background of high-purity oxygen at a pressure of 30 mTorr. Substrate heating was provided by attaching the MgO substrate using silver paste to a radiatively heated stainless-steel block which was positioned 4 cm from the target. Substrate temperature and background oxygen pressure were held constant during deposition using a temperature controller with a thermocouple imbedded in the center of the stainless-steel heater block and a capacitance manometer with a controllable needle valve. In order to reduce rutting of the target and to improve film uniformity (e.g., composition and thickness), the focused laser beam was rastered across the face of the target while simultaneously rotating the target.

III. STRUCTURAL RESULTS

The thickness and microstructure of the as-deposited films were determined using scanning electron microscopy (SEM). The films were first sputtered coated with 100 Å of platinum since the films are insulating. After fracturing the films into two equal halves, cross-section SEM micrographs were taken. The thicknesses of all of the PLD films were measured to be about 0.4 μm. The surface and cross section of the films were devoid of any visible microstructure at all substrate temperatures. The films were very dense with a smooth surface morphology and very few particulates.

The composition of the as-deposited films was measured using Rutherford backscattering spectroscopy (RBS) and also x-ray fluorescence (XRF). Specifically, RBS was used to measure the oxygen content of the films in terms of the oxygen to iron and cobalt ratio (i.e., O/Co+Fe), while XRF was used to measure the metal ratio of the films (i.e., Fe/Co). The RBS data were collected using 6.2 MeV He^{2+} ions and the analysis was performed using a RUMP simulation which does not require standards.[7] The XRF data, however, were obtained using thin film standards of iron and cobalt which are valid for determining the composition of films up to 1.0 μm in thickness. The RBS and XRF results for the PLD films are shown in Table I. The PLD process is typically known for producing films whose stoichiometry matches the target even for multicomponent materials. In this specific case, the metal ratios and oxygen to metal ratios are consistent with the target indicating that the films have the nominal composition of $CoFe_2O_4$.

A standard $\theta/2\theta$ x-ray diffraction (XRD) setup was used to determine the phase and orientation of the PLD Co-ferrite films. XRD measurements were performed using a Cu K_α target operating at 20 kV and 30 mA. All of the films, regardless of substrate temperature, exhibited x-ray diffraction

TABLE I. XRF and RBS composition data for PLD films deposited from a $CoFe_2O_4$ target onto (100) MgO substrates in 30 mTorr of O_2 as a function of substrate temperature.

Substrate temperature (°C)	Fe/Co	O/(Co+Fe)
200	2.11	1.58
400	2.17	1.61
600	2.16	1.60
800	2.14	1.46

peaks corresponding to the (400) and (800) diffraction lines of the spinel structure. There were no other film diffraction peaks present in the XRD patterns and all of the films exhibited narrow ω scans about the (400) diffraction plane (see Table II). These results reveal that the films are well oriented and are of high crystalline quality. However, the positions of the (400) and (800) diffraction peaks shifted as a function of substrate temperature indicating a change in the cubic lattice parameter of the films. The accepted literature value for the bulk lattice parameter a of Co-ferrite is 8.38 Å, while the unit cell length for MgO is 4.21 Å.[8,9] The calculated unit cell lengths of the Co-ferrite films, based on the experimentally measured d spacings for the (400) and (800) diffraction peaks, are summarized in Table II. At substrate temperatures of 600 and 800 °C, the PLD Co-ferrite films have a cubic lattice parameter which closely matches the bulk value. At 200 and 400 °C, however, the cubic lattice parameter normal to the film plane is 0.48% larger than the bulk value for $CoFe_2O_4$ which indicates that the PLD Co-ferrite films are under a compressive stress in the film plane.

IV. MAGNETIC RESULTS

The saturation magnetization ($4\pi M_s$), coercive field (H_c), and remanence ratio (B_r/B_s) of the PLD Co-ferrite films were measured using a vibrating sample magnetometer (VSM) with a maximum dc magnetic field of 16 500 Oe. The VSM measurements were performed with the dc magnetic field applied normal to the film plane (i.e., parallel to the ⟨100⟩ direction) and in the film plane along both the ⟨001⟩ and ⟨011⟩ crystallographic directions. The $4\pi M_s$ values as a function of substrate temperature are graphed in Fig. 1. The results show that $4\pi M_s$ increases with increasing substrate temperature and then reaches the bulk $4\pi M_s$ value for Co-ferrite, which is 5300 G, at a substrate temperature of 800 °C.[8] The coercive field and remanence ratio are shown in

TABLE II. XRD results for PLD Co-ferrite films summarizing the calculated unit cell length for the films and the full width at half-maximum (FWHM) values for ω scans about the (400) film plane.

Substrate temperature (°C)	ω scan FWHM about the (400) film plane (°)	Cubic lattice parameter (Å)
200	0.142	8.424
400	0.138	8.433
600	0.125	8.361
800	0.156	8.388

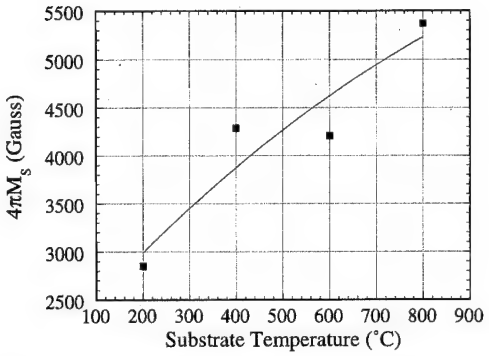

FIG. 1. The saturation magnetization ($4\pi M_s$) as a function of substrate temperature for 0.4-μm-thick PLD Co-ferrite films grown on (100) MgO in 30 mTorr of O_2.

Figs. 2 and 3, respectively. The values in these graphs are the result, in part, of the presence of a large magnetic anisotropy in the PLD Co-ferrite films which changes from a uniaxial to a planar anisotropy as a function of substrate temperature and causes the films to be magnetically anisotropic with respect to the film normal. Films grown at 200 and 400 °C are magnetically easy in the film plane with a hard direction normal to the film. Or, in other words, the uniaxial magnetic anisotropy term K_u is a negative quantity. PLD Co-ferrite films grown at 600 and 800 °C are easy normal to the film plane and magnetically hard in the film plane such that K_u is a positive quantity. At all substrate temperatures, however, the films are nearly isotropic in the plane. Consequently, H_c and B_r/B_s follow similar trends as a function of substrate temperature when measured along the ⟨001⟩ and ⟨011⟩ crystallographic directions. The VSM hysteresis curves for the PLD Co-ferrite films grown at 200 and 600 °C are shown in Figs. 4 and 5, respectively. These hysteresis curves qualitatively demonstrate the change from an easy planar anisotropy to an easy axis normal to the film plane. Only one in-plane hysteresis curve is shown for each substrate temperature, even though two in-plane directions were measured, since the films are nearly isotropic in the plane.

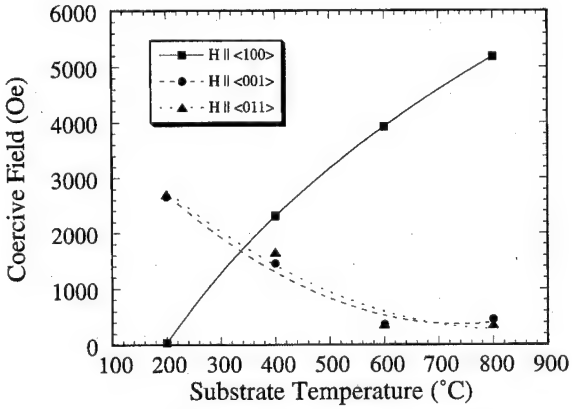

FIG. 2. The coercive field (H_c) along the ⟨100⟩, ⟨011⟩, and ⟨001⟩ crystallographic axes as a function of substrate temperature for 0.4-μm-thick PLD Co-ferrite films grown on (100) MgO.

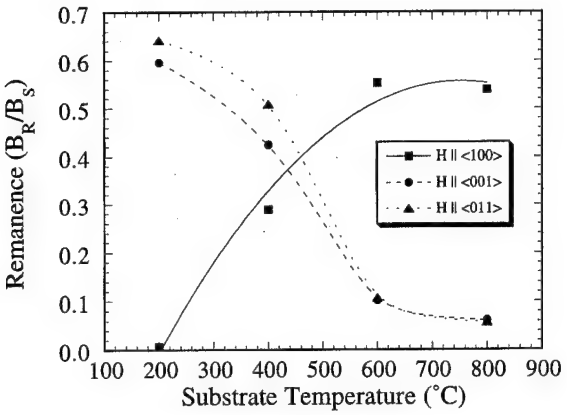

FIG. 3. The remanence ratio (B_r/B_s) along the ⟨100⟩, ⟨011⟩, and ⟨001⟩ crystallographic axes as a function of substrate temperature for 0.4-μm-thick PLD Co-ferrite films grown on (100) MgO.

V. DISCUSSION AND CONCLUSION

Experimental results from RBS, XRF, and XRD demonstrate that well-oriented (100) $CoFe_2O_4$ films can be grown on (100) MgO substrates using PLD. The PLD Co-ferrite films grown at 200 and 400 °C have a cubic lattice constant normal to the film plane which is larger than bulk value of $CoFe_2O_4$ indicating that the film is compressively stressed. In-plane XRD measurements of the in-plane lattice constant would confirm the existence of a compressive stress since the in-plane lattice constant should show a corresponding reduction in size in order to maintain the unit cell volume at a constant value. This would then rule out other factors, such as compositional variations, which could also cause changes in the lattice constant of the film. Films grown at 600 and 800 °C had nearly bulk cubic lattice constants indicating that the higher substrate temperatures effectively relieve the stress in the films by allowing the film unit cell length to relax to its bulk value.

An estimate of the uniaxial magnetic anisotropy field (H_u) and cubic magnetocrystalline anisotropy field (H_A) exhibited by the PLD Co-ferrite films can be made based on the VSM hysteresis curves. The estimation can be made using the difference in the applied magnetic fields required for saturation along the hard and easy directions. In the case of H_u, the films could not be readily saturated in the hard direction with the available magnetic field, so the hard direction hysteresis curve must be extrapolated to saturation. Extrapolating to saturation for the two cases of the PLD films grown at 200 and 600 °C gives H_u values of 59 and 26 kOe, respectively. The most likely origin of such large uniaxial magnetic anisotropy fields in Co-ferrite would be due to its large magnetostriction terms.[8,10–12] However, the films grown at 600 and 800 °C appear to have little or no uniform stress present so magnetostriction would seem to be an unlikely candidate for producing such a large magnetic anisotropy. In the films grown at 200 and 400 °C, magnetostriction does play a role. The presence of the compressive stress would cause the magnetization to lie normal to the film plane (i.e., normal to the compressive stress) since the sign of the magnetostriction term is negative for Co-ferrite. As was shown, this is the case. Finally, Co-ferrite has a significant cubic anisotropy field of about 6800 Oe which should manifest itself in the in-plane hysteresis curves along the ⟨001⟩ and ⟨011⟩ directions.[8,10–12] There is essentially no difference in the hysteresis curves for these two orientations, however, so the first-order cubic magnetocrystalline anisotropy term (K_1) can be considered to be negligible in these PLD Co-ferrite films.

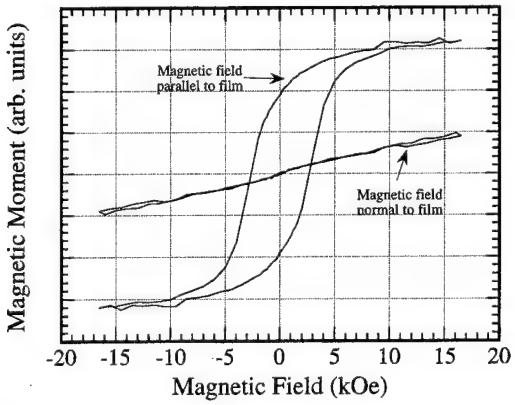

FIG. 4. The VSM hysteresis curves measured normal to the film plane (i.e., magnetic field parallel to the ⟨100⟩ axis) and parallel to the film plane (i.e., magnetic field parallel to the ⟨001⟩ axis) for 0.4-μm-thick PLD Co-ferrite films grown on (100) MgO at 200 °C.

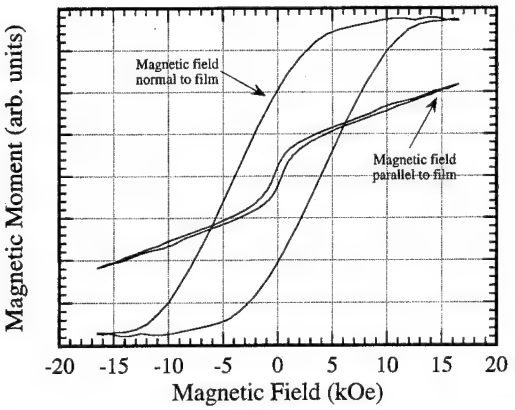

FIG. 5. The VSM hysteresis curves measured normal to the film plane (i.e., magnetic field parallel to the ⟨100⟩ axis) and parallel to the film plane (i.e., magnetic field parallel to the ⟨001⟩ axis) for 0.4-μm-thick PLD Co-ferrite films grown on (100) MgO at 600 °C.

Permanent magnetic materials based on iron, cobalt, and rare earths have been extensively studied during the past years. It is very interesting to study the physical properties of film type permanent magnet materials. In this investigation, we report the optical and magnetic properties of SmCo, SmFe, Sm, Co, and Fe films as well as the comparison of the electrical resistivity and magnetization behaviors between these films. The optical transmittance and reflectance have been measured as functions of the wavelength and the thickness for all the films with thickness less than 2000 Å. The electrical resistivity and magnetization have been measured below room temperature. The slope of electrical resistivity is decreased with decreasing the thickness of the films. The films are transparent with thickness less than 800 Å for magnetic films. For films with thickness at 200 Å, the values of the transmittance are 50, 48, 38, 18, and 14 for Sm, SmCo, SmFe, Co, and Fe, respectively. This is explained due to the difference of the magnetic permeability of all the films. The oscillatory behaviors of reflection for all the films are qualitatively consistent with that of the theoretical predict for an absorbing surface. Up to now, the best magnetic properties for magnetic films at room temperature are with an intrinsic coercivity of 1450 Oe and an energy product of 4.5 MGOe. [S0021-8979(96)65508-1]

Aspects of sintering barium hexaferrite with SiO_2, Al_2O_3, $CaCO_3$, and $Y_6Fe_{10}O_{24}$ additions for microwave applications (abstract)

J. G. Fagan, R. L. Snyder, C. Hach, and L. Jones
NYS College of Ceramics, Alfred, New York 14802

J. B. Ings, J. May, and J. J. Simmins
TransTech., Adamstown, Maryland 21710

Results are presented regarding the sintering mechanisms of barium hexaferrite ($BaFe_{12}O_{19}$) and modification thereof via secondary phase additions. Additional studies are presented concerning the effect of additives and microstructural development on the resultant microwave frequency magnetic and dielectric loss properties. The increasing demands on materials for microwave application has required development of barium hexaferrites to achieve fine grain size (i.e., $\leqslant 1$ μm), a high degree of c axis alignment, high density and a minimum in dielectric loss. To accomplish such a task one area of interest is that of incorporating secondary phases. Additions of SiO_2, Al_2O_3 and $CaCO_3$ are examined in terms of grain size, magnetic, and dielectric loss properties. Thermal analysis methods revealed a redox reaction associated with the sintering process in barium hexaferrite. The use of yttrium iron garnet ($Y_6Fe_{10}O_{24}$) indicated an enhanced densification behavior in comparison to undoped barium hexaferrite which was associated to a decreased redox reaction temperature. The inclusion of the SiO_2, Al_2O_3, and $CaCO_3$ additions were seen to inhibit the redox reaction as measured via thermal analysis while liquid phase sintering occurred. [S0021-8979(96)65608-3]

Finite element modeling of powder aligning and multipole magnetizing systems for anisotropic bonded permanent magnets

C. D. Riley, G. W. Jewell, and D. Howe
Department of Electronic and Electrical Engineering, University of Sheffield, Sheffield S1 3JD, United Kingdom

The manufacture of anisotropic bonded permanent magnets involves the application of an aligning field during the moulding of the magnet, and in most cases, particularly those involving anisotropic NdFeB powder, the subsequent application of a considerably larger magnitude magnetizing field, which in turn is usually produced by a capacitor discharge magnetizer and a geometry specific fixture. A finite element based method for modeling both of the production stages is presented, and the method is validated by a case study, which includes extensive material characterization on a four-pole anisotropic NdFeB cylinder. © *1996 American Institute of Physics.*
[S0021-8979(96)35308-3]

I. INTRODUCTION

Bonded permanent magnets based on anisotropic permanent magnet powders are attractive for many applications since they offer significant advantages in terms of flexibility of manufacture compared to sintered magnets, while having magnetic properties which are superior to the isotropic forms of the same material type. However, the manufacture of anisotropic bonded magnets, by either injection or compression moulding, requires that the cavity of the mould is exposed to a magnetic field of the appropriate orientation. The aligning field, which is produced by either an electromagnet or an array of permanent magnets, can be a simple two-pole axial pattern, a homopolar radial pattern, or more complex multipole patterns.

Following the moulding process, the aligned magnet is partially magnetized as a result of the applied aligning field. However, in almost all cases involving NdFeB anisotropic bonded magnets, a secondary impulse magnetization at a considerably higher field level is required in order to establish the full potential properties.

This article is concerned with the electromagnetic finite element modeling of these two coupled production stages, with particular emphasis on modeling the effects of complex and often incomplete alignment and magnetization within a permanent magnet component. Although the material characterization and the case study presented are based on an injection moulded NdFeB anisotropic magnet, the modeling techniques developed are entirely general, and can, with the appropriate material characterization, be equally applied to compression moulding and other materials such as anisotropic ferrite bonded magnets.

II. MATERIAL CHARACTERIZATION

The finite element modeling of the alignment and magnetization production steps requires extensive characterization of the permanent magnet material, since the remnant properties exhibited by localized regions within the finished permanent magnet component are a function of both the magnitude and orientation of the aligning field and the subsequent impulse magnetizing field.

The extent of the data required for the modeling can be illustrated by considering the characterization of an anisotropic NdFeB injection moulding compound (Dai Nippon Ink and Chemicals Compodic NDA502E, 65% NdFeB volume loading). To characterize the material, a large number of 8 mm cube samples were injection moulded on a small laboratory scale pneumatic injection moulding machine. Each sample was produced under the same moulding conditions, viz., a barrel temperature of 280 °C, a mould temperature of 80 °C, and an injection pressure of 12.4 MPa (1800 psi), conditions which resulted in measured sample densities of ~5.2 g/cc.

To measure the effect of the aligning field on the subsequent properties of the samples, a constant dc uniaxial aligning field was applied throughout the moulding process in an orthogonal direction to the direction of injection. The field was generated by an electromagnet with 40 mm×40 mm pole face, designed to produce a uniform field in the region occupied by the mould cavity. The magnitude of the aligning field was increased from 0 A/m to 800 kA/m (0.0 to 1.0 T), in 80 kA/m uniform increments.

The second quadrant demagnetization curves were measured in an iron yoked dc permeameter, either directly from the mould or following impulse magnetization with a specified magnetizing field strength in a two-pole, air-cored solenoid. The demagnetization characteristics were measured in directions both parallel and perpendicular to the direction of the applied aligning field. In both cases, the impulse magnetizing field was applied in a direction parallel to the direction of measurement. A number of the measurements were systematically repeated in order to ensure that the measured magnetic properties were not significantly affected by the barrel residence time (i.e., the time that the compound remains in the barrel at 280 °C, which in a laboratory scale moulder is not necessarily representative of volume production conditions).

Figures 1 and 2 show the variation of the resultant remanence with the magnitudes of the aligning field and the subsequent impulse magnetizing field. In the absence of an aligning field, a remanence of 0.44 T was measured in three orthogonal directions, which confirms the absence of any significant flow induced anisotropy in the magnet samples.

The surface plots of Figs. 1 and 2 are useful in summarizing the levels of aligning field and magnetizing field required in order to obtain the full potential properties of the

 0021-8979/96/79(8)/6342/3/$10.00

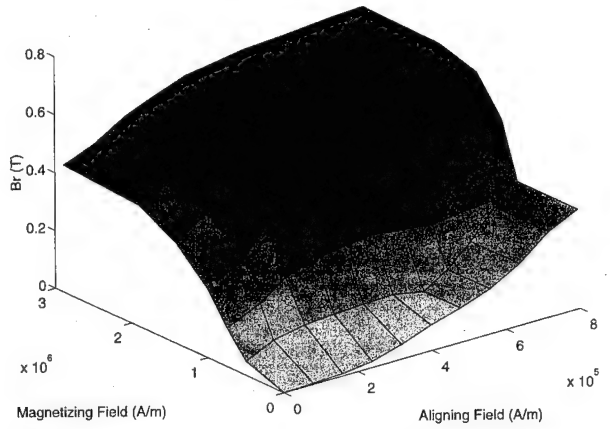

FIG. 1. Remenance of magnet samples measured in the direction of alignment as a function of the aligning field and the subsequent magnetizing field.

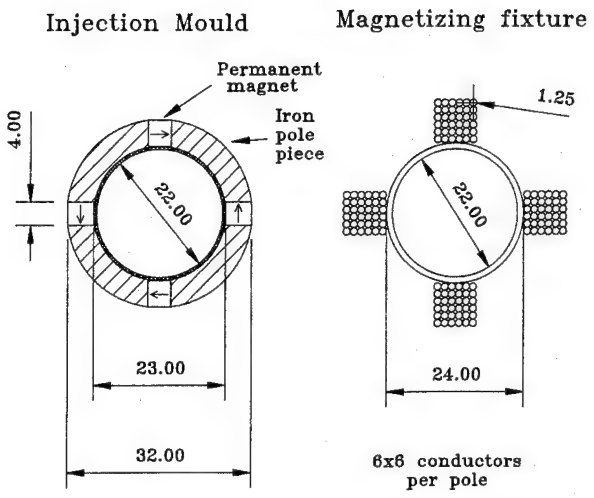

FIG. 3. Leading dimensions of mould and impulse magnetizing fixture.

material. However, to accurately model the behavior of the magnet requires a demagnetization characteristic in a direction both parallel and perpendicular to the aligning field for each combination of aligning field and magnetizing field, a total of 154 curves for the increments chosen in this case.

In order to account for nonlinear behavior of the magnet material in the first quadrant in both the moulding and magnetizing steps, it is necessary to measure the various magnetization curves of the material for each aligning field in directions both parallel and perpendicular to the aligning fields. Magnet samples were moulded in a known aligning field and demagnetized in a dc permeameter, following which the initial magnetization curves were measured.

III. MODELING METHODOLOGY

Having generated the appropriate material data, the following finite element calculations are performed:

(i) The field distribution in the mould cavity is predicted using an in-house developed magnetostatic nonlinear finite element package. Since the initial magnetization curve of the material during the moulding process is itself a function of the magnitude of the localized aligning field, the initial magnetization curve within each element is iteratively modified to reflect the level of aligning field to which it is exposed. From the resultant field distribution, the direction and magnitude of the aligning field in each individual finite element within the region occupied by the moulded magnet can be determined. The subsequent behavior of the element to externally applied magnetizing fields can then be modeled by reference to the appropriate series of demagnetization curves for the calculated aligning field, with due interpolation between the discrete measured characteristics.

(ii) The model of the aligned magnet is placed in a finite element model of the impulse magnetizing fixture in order to calculate the magnitude and direction of the magnetizing field. In the majority of cases involving the magnetization of the magnet alone, a single nonlinear magnetostatic finite element solution with the calculated peak fixture current will usually suffice. However, in some instances, e.g., the magnetization of a component containing a significant region of solid soft magnetic material such as an assembled rotor for a machine, recourse to a transient, circuit-coupled, finite element simulation may be necessary to include the effect of eddy currents and saturation of the soft magnetic parts on the predicted field distribution and fixture current.[1] The calculated magnetizing field within each element, can be resolved into components along the "preferred" and "nonpreferred" directions of the element, i.e., the direction parallel and perpendicular to the aligning field calculated during the modeling of the moulding process. The resultant second quadrant demagnetization characteristics for this particular element in both its preferred and nonpreferred directions can then be established from the measured material characteristics.

(iii) The model of the magnet, which may well include individual elements which are not fully aligned and/or fully saturated, can be incorporated in a finite element model of the fully assembled device. The resulting predicted field distributions can be used to assess the final device performance, e.g., emf and cogging torque wave forms in the case of a permanent magnet machine.

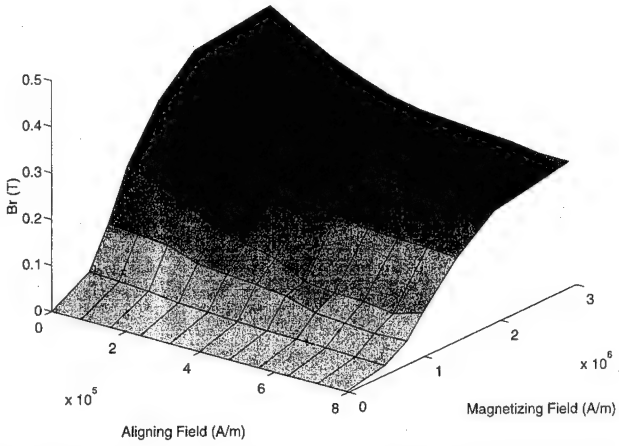

FIG. 2. Remenance of magnet samples measured perpendicular to the direction of alignment as a function of the aligning field and the subsequent magnetizing field.

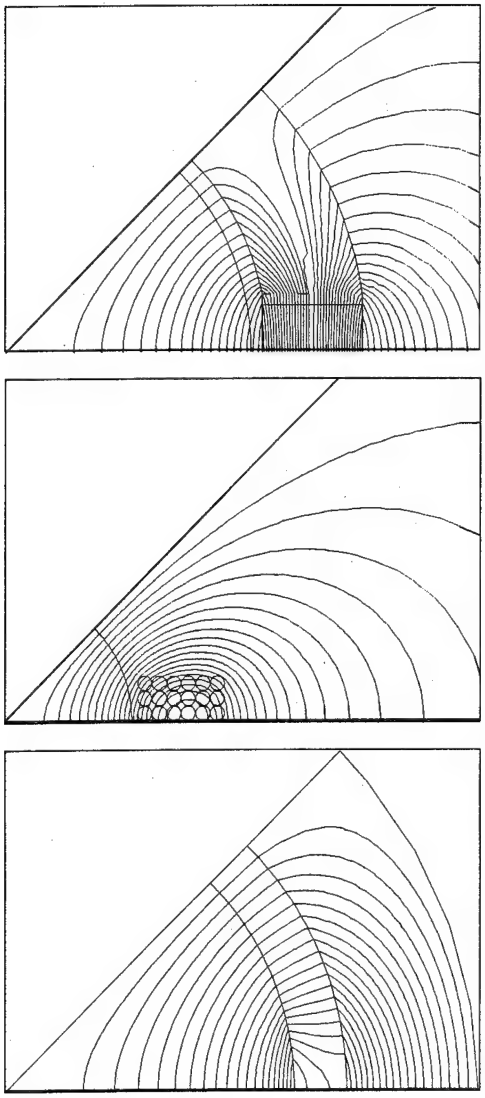

FIG. 4. Predicted magnetostatic field distributions of the aligning system, the impulse magnetizing fixture and the magnet within the mild steel sleeve.

IV. VALIDATION

In order to validate the technique, a mould and fixture to produce a four-pole self-shielding anisotropic NdFeB magnet with a diameter of 22 mm, and an axial length of 25 mm were modeled and constructed for experimental assessment. The leading dimensions of the injection mould and the impulse magnetizing fixture are shown in the cross sections of Fig. 3. The four-pole aligning field in the mould is produced by an array of sintered NdFeB magnets (Ugistab 300H), whose properties were measured at the mould operating temperature of 80 °C for inclusion in the finite element model. The magnetizing fixture draws a current pulse which has a peak magnitude of 3380 A and a time to peak of 0.78 ms when connected to a capacitor discharge magnetizer with a stored energy of 1.72 kJ (7000 μF at 700 V).

Although the geometry of the aligning system in the mould is in some respects representative of that which would be used in the manufacture of a multipole self shielding rotor, the relative dimensions of the various components were specifically chosen to produce regions within the moulded

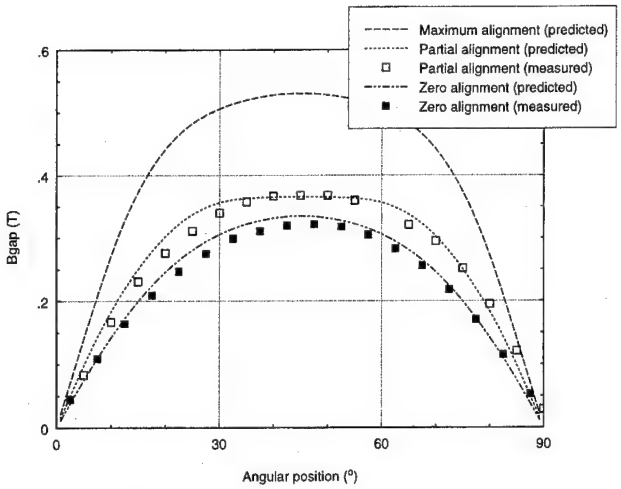

FIG. 5. Measured and predicted airgap flux density wave forms.

magnet which are exposed to aligning fields significantly lower than those required to achieve near full alignment, i.e., <800 kA/m (1.0 T). Further, there is a certain degree of misalignment between the orientation of the applied magnetizing field and the orientation of the magnet alignment. In the integrated design of a mould and its associated magnetizing fixture, one would endeavor to avoid both of these situations. However, for the purposes of a general validation, the specified problem is considerably more demanding to model than a well-aligned material with a well-matched magnetizing fixture.

Following the magnetization stage the magnet was located within a 5-mm-thick mild steel sleeve with an air gap of 2 mm. The calculated field distributions during the moulding process, the impulse magnetization, and after incorporation in the mild steel sleeve are shown in Fig. 4. Profiles of the normal component of flux density 1mm from the surface of the magnet were measured by a Hall probe, the location of which was maintained by a precision machined nonmagnetic insert. The process was repeated for a second sample for which the sintered magnets were removed from the mould to give a zero aligning field. Figure 5 shows the measured and predicted profiles of radial flux density in the gap and a predicted profile of a fully aligned sample for comparison. In both cases, there is good agreement between the measured and predicted profiles.

V. CONCLUSIONS

A finite element based method for modeling both the production stages in the fabrication of an anisotropic injection moulded magnet and the subsequent performance evaluation have been presented. The method has been validated on a four-pole anisotropic NdFeB cylinder for which the aligning system was specifically designed to produce fields sufficient to only partially align the magnet. The method can be utilized in the design of combined alignment and magnetization systems in order to extract maximum leverage from the available injection moulded magnet materials.

We study the possibility of an excitonic transition in a two-band model and show that a true phase transition does not occur in the presence of hybridization since the one-body mixing term acts as a conjugate field to the order parameter of the excitonic phase. We suggest an alternative interpretation for recent experiments on rare earth semiconductors based on a metal-insulator transition associated with the opening or closing of a hybridization gap at a critical pressure.
 [S0021-8979(96)25108-7]

Recently Wachter and colaborators[1,2] have claimed to observe a transition to an excitonic insulator in a doped narrow-band-gap semiconductor at moderate pressures and in a strongly correlated metal.[2]

With renewed interest in this subject motivated by these challenging experiments[1,2] and the close connection of the materials which have been investigated with Kondo insulators,[3] we study the possibility of this excitonic transition in the presence of hybridization in a two-band model. We point out that no sharp excitonic phase transition occurs, within our model, when external pressure is applied. The reason is that the hybridization, which depends on pressure, acts as a conjugate field to the order parameter of the excitonic phase and destroys this transition.[4] We obtain however that the mixing term is strongly renormalized by excitonic correlations and suggest an alternative interpretation for the experiments of Wachter *et al.*[1,2] on the basis of the appearance of a hybridization gap at a critical pressure. This metal-insulator transition is in the same universality class of the *density-driven transitions* for which the relevant critical exponents have been previously obtained. A characteristic feature of this metal-insulator transition is that the gap opens linearly with pressure close to the critical pressure. This is a direct consequence of the fact that the gap exponent assumes the value $\nu z = 1$.[4]

The Hamiltonian which describes the dynamics of our system is:

$$H=\sum_k \epsilon_k^a a_k^\dagger a_k+\sum_k \epsilon_k^b b_k^\dagger b_k+\sum_k V_k(a_k^\dagger b_k+b_k^\dagger a_k) - \sum_{k,k',q} G(q) a_{k+q}^\dagger a_k b_{k'-q}^\dagger b_{k'}, \tag{1}$$

where ϵ_k^a and ϵ_k^b represent the energies for electrons in the narrow *a-band* and in the broad conduction *b-band*, respectively. The operators $a_k^\dagger$, a_k create and destroy electrons in the narrow band and $b_k^\dagger$, b_k are creation and annihilation operators of electrons in the wide conduction band; V is the mixing term, which arises from the crystalline potential and G is the effective attractive interaction between spinless electrons and holes.[5] For the situation we are interested G is the most important interaction and consequently we do not take into account the Coulomb repulsion between the electrons in the narrow band. We shall employ the equation of motion method[6] to calculate the order parameter associated with the excitonic phase, namely, $\Delta = \Sigma_k \langle b_k^\dagger a_k \rangle$. We calculate the frequency-dependent Green's function $\langle\langle a_k ; b_k^\dagger \rangle\rangle_\omega$ and use a convenient mean-field approximation, so that, neglecting the k-dependence of G, we obtain

$$\langle\langle a_k ; b_k^\dagger \rangle\rangle_\omega = \frac{\tilde{V}_k}{[(\omega-\epsilon_k^a)(\omega-\epsilon_k^b)-\tilde{V}_k^2]}, \tag{2}$$

where $\tilde{V}_k = V + G\Delta_k$, with $\Delta_k = \langle b_k^\dagger a_k \rangle$. The new energies of excitation of the system are given by the poles of the propagator

$$\omega_{1,2}(k) = \tfrac{1}{2}\{\epsilon_k^a + \epsilon_k^b \pm \sqrt{(\epsilon_k^a - \epsilon_k^b)^2 + 4\tilde{V}_k^2}\}. \tag{3}$$

In order to obtain explicit results for the excitonic order parameter we adopt the homothetic band model[7] which consists in taking $\epsilon_k^b = \epsilon_k$ and $\epsilon_{k\sigma}^a = \alpha\epsilon_k + \beta$. The quantity α ($\alpha < 1$) may be interpreted as taking into account the different effective masses of the electrons in the narrow a-band and the broad b-band, i.e., $(m_b/m_a) = \alpha$. The quantity β gives the shift of the narrow band with respect to the broad band.

The energies at the bottom of the hybrid bands are

$$E_B^{2,1} = \tfrac{1}{2}\{\beta \pm [\beta^2 + 4\tilde{V}^2]^{1/2}\}, \tag{4}$$

and the energies at the top are

$$E_T^{2,1} = \frac{D}{2}\left\{(1+\alpha) + \frac{\beta}{D} \pm \left[\left((\alpha-1)+\frac{\beta}{D}\right)^2 + 4\left(\frac{\tilde{V}}{D}\right)^2\right]^{1/2}\right\}, \tag{5}$$

 0021-8979/96/79(8)/6345/2/$10.00

where D is the bandwidth of the wide conduction b-band.[8]

The expression for the gap Δ_G between the two bands as a function of the hybridization V and the electron-hole interaction G is given by

$$\frac{\Delta_G}{D}=\frac{1}{2}\left\{\left[\left(\alpha-1+\frac{\beta}{D}\right)^2+4\left(\frac{\tilde{V}}{D}\right)^2\right]^{1/2}+\left[\left(\frac{\beta}{D}\right)^2+4\left(\frac{\tilde{V}}{D}\right)^2\right]^{1/2}-(1+\alpha)\right\}. \tag{6}$$

Consequently for a two-band system the opening of a hybridization gap, contrary to what occurs for the Anderson lattice model,[9] requires a critical value of renormalized hybridization $(\tilde{V}/D)_c$ given by

$$\left(\frac{\tilde{V}}{D}\right)_c=\frac{1}{2}\left[\frac{\left[2\alpha-\frac{\beta}{D}(\alpha-1)\right]^2}{(1+\alpha)^2}-\left(\frac{\beta}{D}\right)^2\right]^{1/2}. \tag{7}$$

Notice that for $\alpha\to 0$, $\tilde{V}_c\to 0$ as expected for a collection of localized levels. In this case[9] also $\Delta_G\propto\tilde{V}^2$ contrary to our two-band problem where close to $(\tilde{V}/D)_c$ we find

$$\frac{\Delta_G}{D}=\left|\left(\frac{\tilde{V}}{D}\right)-\left(\frac{\tilde{V}}{D}\right)_c\right| \tag{8}$$

so that the gap opens linearly close to $\tilde{V}_c$, i.e., $\nu z=1$, as in the non-interacting case.[4] Within the assumption that $|(\tilde{V}/D)-(\tilde{V}/D)_c|\propto|P-P_c|$ where P_c is the critical pressure, this result, i.e., $\Delta_G\propto|P-P_c|$, describes the observed behavior for $Sm_{0.75}La_{0.25}S$[2] and also for the compound SmB_6[10,11] (see Fig. 1). We point out that the relevant variable here is $(\tilde{V}/D)$ which can either increase or decrease with pressure, for a given pressure range, depending on the relative pressure dependence of the hybridization and bandwidth.

We give now the scaling results for the properties of the Fermi liquid in the metallic phase close to the metal-insulator transition.[4] We find that the thermal mass m_T, defined as the coefficient of the linear term of the specific heat scales as $m_T\propto|P-P_c|^{(d/2)-1}$ and in three dimensions vanishes as $m_T\propto|P-P_c|^{1/2}$. The same scaling is found for the uniform susceptibility χ_0, the compressibility κ and the density of states at the chemical potential. The number of carriers $n_c\propto|P-P_c|^{d/2}$. The behavior of the thermal mass obtained above is opposite to that found in heavy fermions,[12] where it is enhanced as the system approaches the critical point. The characteristic or coherence temperature in the metallic phase scales as $T_c\propto(P-P_c)$ since $\nu z=1$.[4] The existence of a small coherence temperature close to the density-driven phase transition gives rise in the presence of electron-electron interactions to a significant T^2 term in the resistivity even in wide band materials as Yb.[13] If we write $\rho\approx\rho_0+AT^2$ for $T\ll T_c$, then the coefficient A scales as $A\propto T_c^{-2}\propto(P-P_c)^{-2}$.

At the critical pressure, $P=P_c$, we expect to find non-Fermi liquid behavior with the specific heat vanishing with temperature as $C\propto T^{3/2}$ and $\chi_0\propto T^{1/2}$. In actual systems the states in the tails of the density of states due to impurities or disorder and which are responsible for the saturation of the resistivity in the *insulating phase* may spoil this simple behavior.

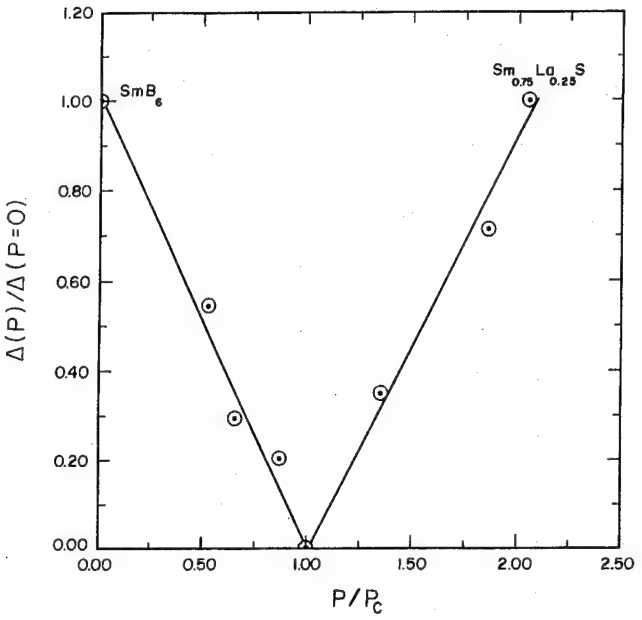

FIG. 1. Normalized gap vs normalized pressure. P_c is the critical pressure where the gap vanishes. The data for SmB_6 are collected from Ref. 11 and for $Sm_{0.75}La_{0.25}S$ from Ref. 2. The solid straight lines are a guide to the eye.

In conclusion the possibility of an excitonic phase transition in a two-band model has been investigated. The dominant interaction was taken to be the electron-hole attraction. We argued that a phase transition to an excitonic phase does not occur within this model in the presence of hybridization since the one-body mixing term acts as a conjugate field to the order parameter of this phase. We find however that the hybridization is strongly renormalized by the presence of excitonic correlations.

From our x-ray (L_{III}-edge) absorption (XAS) investigations of $Ce_2Ni_3Si_5$, we show that Ce-valence is temperature dependent; it is 3.07 and 3.11 at 280 and 8 K, respectively. We also report on our resistivity measurements of two related materials $Ce_{2-x}R_xNi_3Si_5$ (R=Y, Gd and $x=0.1$). Absence of any qualitative difference in the resistivities of these two samples suggests that the enhancement of resistivity at low temperature on introduction of impurity atoms is due to Kondo hole scattering implying that $Ce_2Ni_3Si_5$ is a concentrated Kondo system. © *1996 American Institute of Physics.* [S0021-8979(96)25208-3]

Cerium based compounds often exhibit anomalous physical properties, such as Kondo behavior, valence fluctuation (VF), heavy fermion, heavy fermion superconductivity, etc. The close proximity of the cerium $4f$-level *w.r.t.* the Fermi level is responsible for the origin of such behaviors. We had shown earlier that Ce in $Ce_2Ni_3Si_5$ is in the VF state[1] by resistivity, magnetic susceptibility and specific heat measurements. As the resistivity shows a Kondo type behavior at high temperatures and decreases because of onset of coherence at low temperature, it is of interest to study the effect of magnetic and nonmagnetic impurity on the coherence effect. Here we present the results of our investigations on dilute substitution of Ce by Y (nonmagnetic) and Gd (magnetic) in $Ce_2Ni_3Si_5$. We also present the results of x-ray absorption (L_{III}-edge) spectroscopic measurements which confirm the VF behavior of Ce ions in this compound.

$Ce_{2-x}R_xNi_3Si_5$ (R=Y, Gd; $x=0$, 0.1) were prepared by melting high purity (>99.9%) constituent elements by standard arc melting procedure.[1] Room temperature powder x-ray diffraction pattern was obtained using Cu K_α radiation on an x-ray diffractometer (JEOL, Japan). X-ray absorption studies at the L_{III}-edge, for investigation of valence state of rare earth ions, were carried out at the French synchrotron facility, Laboratoire pour l'Utilisation du Rayonnement Electromagnetique (LURE) at Orsay, France. The details of the experimental setup has been given elsewhere.[2]

The L_{III}-edge spectra of the material taken at 280 K and 8 K (Fig. 1) show a double edge structure as expected for a VF system. The two edges correspond to Ce^{3+} and Ce^{4+} states. In order to determine the relative population of the two valence states, the observed spectra were deconvoluted using the procedure given in Ref. 3. The average valency of Ce in this compound thus deduced is 3.07 and 3.11 at 280 K and 8 K, respectively. The *temperature dependence* of the intensity of the two edges confirms that the observed double edge is due to VF phenomenon (and not due to XANES or impurity phases) as, in the case of VF, a change of relative population of the two valence states with temperature is expected. We should point out that x-ray absorption spectroscopy measurement *underestimates* Ce valence. This is due to

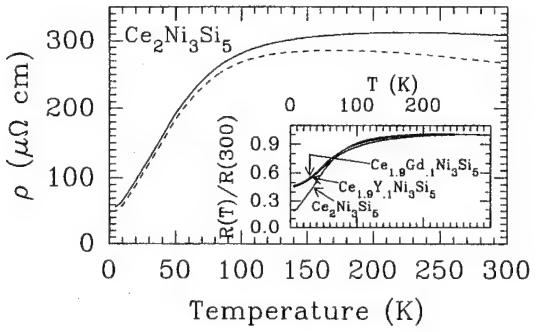

FIG. 2. Resistivity of $Ce_2Ni_3Si_5$ (solid line) as a function of temperature. Dashed line represents the $4f$ contribution of Ce to the resistivity obtained by subtracting the resistivity data of $Y_2Ni_3Si_5$ from the resistivity data of $Ce_2Ni_3Si_5$. Inset: Normalized resistivity of $Ce_{2-x}R_xNi_3Si_5$ (R=Y, Gd; $x=0$, 0.1). The agreement of the resistivity of the three samples in the high temperature region and the resistivity of the substituted samples below ~100 K is to be noted.

the existence of a shake-down satellite located at the same energy as the main peak of Ce^{3+}.[4]

Resistivity, $\rho(T)$, of $Ce_2Ni_3Si_5$ (Fig. 2) exhibits anomalous behavior:

(i) Magnitude of $\rho(T)$ in $Ce_2Ni_3Si_5$ is rather high ($\approx$300 $\mu\Omega$ cm at 300 K) than that observed in $Y_2Ni_3Si_5$ and $Gd_2Ni_3Si_5$ ($\approx$40 $\mu\Omega$ cm at 300 K).

(ii) $\rho(T)$ in $Ce_2Ni_3Si_5$ is nearly temperature independent in the interval 100 K $\leq T \leq$ 300 K.

This is to be compared with the temperature dependence of $\rho(T)$ of nonmagnetic $Y_2Ni_3Si_5$ (Ref. 1) and magnetic $Gd_2Ni_3Si_5$ (Ref. 5) which exhibit normal metallic behavior. These considerations suggest that the Kondo scattering dominates the resistivity of $Ce_2Ni_3Si_5$. A similar overall resistivity behavior has been earlier observed in other known VF systems, such as, CeRhIn,[6] $CeIr_2Si_2$,[7] $CePd_3$.[8] $\rho_{4f}(T)$, the $4f$-contribution of Ce to the resistivity, obtained by subtracting the phonon contribution (using the resistivity data of $Y_2Ni_3Si_5$, considering both the materials to have similar phonon contributions) has a negative slope with a broad maximum centered around 150 K and falls relatively sharply below 100 K.[1] Such a behavior is typical of a concentrated Kondo system. The resistivity drop observed at low temperatures, seen in other concentrated Kondo systems also, has been ascribed to the onset of coherence.[1,9] In order to obtain further insight into the behavior, we investigated the effect of impurities on the resistivity behavior. For this purpose, we substituted 5% of Ce by Gd (magnetic) and Y (nonmagnetic) ions in $Ce_2Ni_3Si_5$.

For comparison, considering that effects of dilute substitution may not affect resistivity significantly, the resistivity data of the substituted samples are plotted in inset of Fig. 2, normalized to room temperature value. From the figure we see that the normalized resistivity for all the three sample, viz., $Ce_2Ni_3Si_5$, $Ce_{1.9}Y_{0.1}Ni_3Si_5$, and $Ce_{1.9}Gd_{0.1}Ni_3Si_5$, are similar in the temperature range 70–300 K. This is to be expected because, at high temperatures, there is no coherence and the scattering due to impurity will be negligible compared to scattering by Ce ions. At low temperature end, both the Y and Gd doped samples show a similar increment in the resistivity with respect to undoped material which is remarkable considering that Gd ions are magnetic. That implies that the increase in resistivity at low temperature is due to a *common* effect in $Ce_{2-x}Y_xNi_3Si_5$ and $Ce_{2-x}Gd_xNi_3Si_5$. A similar behavior has also been seen in the system $Ce_{1-x}R_xPd_3$ (R=Y, Gd).[8]

The absence of any qualitative difference in the resistivities of the samples doped with small concentration of a magnetic ion (Gd) and nonmagnetic ion (Y), shows that the impurity-spin scattering does not have much effect on resistivity. We understand this in terms of *Kondo hole* as explained in the case of $CePd_3$ (Ref. 10) where it was shown that coherence is destroyed by the creation of *holes* in an otherwise regular Ce lattice by removing cerium atoms and substituting other atoms in their place. Such removed Ce ions are called *Kondo holes*. The scattering potential due to the impurity is small in comparison to that of the "Kondo hole" term and, as a result, the total resistivity at low temperatures is insensitive to the nature of solute. The total resistivity is primarily controlled by the integrity of the cerium lattice.

In conclusion, we have confirmed here the VF nature of Ce in $Ce_2Ni_3Si_5$ from the temperature dependence of x-ray L_{III} edge results. The alloying of $Ce_2Ni_3Si_5$, by magnetic Gd or nonmagnetic Y, exhibits a Kondo hole pattern in resistivity and strengthens our earlier interpretation of Kondo coherence in resistivity at low temperature in this material.

$SmRuSn_3$ is a unique compound among the known Sm-based valence fluctuation (VF) systems. Its crystallographic structure has two inequivalent Sm sites and Sm ions at *only* one of them are in VF state while the Sm ions in the other site orders magnetically. Our ^{119}Mössbauer studies show a quadrupolar splitting at the Sn site, consistent with the noncubic symmetry of the Sn site. A broadening of the Mössbauer spectrum is seen due to magnetic ordering of the material. The transferred hyperfine field at Sn site at 4.2 K is small. © *1996 American Institute of Physics.* [S0021-8979(96)25308-X]

$SmRuSn_3$ was reported to be the first ternary Sm-based valence fluctuating (VF) compound.[1] This compound forms in the cubic (space group $Pm3n$) crystal structure. Sm ions occupy two distinct crystallographically inequivalent sites, i.e., $2a(0,0,0)$ and $6d(\frac{1}{4},\frac{1}{4},0)$.[2] From the lattice constant, transport and magnetic properties measurements, Fukuhara *et al.*[1] concluded that all Sm ions are in VF state. They also showed that $SmRuSn_3$ undergoes a magnetic transition at 6 K. Simultaneous occurrence of VF and magnetic ordering is noteworthy as this is the only Sm based material exhibiting this behavior. Only two Sm-based compounds (both binary), SmS (Ref. 3) and SmB_6,[4] are known to exhibit VF phenomena and they do not order magnetically. In view of this unusual behavior, we reinvestigated[5] the physical properties of $SmRuSn_3$. Our magnetic, specific heat and L_{III} edge results of $SmRuSn_3$ established the mixed valence nature of Sm in this system. Here we briefly highlight our earlier work to emphasize the uniqueness of the system and present the results of our investigations of ^{119}Sn Mössbauer spectroscopy in this system.

Details of sample preparation of $SmRuSn_3$ are given elsewhere.[5] The lattice parameter, a, of our sample of $SmRuSn_3$ is 9.666 Å[5] implying that the valence state of Sm ions does not differ significantly from 3+. We may point out that Fukuhara *et al.* reported a value of a(=9.73 Å)[1] which deviates from the lanthanide contraction expected for Sm^{3+}. Electron microprobe analysis showed that our sample is largely homogeneous having a composition $Sm_{0.98}RuSn_{3.10}$ (normalized to Ru). Small inclusions (≈50 μm^2), of Sn metal and some inclusions of composition SmRu were observed occasionally.

Our magnetic susceptibility data show a cusp around 6 K (inset Fig. 1), which indicate antiferromagnetic ordering of the material. Since only Sm^{3+} ions carry a magnetic moment, the magnetic order must be due to Sm^{3+} ions. The magnetic susceptibility (Fig. 1) at room temperature is larger than what one would expect for a Sm^{3+} material. Our theoretical calculations[6] showed that the observed susceptibility cannot be accounted by mixing of excited state and/or crystal field contributions. We could account for the observed room temperature susceptibility (also taking into account the temperature independent van Vleck susceptibility) if about 14% of Sm ions are in divalent state (Fig. 1). We note here that

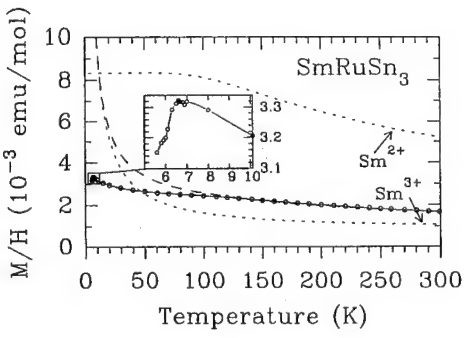

FIG. 1. Temperature dependence of dc magnetic susceptibility (○) of $SmRuSn_3$ (corrected *w.r.t.* dc magnetic susceptibility data of $LaRuSn_3$). Short dashed lines are the calculated susceptibility for free Sm^{3+} and Sm^{2+} ions. Long dashed line represents the susceptibility, $(1-x)\chi(Sm^{3+})+x\chi(Sm^{2+})$, with x having a value 0.14. Inset shows the expanded region near the magnetic ordering temperature.

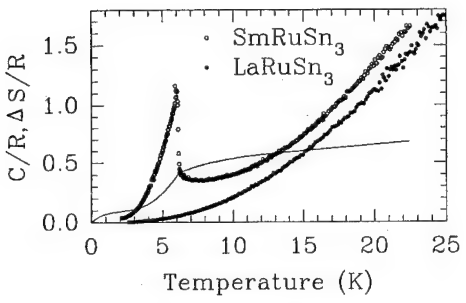

FIG. 2. Specific heat of $SmRuSn_3$ (○) and $LaRuSn_3$ (●). Solid line is the calculated magnetic entropy for $SmRuSn_3$ (obtained by subtracting specific heat data of $LaRuSn_3$ from that of $SmRuSn_3$). R is the molar gas constant.

though Sm^{2+} ions in the ground state do not carry a magnetic moment, it has a relatively large susceptibility due to mixing of low lying excited state. Thus, susceptibility data indicate mixed valence behavior of Sm ions in the material.

A quantitative estimate of the Sm ions taking part in magnetic order was obtained from magnetic entropy estimated from specific heat measurements on $SmRuSn_3$.[5] Specific heat measurements confirmed the magnetic ordering around 6 K (Fig. 2). The presence of strong crystal field effects is evident from the specific heat data of $SmRuSn_3$. If all the Sm ions would have contributed to the magnetic entropy, at the magnetic transition temperature, one would expect a minimum magnetic entropy of $R \ln 2$ ($\approx 0.693R$) as observed for a material having a crystal field doublet ground state. The magnetic entropy at the ordering temperature is much lower ($\sim 0.5R$ at 6 K) and can be accounted for properly, if one assumes that *only* the Sm ions at the $6d$ crystal site (having a crystal field doublet ground state) contribute toward magnetism, resulting a total minimum magnetic entropy of $(3/4)R \ln 2$ at the magnetic transition temperature, which matches very well with the experimental observation. The Sm ions at $2a$ site is nonmagnetic or weakly magnetic and hence do not contribute toward magnetic entropy. The specific heat results in conjunction with the magnetic susceptibility results can be consistently interpreted if Sm ions at $6d$ sites are in stable trivalent state and those at $2a$ sites are not in stable divalent state but are in VF state with an average valency of ~ 2.6 at room temperature, making the material a unique one in the field of VF.

Our x-ray absorption (L_{III} edge) spectroscopic measurements on $SmRuSn_3$[7] exhibited a temperature dependent bimodal structure which confirm that some of the Sm ions in the material are in VF state with the average valence varying from 2.88 at 10 K to 2.91 at 300 K. This total average valence is consistent with the above distribution of the valence of Sm at the two sites of the material.

Mössbauer spectroscopy, with a probing time of $\approx 10^{-8}$ s (which is slower than the usually encountered fluctuation time $\approx 10^{-13}$ s) is a complementary technique with respect to L_{III} edge absorption spectroscopy (probing time $\approx 10^{-16}$ s) in the investigation of valence fluctuation phenomenon. This fact has been successfully utilized in the case of Eu-based VF systems using ^{151}Eu Mössbauer spectroscopy.[8] Although, fluctuation effects primarily take place at the rare earth site,

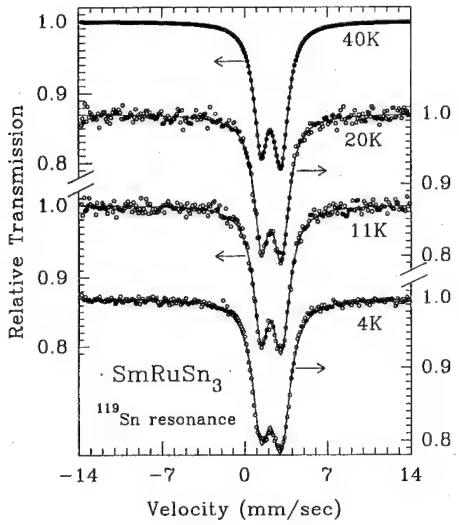

FIG. 3. ^{119}Sn Mössbauer spectroscopic result on $SmRuSn_3$ at different temperatures. The solid lines are fit to experimental data.

^{119}Sn Mössbauer spectroscopy has been fruitfully used in the investigation of certain VF systems.[9–11] One can also obtain information on magnetic ordering of Sm ions through transferred hyperfine interactions at the Sn site. Mössbauer spectra of $SmRuSn_3$ were taken against a ^{119}Sn source in $CaSnO_3$ matrix in the temperature range 4.2–300 K. A conventional constant acceleration-type spectrometer in conjunction with a home built multiscaler analyzer was used in the studies. Measurements were made with absorbers of different thickness (12 mg/cm^2 and 30 mg/cm^2) to estimate thickness broadening effects in the line width of the resonance.

Figure 3 shows the ^{119}Sn Mössbauer spectra on $SmRuSn_3$ at different temperatures. The spectrum at all temperatures is a doublet but the intensities of the two components are not equal. Since there is only one crystallographic site, $24k$, for Sn in this compound, a doublet structure would primarily arise from quadrupole interaction from the presence of electric field gradient at the Sn site. Furthermore, for the same reason, the asymmetry of intensity in the doublet cannot originate from different Sn environments. One may consider the possibility of attributing the asymmetry to fluctuation effects. However, a careful analysis of the spectra reveals that the position of the more intense peak of this doublet is very close to that of pure Sn-metal. It should be noted here, as mentioned earlier, the electron microprobe measurements on $SmRuSn_3$ reveals a few small inclusions of Sn metal in our sample of $SmRuSn_3$. Considering this, we explain the spectrum in terms of a superposition of a doublet, arising out of the non-cubic site symmetry of Sn site, and a single line of small intensity due to Sn metal.

We have analyzed our spectra in terms of a singlet due to Sn metal [(fixed isomer shift (IS) (2.5 mm/s w.r.t. $CaSnO_3$) and fixed width (1.2 mm/s)] and a quadrupole doublet due to $SmRuSn_3$. The fit yields the IS as 2.15 mm/s (w.r.t. $CaSnO_3$), $e^2Qq/2$ (where e is the electronic charge, Q is the nuclear quadrupole moment, and eq is the electric field gradient along the principle axis) as 1.75 mm/s and width of each line as 1.5 mm/s for the Sn-Mössbauer spectra of $SmRuSn_3$. The

result is essentially temperature independent above the magnetic ordering temperature. At 4.2 K, a small broadening of ^{119}Sn Mössbauer line indicates the magnetic ordering taking place in this compound. However, the transferred hyperfine field, measured at 4.2 K, at the Sn site is very small. Apart from the antiferromagnetic nature of the ordering, the measurement temperature (4.2 K) being very close to magnetic ordering temperature (6 K) may also be one of the reasons responsible for the small transferred hyperfine field. Sm-ions at $2a$ sites, being in non ordered state, do not contribute to the transferred field. Investigations, such as elastic neutron scattering, will be useful to understand the detailed magnetic structure.

To conclude, specific heat and magnetic susceptibility measurements on $SmRuSn_3$ suggest that Sm ions in $2a$ crystallographic site are valence fluctuating, while Sm ions in $6d$ crystallographic site order antiferromagnetically. The valence fluctuating behavior of Sm ions in is confirmed by L_{III}-edge spectroscopic measurements. ^{119}Sn Mössbauer spectroscopy results on $SmRuSn_3$ exhibit a temperature independent isomer shift and electric field gradient (arising due to noncubic site-symmetry). The asymmetry that we observe is not likely to be due to VF. The transferred hyperfine field at Sn site is small at 4.2 K.

We would like to thank S. K. Paghdar in Mössbauer spectroscopy measurements.

The effect of the substitution of Ni by Cu on the CeNi compound is analyzed by means of susceptibility, magnetization, and magnetoresistance measurements on the pseudobinary $CeNi_{0.4}Cu_{0.6}$ compound. Down to 2 K, the lowest investigated temperature, the compound does not present any magnetic order, but magnetic measurements suggest an ordering temperature (T_C) not far below 2 K. Magnetization and magnetoresistance data show an important Kondo interaction leading to a Kondo temperature (T_K) higher than T_C. The results are discussed considering the Kondo, magnetic exchange, and crystalline electric field interactions. © *1996 American Institute of Physics.* [S0021-8979(96)25408-6]

Cerium ions in a metallic environment give rise to great variety of fascinating many body effects (intermediate valence, heavy fermions or Kondo-type behavior). Among all the different Ce compounds showing these phenomena, $CeNi_xPt_{1-x}$ alloys and their dilutions with yttrium and lanthanum,[1–4] illustrate quite well these different behaviors. In particular the physical properties of this system are well understood from simple ideas concerning Kondo lattice models with "volume effects" playing an important role. Recently, the specific heat of these compounds[4] have been interpreted using a resonant level model, developed in Ref. 5, which accounts for the reduction of the jump of the λ-type anomaly at the Curie temperature in the specific heat when the $4f$-conduction band hybridization increases.

CeNi is a well known intermediate valence compound characterized by an enhanced Pauli paramagnetism.[6] Taking this composition as a starting point, the substitution of Ni by Cu will allow us to investigate the role of conduction electrons in the anomalous properties of these cerium compounds, because the volume effects are expected to be less important. Furthermore, the dilution with Cu have been proved to be particularly attractive, specially in other RNi_xCu_{1-x} pseudobinary compounds.[7,8] Two aspects must be stressed in these systems: On the one hand, the crystalline structure evolves from a CrB type one (Cmcm space group) for Ni rich compounds to a FeB type one (Pnma space group) for largest Cu contents, and on the other hand, from the magnetic point of view, the introduction of Cu yields a change from ferromagnetism to antiferromagnetism which takes place around $x=0.85$ for the $NdNi_{1-x}Cu_x$ compounds.[8] Supporting this evolution, previous results on CeCu[9] report a FeB type structure and an antiferromagnetic behavior ($T_N=3.1$ K) for this compound. In the actual study we present a first survey of the physical properties of the new pseudobinary $CeNi_{0.4}Cu_{0.6}$ compound which is a characteristic representative of the $CeNi_{1-x}Cu_x$ series. The obtained results are discussed under the scope of the main mechanisms of Ce compounds, namely Kondo, RKKY exchange, and crystalline electric field (CEF) interactions.

Polycrystalline $CeNi_{0.4}Cu_{0.6}$ sample has been prepared from stoichiometric amounts of elements using high frequency melting under protective argon atmosphere. The phase purity of the sample has been proved from x-ray diffraction (Cu $K\alpha$ radiation) and its temperature evolution has been followed with neutron diffraction down to 2 K. As expected from the previous $RNi_{1-x}Cu_x$ studies,[7,8] the compound crystallizes in the FeB (Pnma) orthorhombic structure. The cell parameters at 300 K are $a=7.349(2)$ Å, $b=4.493(1)$ Å, and $c=5.648(1)$ Å. This structure remains down to the lowest studied temperature. The relative volume variation from 300 to 2 K is $\Delta V/V$ is around 0.2%. No trace of magnetic intensities was observed in the 2 K neutron diffraction pattern. On the other hand, it is worth mentioning that the volume changes due to dilutions with Cu are much smaller than those coming from dilutions with Pt.

The magnetic and magnetoresistivity measurements have been performed at the Laboratorio de Física de la Materia Condensada of the Universidad de Cantabria using a PPMS (Quantum Design) device. Figure 1 shows the temperature dependence of the magnetic reciprocal susceptibility $\chi^{-1}(T)$ for $CeNi_{0.4}Cu_{0.6}$. A Curie–Weiss behavior is observed at temperature higher than 30 K, giving rise to an effective paramagnetic moment of $\mu_{\text{eff}}=2.1\mu_B$, streakingly small compared with the $\mu_{\text{eff}}=2.54\mu_B$ of the free Ce^{3+} ions.

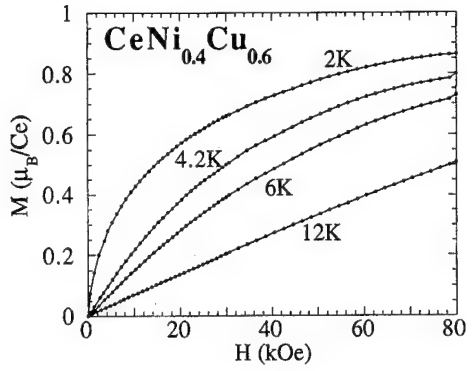

FIG. 2. Isothermal magnetization curves for $CeNi_{0.4}Cu_{0.6}$ at low temperatures.

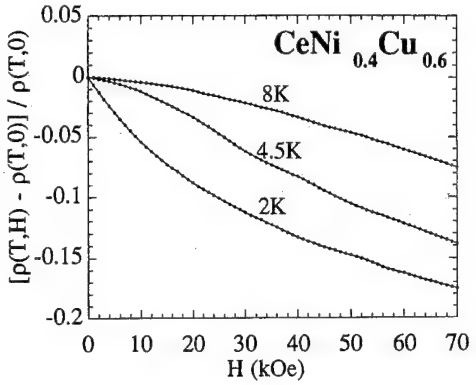

FIG. 4. Field dependence of the magnetoresistivity for $CeNi_{0.4}Cu_{0.6}$ up to 70 kOe at different fixed temperatures.

The extrapolation toward 0 K of χ^{-1} vs T leads to a negative paramagnetic Curie temperature (θ_p) close to -10 K.

The Arrot plots at low temperature (inset Fig. 1) confirm the absence of magnetic order down to 2 K. However the extrapolation of the H/M values vs T indicates a possible magnetic order about 1 K, lower than the minimum temperature experimentally available in our device. The isothermal magnetization curves up to 80 kOe, depicted in Fig. 2, are characteristic of a paramagnetic behavior at all the investigated temperatures, although the magnetization at 80 kOe and 2 K reach $0.86\mu_B$/Ce, which is a similar value than that observed in the CePt ferromagnetic compound.[1] This provides another indication that the magnetic order is not far below 2 K.

Figure 3 shows the temperature dependent electrical resistivity $\rho(T)$ of $CeNi_{0.4}Cu_{0.6}$ at various values of the magnetic field, which has been applied parallelly to the electrical current direction. Qualitative changes in the temperature dependence of ρ are observed under magnetic field: The zero field resistivity $\rho(H=0)$ has a maximum around 4 K and a shallow minimum centered around 15 K, and both of them disappear when the applied magnetic field increases. These features are usually found in Kondo lattice compounds but in $CeNi_{0.4}Cu_{0.6}$ the maximum in $\rho(H=0)$ does not correspond to the ordering temperature as occurs in the $CeNi_xPt_{1-x}$ series.[1–3]

The magnetoresistivity, $\Delta\rho/\rho=[\rho(H,T)-\rho(0,T)]/\rho(0,T)$ of $CeNi_{0.4}Cu_{0.6}$ as a function of the magnetic field is presented in Fig. 4 at different temperatures. This magnetoresistivity is always negative and decreases with the increasing magnetic field. Furthermore, it is worth noting that in the 0–30 kOe range, the $\Delta\rho/\rho$ curves at 8 and 4.5 K have negative curvature while at 2 K in the same range of magnetic field the curvature is positive. At 2 K and 70 kOe $\Delta\rho/\rho$ is 18%, this value is quite large and close to that of $CeNi_xPt_{1-x}$,[10] although this comparison must be taken with caution due to the influence of the residual resistivity. In Fig. 5 $\Delta\rho/\rho$ is represented as a function of the temperature for $H=70$ kOe. From 30 K, when the temperature decreases $\Delta\rho/\rho$ becomes negative and monotonically decreases. However, at low temperatures this variation suddenly reaches the saturation showing a plateau down to 2 K.

From the present results, it is clear that $CeNi_{0.4}Cu_{0.6}$ does not show magnetic order down to 2 K, however some trends suggest the existence of an ordering temperature not far below this temperature. From the shape of the magnetization curves a ferromagnetic order could be expected at lower temperatures. As CeCu has been reported as an antiferromagnet,[9] then the change from ferromagnetism to antiferromagnetism observed in the other $RNi_{1-x}Cu_x$ compounds[7,8] has not taken place in the Ce based com-

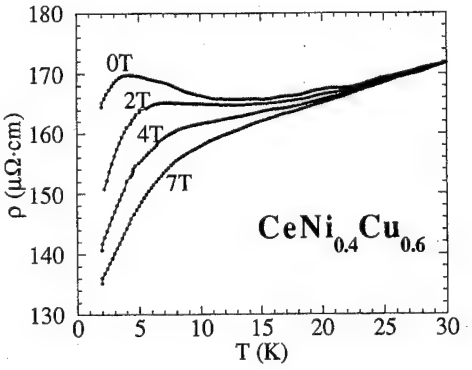

FIG. 3. Temperature dependence of the electrical resistivity for $CeNi_{0.4}Cu_{0.6}$ at various applied magnetic fields.

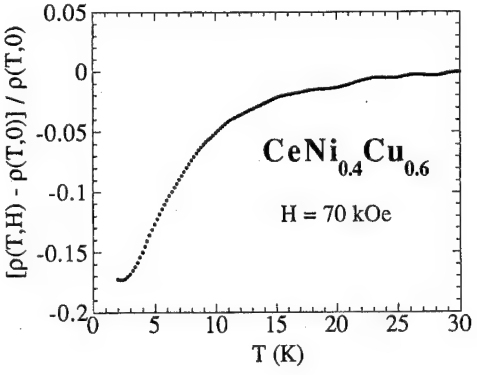

FIG. 5. Temperature dependence of the magnetoresistivity for $CeNi_{0.4}Cu_{0.6}$ corresponding to a 70 kOe applied magnetic field.

pounds at $x=0.6$. On the other hand, the strongly reduced magnetic moment at 80 kOe and 2 K ($0.86\mu_B$/Ce) and the negative value of $\theta_p=-10$ K are clear indications of the existence of a Kondo interaction which seems to be larger than the exchange interactions ($T_K>T_C$). This Kondo behavior is also revealed by the electrical resistivity measurements. The crystalline electric field yields three doublets for these low symmetry orthorhombic structures and then the maximum observed at 4 K is related to the pseudo-Schottky anomaly coming from the splitting of the doublet groundstate due to Kondo interaction. At temperatures just above the maximum a $-\ln T$ law is found. The maximum disappears with the applied magnetic field according to the calculations from Lassailly *et al.*[11] for a doublet groundstate. The fact that the maximum in $\rho(T)$ does not correspond to the ordering temperature as occurs in other Kondo compounds,[1] is commonly observed in systems where T_K is greater than T_C, such as $CePd_2Si$.[12] In other cases in which a well defined maximum in $\rho(T)$ exists, such as $CeCu_6$,[13] it can disappear with dilutions [e.g., $Ce(Cu_{1-x}Au_x)_6$[14]] as a consequence of the destruction of Kondo lattice coherence, but this seems not to be the main mechanism in our compound, in which Ni and Cu share the same crystallographic site.

The magnetoresistance variations reflect the competition between Kondo and exchange interactions, and the observed change in the curvature (see Fig. 4) should be a consequence of the greater importance of exchange at low temperatures according to the calculations of Reference 15. From Fig. 5, we see no clear minimum in the $\Delta\rho/\rho$ vs T variation; some theories[13,16] predict the existence of a minimum corresponding to T_K. However, these theories do not consider the existence of the molecular field as occurs in our case.

All these features indicate that the dilution with copper introduces new interesting aspects in this low symmetry system. Then, the present results encourage us to complete the study of the magnetic properties of $CeNi_{1-x}Cu_x$ compounds in order to understand the exciting changes of the Ce $4f$ electron properties along this series.

Temperature dependence of the electrical resistivity and thermopower of U_2Ni_2In and Nd_2Ni_2Sn

R. P. Pinto, M. M. Amado, M. E. Braga, and J. B. Sousa
Instituto de Materiais (IFIMUP-IMAT) and CFUP, Pr. Gomes Teixeira, 4050 Porto, Portugal

B. Chevalier, D. Laffargue, and J. Étourneau
Inst. Chimie Mat. Conden. Bordeaux, Av. A. Schweitzer, 33600 Pessac, France

Accurate measurements of the electrical resistivity (ρ,$d\rho/dT$) and of the thermoelectric power (S,dS/dT) were performed in the ternary compounds U_2Ni_2In and Nd_2Ni_2Sn from 4 K to 250 K, and the results are compared with those previously obtained in U_2Ni_2Sn. The pair U_2Ni_2In/U_2Ni_2Sn enables us to study the influence of the p-electron character (and other band effects related to the elements In/Sn) on the transport properties, whereas the pair Nd_2Ni_2Sn/U_2Ni_2Sn provides direct information on the role played by the $4f/5f$ electrons. All these compounds order initially in the antiferromagnetic state, exhibiting a characteristic minimum in $d\rho/dT$ at T_N. In the U_2Ni_2In compound a drastic reduction is observed in $\rho(T)$ slightly below T_N, suggesting the coexistence of the antiferromagnetic state with a coherent Kondo effect when $T \leqslant 0.8\ T_N$. In Nd_2Ni_2Sn we observe two distinct phase transitions below T_N, of first-order character and likely associated with order-order magnetic transitions. The anomalous behavior of $\rho(T)$ in the paramagnetic phase of the Nd_2Ni_2Sn compound can be satisfactorily described in terms of crystal field effects associated with the $4f$-electron levels. © *1996 American Institute of Physics.* [S0021-8979(96)25608-9]

I. INTRODUCTION

We have shown recently that the tetragonal stannide U_2Ni_2Sn orders antiferromanetically at T_N=25 K, exhibiting a cusp in the magnetic susceptibility (χ) and characteristic minima in the temperature derivatives of the electrical resistivity (ρ/dT) and thermopower (dS/dT).[1] By substituting the Sn element by In one can appreciably change the electronic band structure, since Sn has an extra valence electron and a smaller atomic diameter. In particular one expects significant differences in the degree of hybridization of the uranium $5f$ electron states with the s-p-d electron states from the transition metal and the s-p states from Sn or In. Important changes may then occur in the transport and magnetic properties, reflecting in particular the influence of the transition metal d-states on the magnetic behavior of uranium.

The role played by the $5f/4f$ substitution is here analyzed with a comparison of the behavior of the transport properties in U_2Ni_2Sn and Nd_2Ni_2Sn, using experimental results on the electrical resistivity (ρ) and thermopower (S) in the temperature range from 3.7 to 300 K.

Both compounds exhibit antiferromagnetism, enabling us to investigate the possible coexistence of this magnetic phase with a heavy fermion state at sufficiently low temperatures, as recently observed in some compounds of the same series.[2]

II. RESULTS AND DISCUSSION

All the polycrystalline buttons were prepared by rf levitation melting followed by annealling at 800 °C for one week in evacuated quartz tubes X-ray powder diffraction showed a single phase tetragonal ordered structure derived from the U_3Si_2 type structure. Paralelipipedic samples were subsequently cut with a spark machine, for the transport measurements.

A. U_2Ni_2In versus U_2Ni_2Sn

The temperature dependence of the electrical resistivity of U_2Ni_2In and U_2Ni_2Sn is shown in Fig. 1 for the temperature range 4–250 K. A high concentration of internal cracks in these samples hampered the accurate determination of the appropriate geometrical factors, so only relative values of resistivity are displayed.

The U_2Ni_2Sn and U_2Ni_2In compounds order antiferromagnetically at T_N=25 K and T_N=14 K, respectively, exhibiting the characteristic minimum in $d\rho/dT$ at the transition point, as shown in the inset of Fig. 1. The lower value of T_N for U_2Ni_2In indicates a stronger delocalization of the $5f$ states in this compound. This seems to be a general feature of the In compounds of 2:2:1 type relative to their Sn counterparts.[3]

In the paramagnetic phase $\rho(T)$ in U_2Ni_2In reveals a pronounced increase over a wide temperature range, with a progressive reduction in the curvature towards saturation above ~200 K. This later behavior contrasts with that ob-

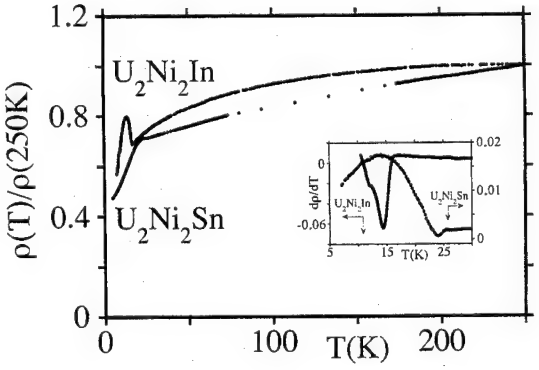

FIG. 1. Temperature dependence of the electrical resistivity (ρ) of U_2Ni_2In and U_2Ni_2Sn in the range 4–250 K.

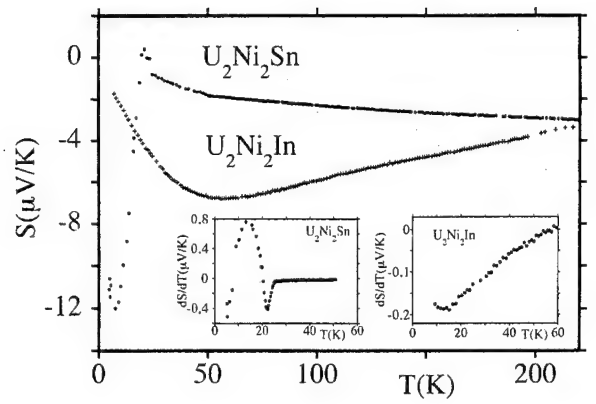

FIG. 2. Temperature dependence of thermopower (S) of U_2Ni_2Sn and U_2Ni_2In in the range 4–250 K. In inset is shown the temperature dependence of dS/dT at low temperatures.

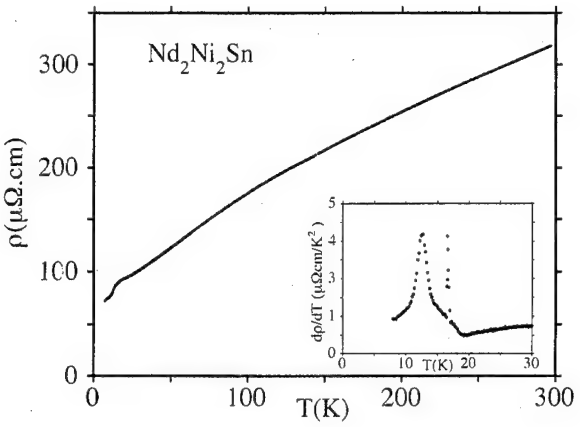

FIG. 3. Resistivity versus temperature for Nd_2Ni_2Sn and its temperature derivative in the inset.

served in U_2Ni_2Sn,[1] where ρ exhibits a linear increase with T at sufficiently high temperatures.

The onset of the antiferromagnetic order also produces a much sharper increase in the electrical resistivity of U_2Ni_2In (just below T_N) than in U_2Ni_2Sn, suggesting in both cases the existence of superzone gap effects associated with the antiferromagnetic periodicity.[4]

Below about 10 K the resistivity of U_2Ni_2In decreases very sharply compared with the usual trend observed in the cooperative phase due to the progressive ordering of the magnetic moments.[5] The enhanced reduction of $\rho(T)$ in U_2Ni_2In can be explained by the rapid decrease in the Kondo scattering in the cooperative state.[6] The same behavior is also observed in U_2Ni_2Sn, but with a smaller slope, which is consistent with the smaller Sommerfeld coefficient of the electronic specific heat, γ=200 mJ/mol K^2 for U_2Ni_2In and γ=172 mJ/mol K^2 for U_2Ni_2Sn.[3]

The thermoelectric power of U_2Ni_2In (shown in Fig. 2) is negative over the whole temperature range and exhibits a negative minimum near 55 K where $S=-7$ μV K^{-1}. For U_2Ni_2Sn a pronounced minima is also observed, but at a much lower temperature, $T\approx 8$ K, where $S=-12$ μV K^{-1}. Minima in the $S(T)$ curves have been reported for heavy fermion systems like U_2Co_3, $CeCu_2Si_2$ and $CeAl_3$ (at T=7, 20, and 4 K, respectively), and explained within the spin fluctuation resonance model.[7,10]

The onset of the magnetic ordering in U_2Ni_2Sn is clearly associated with the upturn in $S(T)$ near T_N=25 K (Fig. 2) and with the sharp minimum in dS/dT (inset of Fig. 2; again suggesting the existence of a superzone gap effect below T_N). As the magnetic transition in U_2Ni_2In occurs in a temperature range where the thermopower exhibits a rapid decrease with increasing temperature, it is not clearly detected in $S(T)$ but only in dS/dT, through a broad minimum near T_N (inset of Fig. 2). This indicates the presence of a background thermopower contribution with a pronounced temperature variation but hardly affected by the magnetic transition.

In the paramagnetic phase and in the temperature range investigated we observe higher thermopower absolute values in U_2Ni_2In than in U_2Ni_2Sn, which may be due to a steeper energy dependence of the density states near E_F in U_2Ni_2In[2,11] or to enhanced crystal field effects.

B. Nd_2Ni_2Sn versus U_2Ni_2Sn

Figure 3 shows the experimental curves of $\rho(T)$ and $d\rho/dT$ for the Nd_2Ni_2Sn compound. The temperature dependence of $d\rho/dT$ (inset Fig. 3) clearly shows the existence of three magnetic transitions. The initial antiferromagnetic ordering occurs at T_N=19.5 K, as revealed by the minimum observed in $d\rho/dT$. At T=17.5 K a small discontinuity is seen in $\rho(T)$, with a sharp positive peak in $d\rho/dT$, indicating a 1st order phase transition. At $T\approx 12$ K we observe a positive peak in $d\rho/dT$, approximately symmetric as usually occurs in order-order phase transitions. The physical origins of the underlying magnetic changes are however still unknown.

In the paramagnetic phase the electrical resistivity of Nd_2Ni_2Sn (Fig. 3) is anomalous, showing a pronounced rise which persists up to 150 K ($\Delta\rho$=40 $\mu\Omega$ cm), where the usual linear increase takes over, due to a dominant electron phonon scattering. We associate the extra contribution up to 150 K with a crystal field effect in Nd_2Ni_2Sn. Not knowing the exact 4f-levels scheme, we use a single spacing (δ) crystal field model for an order of magnitude estimate,[12]

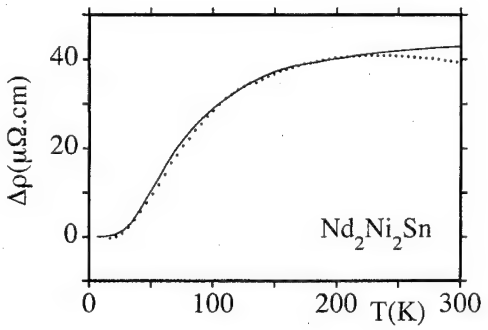

FIG. 4. Theoretical curve (−) and experimental values (●) of the temperature dependence of the electrical resistivity after subtracting the residual, phonon and spin disorder resistivity.

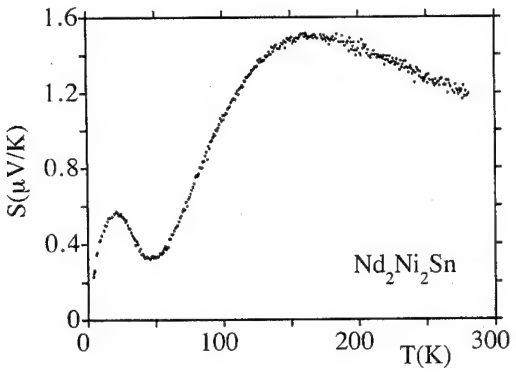

FIG. 5. Temperature dependence of the thermopower S for Nd_2Ni_2Sn.

$$\rho_{CF}(T)=\rho_{CF}(\infty)\,\frac{1}{ch^2(\delta/2KT)}\,.$$

A least square fit gives $\rho_{CF}(\infty)=43\ \mu\Omega$ and $\delta=130$ K, providing a good description of the experimental data up to 220 K, as shown in Fig. 4.

Figure 5 gives the S versus T dependence for Nd_2Ni_2Sn, exhibiting a double-peak structure as usually observed in heavy fermion materials. The maximum at $T=150$ K is again attributed to the crystal field splitting of the $4f$ ground state configuration. A detailed analysis of $S(T)$ is in progress, with the extension of the measurements to higher temperatures.

A comparison of the transport properties of this compound with those previously measured in U_2Ni_2Sn reveals important differences:

(i) in the paramagnetic phase, the electrical resistivity of the Nd compound increases considerably before reaching the classic linear increase with T (electron-phonon scattering), indicating an appreciable crystal field effect in $\rho(T)$ due to the $4f$ electron levels. The same effect is also present in the $S(T)$ data.

(ii) The Néel temperature is considerably lower in the Nd compound, reflecting the localized character and the indirect exchange coupling (RKKY) of the $4f$ magnetic moments.

(iii) In the cooperative phase of the Nd compound several magnetic transitions are observed below T_N, reflecting a subtle competition between different magnetic contributions as usually occurs in $4f$ rare earth elements (e.g., competing anisotropy, crystal field, and exchange effects).

Magnetization, magnetic susceptibility, electrical resistivity, and specific heat measurements of UNiAl point to antiferromagnetic ordering below 19.3 K, which is confirmed by neutron-diffraction experiments. The enhanced γ value of 167 mJ/mol K^2 is reflecting pronounced presence of magnetic fluctuations, which influence also the other electronic properties down to low temperatures. The thermal expansion of UNiAl was measured in the temperature range 1.5–210 K on a single crystal along the a and c axis. Similar to other bulk properties, also the thermal expansion of UNiAl is highly anisotropic. The a axis is monotonously expanding with increasing temperature in the whole temperature range. Along the c axis, the lattice first collapses with increasing temperature up to 35 K. Around this temperature, the thermal expansion coefficient α_c changes sign and continuous expansion with further increasing temperature is then observed. The sharp anomaly of α near 19.3 K present in both directions is consistent with the magnetic phase transition. The results are discussed in terms of the presence of anisotropic magnetic fluctuations. © *1996 American Institute of Physics.* [S0021-8979(96)25708-5]

I. INTRODUCTION

The study of the formation of U magnetic moments in intermetallic compounds plays an essential role in understanding the electronic properties of f-electron-based systems, specially because of possible participation of U $5f$-electrons in the bonding. It has been well established that the variation of the constituent elements in UTX (T=a transition metal, X=a metal from the p-block) intermetallic compounds can drastically change the type of ground state due to the influence of the d- and p-electron states of these elements on the $5f$ electron states, which are principally involved in magnetism.[1] Also when keeping one type of crystal structure (fixed geometry of the surrounding of the U atom) a broad scale of magnetic behavior ranging from Pauli paramagnetism through spin fluctuations towards local-$5f$-moment behavior and magnetic ordering can be observed.

Another essential issue in U intermetallics is the huge magnetocrystalline anisotropy, which originates from the anisotropic bonding of the $5f$ wave functions in the crystal and from considerable $5f$-orbital moments. Among the highly anisotropic UTX compounds crystallizing in the hexagonal ZrNiAl-type of structure (Fig. 1), UNiAl has attracted considerable attention because of the highest γ value of 167 mJ/mol K^2 in this isostructural group of compounds. In the literature,[1,2] this enhanced γ value qualifies UNiAl as a middle-weight heavy-fermion system.

UNiAl becomes antiferromagnetic below 19.3 K as has been inferred from the magnetization, magnetic susceptibility, specific heat and electrical resistivity behavior.[2] It exhibits a strong uniaxial magnetic anisotropy with the easy-magnetization direction along the c axis, which is reflected also in transport properties. The magnetic structure of UNiAl consists of the U magnetic moments oriented along the c axis modulated sinusoidally within the basal planes and coupled antiferromagnetically between these planes. The propagation vector is $\mathbf{k}=(0.1,0.1,0.5)$. The numerous indications of strong involvement of magnetic fluctuations in low-temperature electronic properties[2] make this compound attractive for further experimental investigations and theoretical treatment.

Here, we report the first thermal expansion measurements performed on a single crystal of UNiAl.

II. EXPERIMENT

A single crystal of UNiAl was grown from a nonstoichiometric melt with a slight excess of U by a modified Czochralski technique in the Center ALMOS at the University of Amsterdam. In order to reduce the mosaicity, the seed was tilted from the easy-growth direction by an angle of about 15°. The quality of the resulting crystal was checked by x-ray diffraction and electron-microprobe analysis. It was

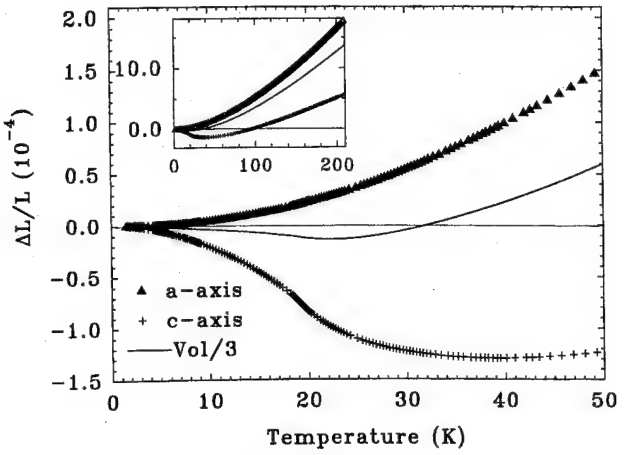

FIG. 2. Temperature dependence of the change of the relative length with respect to 1.5 K measured on a UNiAl single crystal along the a axis (Δ) and the c axis (+), and temperature dependence of the relative volume change (—).

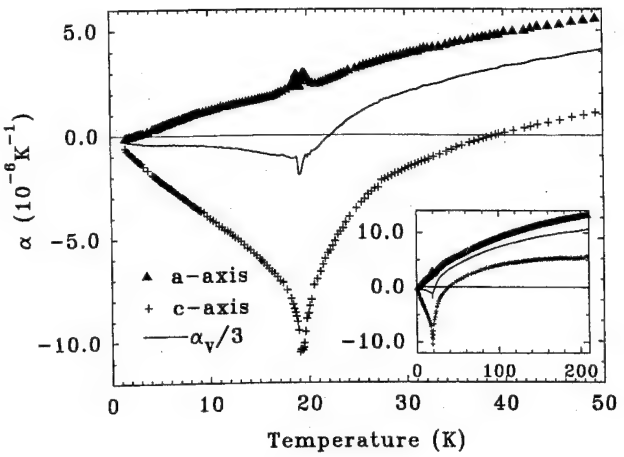

FIG. 3. Temperature dependence of the thermal expansion coefficients along the a axis α_a (Δ) and along the c axis α_c (+) measured on a UNiAl single crystal. The corresponding coefficient of the volume expansion $\alpha_V(T)=2\alpha_a(T)+\alpha_c(T)$ is given by the solid line.

found to be single-crystalline; however, a certain amount of included pure U was detected by the electron-microprobe analysis.

By means of spark erosion a semi-cube with a size of each side of about 3.8 mm was cut perpendicular to the a and the c axes. The temperature dependence of the thermal expansion along the a axis $\alpha_a(T)$ and along the c axis $\alpha_c(T)$ was measured with a parallel-plate capacitance method[3] in the temperature range 1.5–210 K. The temperature was changed in steps and stabilised in order to keep the thermal equilibrium of sample and cell during the measurement. The relative accuracy decreases with increasing temperature, reaching a limit in α of about $3\ 10^{-7}\ \mathrm{K}^{-1}$ around 100 K.

III. RESULTS AND DISCUSSION

The temperature dependence of the relative length changes, $(\Delta L/L)_i$ with respect to the length of the sample along the particular direction at 1.5 K are displayed in Fig. 2 together with the relative volume change $(\Delta V/V)=2(\Delta L/L)_a+(\Delta L/L)_c$. The temperature dependence of the coefficient of linear thermal expansion, $\alpha_i=L_i^{-1}(dL_i/dT)$, where i refers to the a or the c axis of the hexagonal UNiAl, is shown in Fig. 3. The corresponding coefficient of volume expansion $\alpha_V(T)=2\alpha_a(T)+\alpha_c(T)$ is given by the solid line.

As can be seen, the thermal expansion of UNiAl is highly anisotropic, similar to most of other bulk properties. Along the a axis the lattice monotonously expands with increasing temperature (α_a is always positive). The c axis direction reveals first considerable shrinking with increasing temperature yielding a sharp deep minimum at 19.3 K. Around 35 K, $\alpha_c(T)$ changes sign and the lattice expands at higher temperatures. The sharp anomaly observed at 19.3 K in both $\alpha_a(T)$ and $\alpha_c(T)$ is consistent with the magnetic phase transition. In the case of the a-axis direction, the anomaly is doubled. As the absolute value of $\alpha_c(T)$ is considerably larger than $\alpha_a(T)$, the coefficient of volume expansion $\alpha_V(T)$ is negative below 22 K. The maximum anisotropy, corresponding to the maximum difference $\alpha_a(T)-\alpha_c(T)$, is found at T_N. At high temperatures, both thermal expansion coefficients can be approximated by a Debye function with distinct Debye temperatures. The best agreement at temperatures above 80–90 K for the coefficient along the c axis is achieved for $\Theta_D=280$ K. For the coefficient along the a axis, a much higher value of $\Theta_D=400$ K is obtained. In this case, the satisfactory agreement is restricted to region above 150 K.

At low temperatures, both $\alpha_a(T)$ and $\alpha_c(T)$ can be approximated by a linear dependence. By fitting in the temperature region 1.5–4 K, the linear coefficients of the thermal expansion $a_a=\alpha_a(T)/T=1.69\times10^{-7}\ \mathrm{K}^{-2}$ and $a_c=\alpha_c(T)/T=-4.57\times10^{-7}\ \mathrm{K}^{-2}$ are obtained, yielding $a_V=2a_a+a_c=-1.19\times10^{-7}\ \mathrm{K}^{-2}$.

The effective Grüneisen parameter $\Gamma_{\mathrm{eff}}(T)$[4]

$$\Gamma_{\mathrm{eff}}(T)=V_m\alpha_V(T)/\kappa c(T), \tag{1}$$

where V_m is the molar volume, $\kappa=-V^{-1}(dV/dp)$ is the isothermal compressibility, and $c(T)$ is the molar specific heat at constant volume, is a parameter which is frequently discussed in the context of heavy-fermion research. The experimental effective Grüneisen parameter $\Gamma_{\mathrm{eff}}(T)$ is in general temperature dependent and consists of several contributions. In the low-temperature limit where the specific heat and thermal expansion vary linearly, the effective Grüneisen parameter $\Gamma_{\mathrm{eff}}(T)$ is driven by the electronic term $\Gamma_e(T)$

$$\Gamma_e=V_m a_V/\kappa\gamma. \tag{2}$$

In the case of UNiAl, the value of the isothermal compressibility is not available and has to be estimated. We have used a value close to that observed for URhAl[5] which amounts to 1.0 Mbar^{-1}. The specific-heat data from Brück *et al.*[2] provide $\gamma=167$ mJ/mol K^2, $V_m=3.18\times10^{-5}$ m^3/mol. Using Eq. (2) we derive for UNiAl $\Gamma_e=-6.8$. This value is about one order of magnitude smaller than for typical heavy-fermion compounds, e.g., UPt_3,[4] although it is considerably enhanced with respect to normal metals ($\Gamma_e\sim2$). It also should be noted that the relatively small value of α_V is a consequence

of mutual cancellation of significantly large coefficients α_a and α_c, one positive and the other negative. Especially, α_c is very large in absolute value indicating a very strong magnetoelastic coupling along c.

It has been pointed out by Brück *et al.*[2] that UNiAl can be classified as an itinerant antiferromagnet with strong indications for the presence of spin fluctuations. Therefore, a partial contribution to α and Γ due to the spin fluctuations is most probable to play an important role in UNiAl. For the characteristic temperature of the spin fluctuations in UNiAl, a value of the order of 10 K follows from the specific-heat data. The electrical resistivity and the magnetic susceptibility data strongly support this conclusion. One can perform an analysis of all the bulk data together with thermal-expansion results using the so-called universal relations which couple the magnetic susceptibility, the specific heat or the electrical resistivity with thermal-expansion data.[6] However, to draw clear conclusions, usually inelastic-neutron-scattering experiments are necessary.

Recently, we have performed both, elastic and inelastic-neutron-scattering experiments on a good-quality UNiAl single crystal.[7] Here we summarize only the points relevant to understand the thermal-expansion results. The analysis of the neutron-diffraction results reveals the presence of strong antiferromagnetic fluctuations in UNiAl. The development of the fluctuations with temperature can be followed from low temperatures up to at least $1.5T_N$. However, no particular dispersion can be assigned to magnetic fluctuations. Instead of that, a wide spread in energy transfer of scattering intensity is present in the inelastic spectrum, both, below and above T_N.

As the magnetocrystalline anisotropy of UNiAl expressed in values of the paramagnetic Curie temperature reaches 300–400 K, the magnetic fluctuations have entirely different behavior along the c axis and within the basal plane. The onset of magnetic fluctuations is visible around 35–40 K where upon lowering the temperature a deviation from the high-temperature behavior of the thermal-expansion coefficient α_a can be observed accompanied by a contraction along the hexagonal axis. Magnetic fluctuations along the c axis are clearly of antiferromagnetic type. The behavior along the a axis is rather regular, except for the critical region around T_N.

IV. CONCLUSION

We have shown that the thermal expansion of UNiAl which crystallizes in the hexagonal ZrNiAl-type of structure is large and highly anisotropic. The magnetic phase transition at 19.3 K is reflected in both directions by a pronounced anomaly. These findings are in good agreement with other bulk magnetic, transport and thermal properties which reflect the huge magnetocrystalline anisotropy as well. The magnetic structure consists of sine-modulated U magnetic moments within the basal plane with adjacent planes coupled antiferromagnetically.

The value of the electronic contribution to the Grüneisen parameter $\Gamma_e = -6.8$ is relatively small compared to values observed for typical heavy-fermion compounds. This is, however, partially due mutual cancellation of the expansion effects along a and c. The large negative expansion along c below 35 K, on the other hand, can be tentatively attributed to the effect of antiferromagnetic fluctuations and to antiferromagnetic ordering in UNiAl below 19.3 K.

U_2Pt_2Sn is crystallizing in an ordered version (space group $P4_2/mnm$) of the tetragonal U_3Si_2 type of structure. Clear anomalies in the magnetic susceptibility, specific heat, and electrical resistivity around 15 K indicate that U_2Pt_2Sn orders antiferromagnetically below this temperature. As expected for an antiferromagnet, the susceptibility and specific heat anomalies are shifted to lower temperatures upon application of external magnetic field. The specific-heat coefficient γ=327 mJ/mol f.u. K^2 remains unchanged in fields up to 5 T. The antiferromagnetic ground state of U_2Pt_2Sn can be concluded also from the metamagnetic transition around 22 T in the magnetization at 4.2 K and from magnetic reflections in the neutron-diffraction pattern at low temperatures. © *1996 American Institute of Physics.* [S0021-8979(96)25808-1]

I. INTRODUCTION

Recently, great attention has been given to the isostructural group of U_2T_2X compounds (T=transition metal and X=In, Sn, Al, or Ga).[1–3] The development of their magnetic properties (from Pauli paramagnetism to local-moment behavior) is influenced by the hybridization of the $5f$-electron states with ligand electron states. The $5f$-d hybridization is demonstrated by the evolution of magnetism with respect to the transition metal component.[1,4,5]

U_2Pt_2Sn has been first reported to adopt the tetragonal U_3Si_2-type structure (space group $P4/mbm$).[6] More recent studies pointed out a derivative form with the space group $P4_2/mnm$.[7] Both related structures consist of two alternating plane sheets, one containing only U atoms and the other accommodating T and X atoms. The shortest interatomic U-U distance in U_2Pt_2Sn is about 350 pm, which places this compound into a critical region between localized and itinerant $5f$-electron behavior in Hill's classification.[8]

The aim of the present contribution is to investigate the type of the crystal structure, the type of the ground state, as well as to study the magnetic, transport and thermal properties of polycrystalline U_2Pt_2Sn.

II. EXPERIMENT

A polycrystalline sample of U_2Pt_2Sn has been prepared by arc-melting appropriate amounts of the constituting elements under argon atmosphere. The purity and composition homogeneity were checked by x-ray diffraction and by electron-microprobe analysis. The microprobe indicated less than 1 vol. % of UPtSn as a secondary phase. The average composition of the main phase only slightly deviates from the ideal stoichiometric composition of U_2Pt_2Sn. A slight U excess and Sn deficiency, both of the order of 1 at. %, were found.

The low-field magnetization and the temperature dependencies of the dc magnetic susceptibility ($\chi=M/H$) were measured between 2 and 300 K in magnetic fields up to 5 T in a Quantum Design SQUID magnetometer on a fine-powder sample with grains fixed in random orientation by diamagnetic glue.

The specific heat was measured by a standard semi-adiabatic method in the temperature region 1.3–50 K in fields up to 5 T.

The electrical resistivity was measured on a small bar-shaped sample by standard ac four-point method. The large error in the geometrical factor (in addition to the expected influence of internal microcracks) makes a reliable estimate of the absolute resistivity values questionable. Therefore, we display the normalized electrical resistivity ρ/ρ_{300K}.

Neutron-diffraction data at 2.6 and 24 K were obtained in the neutron powder diffractometer E6 at the Hahn–Meitner Institute using an incident neutron wavelength of 2.386 Å. For these measurements about 10 g of U_2Pt_2Sn was powdered and encapsulated in a vanadium container under He atmosphere. The data were analyzed by means of the Rietveld profile procedure[9] using the program Fullprof.[10] The neutron-scattering lengths were taken from Ref. 11.

III. BULK MEASUREMENTS

The susceptibility (Fig. 1) above 40 K is nearly field independent, whereas the χ vs T curves show splitting in the

 0021-8979/96/79(8)/6361/3/$10.00

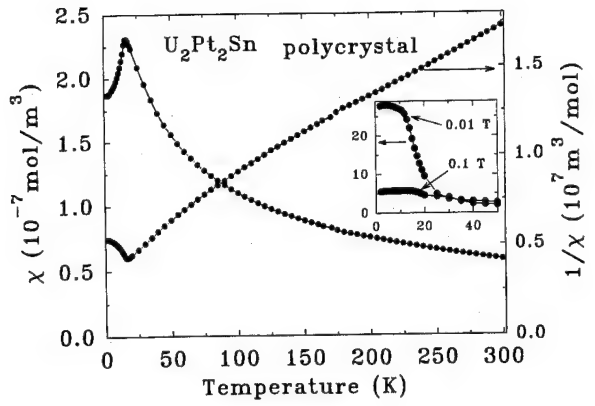

FIG. 1. Temperature dependence of the magnetic susceptibility of U_2Pt_2Sn extrapolated to infinite magnetic field together with its reciprocal value. In the inset the data collected in 0.01 and 0.1 T are shown.

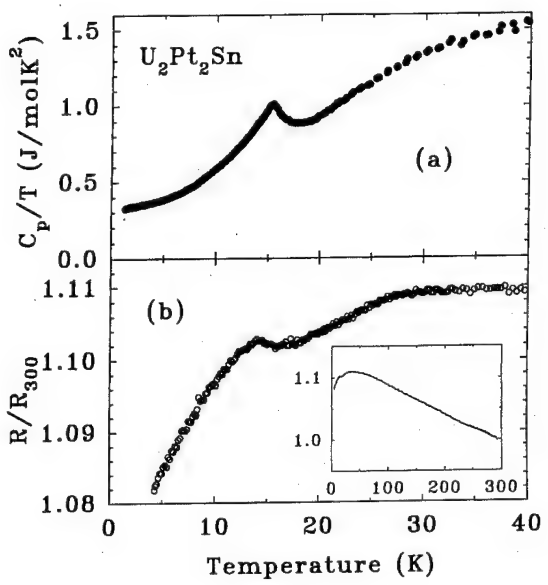

FIG. 2. Temperature dependence of the specific heat of U_2Pt_2Sn in the representation C_p/T vs T (a) and the electrical resistivity (b) in zero magnetic field.

low-temperature region reflecting an increasing amount of a ferromagnetic component with lowering temperature. An upturn becomes progressively pronounced with decreasing magnetic field (the inset of Fig. 1). We tentatively attribute this spurious signal to the UPtSn impurity, which is ferromagnetic below 19 K.[12] In Fig. 1 then the susceptibility data extrapolated to infinite magnetic field are shown. Two regions on the $1/\chi$ vs T above 40 K can be identified: one linear above 160 K, which can be fitted by Curie–Weiss (CW) law

$$\chi = C/(T-\Theta_p), \tag{1}$$

and another strongly curved at lower temperatures which can be approximated only by a modified Curie–Weiss law (MCW)

$$\chi = C/(T-\Theta_p)+\chi_0. \tag{2}$$

In the former case, the fitting parameters are: $C=(2.56\pm0.01)\times10^{-5}$ m^3/mol f.u. K ($\Rightarrow\mu_{\rm eff}=2.86\pm0.02$ μ_B/U atom) and a negative paramagnetic Curie temperature of -141.5 ± 1.6 K. The MCW fit below 160 K is yielding a significantly lower value of $C=(1.11\pm0.01)\times10^{-5}$ m^3/mol f.u. K ($\mu_{\rm eff}=1.88\pm0.02$ μ_B/U atom), a fairly less negative $\theta_p=-6.9\pm0.6$ K, whereas $\chi_0=2.9\times10^{-8}$ m^3/mol f.u. .

These fits should be taken with caution, because the polycrystalline data on highly anisotropic material as most of the U_2T_2X compounds are, may represent an admixture of very different anisotropic components of the susceptibility. These components may follow the CW law, however, the $1/\chi$ vs T dependence measured on polycrystal is strongly curved especially at lower temperatures. Nevertheless, the high-temperature CW fit provides a good estimate of the upper limit of $\mu_{\rm eff}$ (although, even this value is smaller than the values expected for the localized f^{3+} or f^{4+} configuration). The strikingly different values of Θ_p from the high-temperature CW fit and the low temperature MCW fit serve rough estimates of paramagnetic Curie temperatures for the hard- and easy-magnetisation direction, respectively. The $\mu_{\rm eff}$ value from the low temperature fit is only a fraction of the genuine effective moment and depends on the multiplicity of the easy axis. The "temperature independent parameter" χ_0 is then an arbitrary value without any deeper physical meaning.

The magnetic phase transition at $T_N=15$ K is reflected by the peak in the C_p/T vs T curve [Fig. 2(a)]. The peak is shifted by -0.3 K in 5 T as expected for an antiferromagnet. The linear coefficient of the specific heat $\gamma=327.0\pm0.3$ mJ/mol f.u. K^2 follows from the linear extrapolation of C_p/T vs T^2 plot in the region 1.3–8.5 K to zero Kelvin. This value which accounts for two U atoms in the formula unit is not affected by magnetic field to 5 T. The value of 163 mJ/mol K^2 calculated per one U atom is certainly enhanced with respect to normal nonmagnetic metals.

The onset of antiferromagnetic ordering at $T_N=15$ K is reflected also in the electrical resistivity [Fig. 2(b)]. The electrical resistivity is slightly increasing with lowering temperature and passing a shallow maximum around 35 K. This behavior is commonly observed in strongly hybridized U-based materials. After some precursor behavior around T_N the resistivity drops at lower temperatures. No quadratic temperature dependence is observed down to 4.2 K.

The magnetization curves of U_2Pt_2Sn at 4.2 K show a metamagnetic transition at about 22 T.[13] This result corroborates the conclusion about the antiferromagnetic ground state. The magnetization for the field-aligned (random-oriented) powder sample yields a value of 1.49 (1.23) μ_B/f.u. in 56 T. The magnetization curve is far from saturation even in this very high magnetic field. We cannot exclude that another metamagnetic transition may occur in higher fields and therefore, do not dare making any conclusion about the type of anisotropy from comparison of present data obtained on the field-aligned and random oriented samples.

The low-field magnetization exhibits a small hysteresis loop developing below 20 K, which is believed to be due to the ferromagnetic UPtSn impurity.

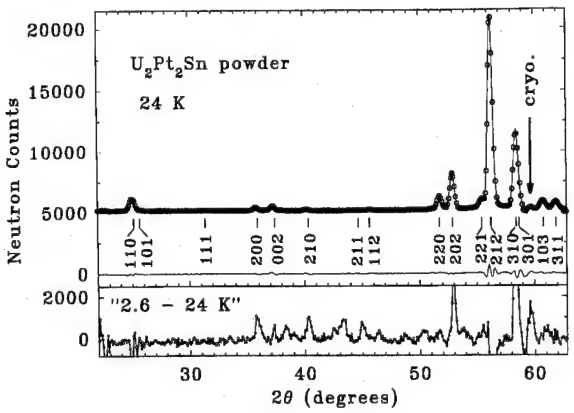

FIG. 3. The neutron-diffraction spectrum of U_2Pt_2Sn recorded at 24 K together with the best fit. The full line at the bottom represents the difference between the experimental data and the fit. The 2.6–24 K spectrum is displayed, as well.

IV. NEUTRON DIFFRACTION RESULTS

As two possible crystal structures for U_2Pt_2Sn have been reported in the literature, the determination of the exact crystal structure was our first task in the neutron-diffraction experiment. Two tetragonal crystallographic structures were considered: the ideal tetragonal U_3Si_2-type of structure (space group $P4/mbm$) and its variant, in which U atoms are forced by relatively large Pt atoms to move from their original positions forming thus zig-zag chains along the c axis (space group $P4_2/mnm$). The pattern recorded (Fig. 3) above the transition temperature, at 24 K, can be fully indexed by using the latter type of structure. The structural parameters are summarized in Table I. Reflections of the very weak UPtSn secondary phase cannot be detected.

In the spectrum recorded at 2.6 K, new—purely magnetic reflections and additional magnetic contributions on some of the nuclear Bragg reflections (see the difference spectrum in Fig. 3) can be resolved. This clearly indicates that the magnetic periodicity is different from the crystallographic one, which is compatible with the antiferromagnetic ordering suggested from bulk experiments. The magnetic structure refinement is difficult from the available powder pattern. In this stage, no magnetic unit cell which would index all observed magnetic peaks could be deduced. Single-crystal data are desirable to choose a proper model out of many, which are roughly satisfying the powder data.

TABLE I. The refined structural parameters of U_2Pt_2Sn at 24 K.

Space group:		$P4_2/mnm$, $Z=2$		$T=24$ K

		$\chi^2=3.30$		

V. CONCLUSIONS

By means of powder neutron diffraction, we have shown that U_2Pt_2Sn crystallizes in an ordered variant (space group $P4_2/mnm$) of the tetragonal U_3Si_2-type of structure and that it orders antiferromagnetically at low temperatures ($T_N=15$ K). The results obtained by means of the magnetic-susceptibility, the specific-heat and the electrical-resistivity suggests that the magnetism in U_2Pt_2Sn is governed by to certain extent delocalized $5f$-electron states in U atoms. However, among the U_2T_2X compounds studied, this material can be considered as an example of a system with rather well-defined U magnetic moments. In order to elucidate the magnetic structure and specific features of magnetic anisotropy, single-crystalline U_2Pt_2Sn are strongly desirable.

The spin-glass state of $Y_{1-x}U_xPd_3$

M. A. Lopez de la Torre,[a] J. Rodriguez Fernandez, and K. A. McEwen
Department of Physics, Birkbeck College, University of London, Malet Street, London WC1E 7HX, United Kingdom

We have performed a detailed study of the magnetization of $Y_{0.6}U_{0.4}Pd_3$ ($T_f \sim 10$ K), which shows thermal, transport, and magnetic properties typical of a spin-glass system. Strong irreversibility is observed among our zero-field-cooled and field-cooled measurements in fields as large as 30 kOe. Thus, the freezing temperature displays an unusual weak dependence with field. We observe a very slow temporal dependence of the magnetization below the freezing temperature. The nonlinear susceptibility coefficients extracted from our data show an increase by a factor of approximately 20 when approaching the freezing temperature from above, but do not show a true divergence at T_f, and a scaling analysis does not seem to be possible. We compare these results with those expected for classical spin glasses, and propose a possible mechanism for the onset of frustration below $x=0.45$ in $Y_{1-x}U_xPd_3$. © *1996 American Institute of Physics.* [S0021-8979(96)25908-8]

I. INTRODUCTION

The pseudobinary metallic compound $Y_{1-x}U_xPd_3$ has been the subject of intensive study in recent years. For $x=0.2$, anomalous thermal, magnetic, and electrical properties are observed, suggesting a non-Fermi liquid ground state.[1,2] Several theoretical models have been proposed in order to explain the origin of this unconventional behavior, from a multichannel Kondo effect to a $T=0$ phase transition. In this case, the actual character of the magnetic ordering taking place for $x>0.2$ determines whether a non-Fermi liquid ground state develops at low temperature.[3]

Regarding $Y_{1-x}U_xPd_3$, in the U concentration range $0.2<x<0.5$ these materials apparently show clear spin-glass ordering below a freezing temperature (T_f) which extrapolates to 0 K in the $x=0.2$ limit.[4] However, close to the upper limit ($x=0.45$), recent experimental evidence indicates the onset of long-range antiferromagnetic ordering,[5] casting some doubts about the spin-glass behavior for all the concentration range. An interesting feature of the spin-glass ordering in these materials is that it develops in a by no means diluted system. On the contrary, canonical spin glasses usually are diluted systems, showing a trend towards long-range magnetic ordering with increasing doping.[6–8]

With the aim of clarifying the actual character of magnetic ordering in this system, we have performed a study of the magnetization of $Y_{0.6}U_{0.4}Pd_3$ ($T_f \sim 10$ K). The results are compared with those expected for classical spin glasses.

II. EXPERIMENT

The polycrystalline sample of $Y_{0.6}U_{0.4}Pd_3$ was prepared by arc melting in an argon atmosphere, and subsequently annealed at 900 °C for one week. X-ray diffraction studies did not reveal the existence of any secondary phase. Magnetization measurements were performed at Birkbeck College in the temperature range between 2 and 20 K and for fields up to 70 kOe using a Quantum Design SQUID magnetometer.

III. RESULTS

In Fig. 1 we show results from dc magnetic susceptibility measured on warming, after cooling the sample to the base temperature in zero applied field (ZFC), and measured while cooling to the base temperature in an external applied field (FC). Even for fields as high as 30 kOe, strong irreversibility is observed below a characteristic temperature (T_{irr}). For low fields, both ZFC and FC magnetic susceptibilities show a peak (T_{max}) at the irreversibility temperature, as it is usually observed in canonical spin glasses. For higher applied fields, both characteristic temperatures are monotonically shifted down, more quickly for T_{irr}. It is also clearly observed from Figs. 1 and 2 that the susceptibility maximum becomes progressively smoothed with increasing applied field, which is usually interpreted as a sign of the nonlinear effects. For 50 and 70 kOe, the magnetic susceptibility is practically constant below T_{max}, and we were able to observe only a weak irreversibility. Due to experimental difficulties, the starting temperature for these last fields was 4.5 K instead of 2 K. Further experiments down to 2 K are in progress to determine T_{irr} for fields higher than 30 kOe.

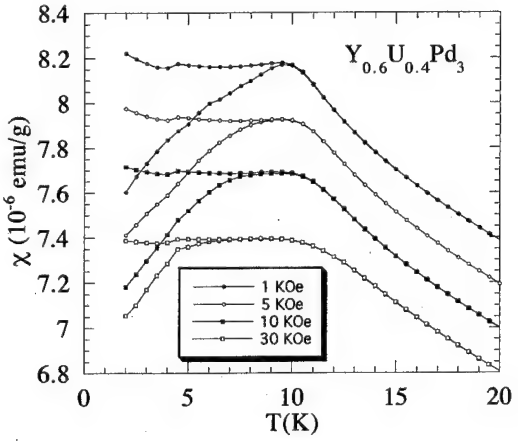

FIG. 1. ZFC and FC magnetic susceptibility of $Y_{0.6}U_{0.4}Pd_3$ as a function of temperature for $H=1$, 5, 10, and 30 kOe. Curves corresponding to 10, 5, and 1 kOe are shifted up for clarity. Solid lines are guides to the eye.

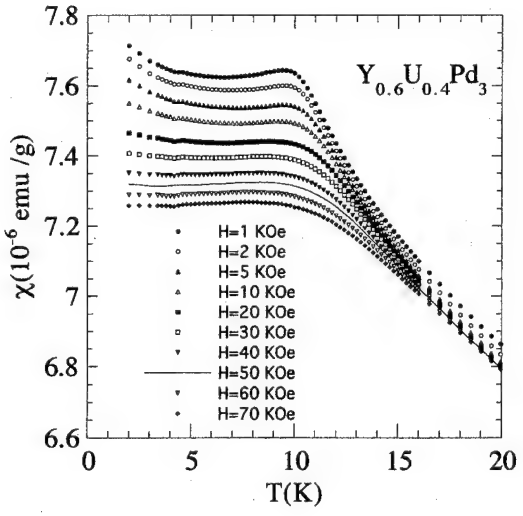

FIG. 2. Field-cooled magnetic susceptibility set of data used for the fits to the nonlinear expression cited in text.

In Fig. 2 we show the results of the FC measurements, from which we extracted M vs H data and performed a classical analysis in terms of nonlinear susceptibility:

$$M = m_0 + \chi_0 H - b_3(\chi_0 H)^3 + b_5(\chi_0 H)^5. \quad (1)$$

The m_0 term is included in order to correct for systematic errors in the low-field data arising from remanent magnetization.[9] In Fig. 3 we show the b_3 and b_5 coefficients obtained from this analysis. The typical error for the b_3 coefficient amounts to 10% of its absolute value, and to 30% for the b_5 coefficient. In spite of the significant uncertainty in its absolute values, both coefficients steadily increase by a factor of about 20 when approaching the freezing temperature from above, reaching a maximum around 10.2 K, which can be interpreted as the actual freezing temperature.

We also checked the temporal dependence of the magnetic properties. In Fig. 4, we show the magnetic susceptibility as a function of time, measured at $T=2$ K, well below the freezing temperature, in a 5 kOe applied field and after the sample had been zero-field cooled. A logarithmic law $\chi(t)=M_0+M_1 \ln T$ clearly does not fit our results, nor an

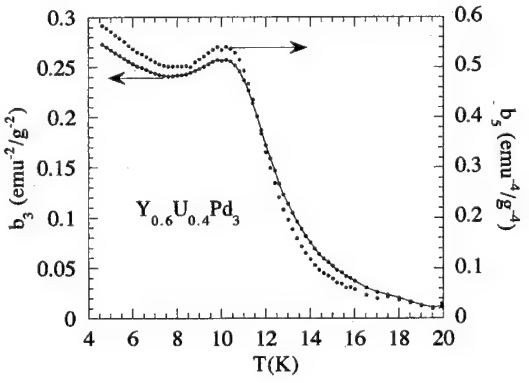

FIG. 3. Temperature dependence of the nonlinear coefficients b_3 and b_5, showing the peak at the freezing temperature.

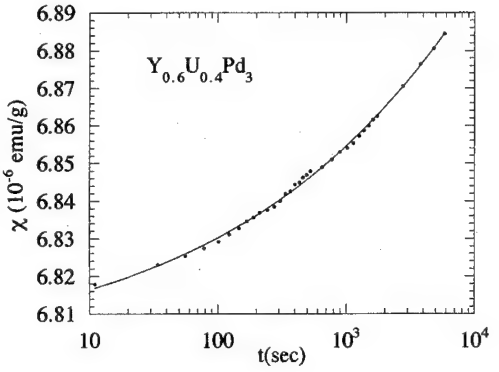

FIG. 4. Magnetic susceptibility as a function of time, measured at $T=2$ K and in 5 kOe applied field after zero-field cooling the sample. Solid line is a fit to the stretched exponential expression cited in text with the coefficients $M_0=7.36\times10^{-6}$ emu/g, $M_1=-5.61\times10^{-7}$ emu/g, $n=0.74$, $t_p=5\times10^6$ s.

algebraic law $\chi(t)=M_0+M_1 t^{-\alpha}$, rather we find that a Kohlrausch law (also called stretched exponential),

$$\chi(t)=M_0+M_1 \exp[-(t/t_p)^{(1-n)}] \quad (2)$$

give us a very good fit, which is a very common behavior for canonical spin glasses. In fact, our value for the coefficient n (0.74 ± 0.01) is very close to the value obtained by Chamberlin *et al.*[10] for diluted AgMn alloys at temperatures well below T_f($n\sim0.69\pm0.01$).

IV. DISCUSSION

From our results, a first conclusion is readily obtained: most of the features observed in the magnetic susceptibility of $Y_{0.6}U_{0.4}Pd_3$ are reminiscent of those usually observed in canonical spin glasses. We will mention several of them: (a) strong irreversibility, (b) a cusp at T_{max} in the ZFC and FC susceptibilities, which at low fields coincides with the onset of irreversibility at T_{irr}, (c) χ_{FC} almost temperature independent below T_{max}, (d) *slow* temporal dependence of the magnetic properties, described by a stretched exponential function.

A remarkable feature that is worth to point out is the magnitude of the fields necessary to destroy the strong irreversibility in the susceptibility ($H>30$ kOe to have $T_{irr}<4.5$ K). For canonical spin glasses, even with freezing temperatures as high as 30 K, 30 kOe would completely destroy the strong irreversibility.[11] However, in our system a weak irreversibility is still present below T_{max} even for 50 and 70 kOe. If we define T_{max} as the actual freezing temperature, then, when applying a field $H=70$ kOe we would have a spin-glass state shifted down 2 K below $T_f(H=0)$, which is only a 20%T_f shift. We have not found in the available literature any material showing such a weak dependence of T_f with magnetic field. Something similar could be pointed out for the temporal evolution of the ZFC susceptibility. Again, we find it quite remarkable that we perform this experiment with an applied field $H=5$ kOe, rather *small* for the frozen state of $Y_{0.6}U_{0.4}Pd_3$ but enormous for any typical spin-glass system.

It is usually stated that conventional spin glasses would show a divergence in b_3, b_5, the coefficients of the nonlinear expansion for magnetization, if there is a true spin-glass transition at T_f.[12] Our results show a substantial increase in both coefficients on approaching the transition from above, but not a strict divergence at T_f. Having extracted from the data the nonlinear susceptibility, it is possible, at least in principle, to obtain the so-called critical isotherm, $\chi_{nl} \propto H^{2/\delta}$, computing then one of the critical exponents (δ), and afterwards to follow with a conventional scaling analysis. Due in part to experimental uncertainty at low fields, it is difficult to extract δ from our results. A log–log plot of χ_{nl} vs H (not shown) only displays linearity in a restricted range, of less than one decade, at high fields. A system that shows such a weak dependence of b_3 and a quite restricted scaling behaviour of the critical isotherm is the *kagomé* system $SrCr_8Ga_4O_{19}$, which is an archetypal highly frustrated system.[9,13] For this material, a nonconventional spin-glass state below T_f has been proposed, which shares an unusual feature with our system: a T^2 term in the low-temperature specific heat, which is not generally observed in spin-glass systems. For the *kagomé* system, it has been suggested that this term could arise from finite size antiferromagnetic regions. As it was pointed out before, $Y_{0.55}U_{0.45}Pd_3$ seems to develop long-range antiferromagnetic order below $T_N \sim 20$ K.[5] Otherwise, apart from the almost typical spin-glass-like thermal, magnetic and electrical properties of $Y_{0.6}U_{0.4}Pd_3$, results from μSR experiments exhibit features expected for spin-glass ordering developing below the freezing temperature.[14] A possible explanation for this spin-glass state is that frustration develops for U concentrations lower than 0.45. For materials with $x \leqslant 0.45$, like ours, it is tempting to consider that we are close to the percolation limit separating spin glass from long-range magnetic order. In that concentration range, antiferromagnetic clusters play an important role. We want to point out that the percolation limit for antiferromagnetic bonding in a fcc lattice is 45%.[7] Following the common nomenclature, $Y_{0.6}U_{0.4}Pd_3$ should be considered as a cluster glass (also called mictomagnet). Because we are in the high concentration limit, and due to the increasing role of antiferromagnetic clusters, we should observe no scaling of the magnetic properties. If our description is correct, with decreasing U concentration the system would evolve steadily to a more conventional spin-glass behavior, recovering the scaling in the low concentration limit.[7]

Considering the non-Fermi liquid ground state developing for $x=0.2$, it seems to develop right at the concentration limit where the freezing temperature approaches zero. Following our discussion, the $T_f \rightarrow 0$ K limit concentration ($x=0.2$), separates a *canonical* spin-glass region (showing, for example, scaling of the magnetic properties) from the Kondo regime. As far as we know, theories in favor of non-Fermi liquid behavior due to a $T=0$ phase transition consider only long-range magnetic order.[2,3] If such a theory can be applied to a spin glass with $T_f=0$ remains an open question.

V. CONCLUSIONS

The dc magnetic susceptibility of $Y_{0.6}U_{0.4}Pd_3$ shows most of the features commonly associated with spin-glass order. However, our results show neither a true divergence of the first two coefficients of nonlinear susceptibility (b_3,b_5) nor scaling of its critical isotherm. This points to a noncanonical spin glass state. Considering the long-range antiferromagnetic ordering reported for the 0.45 compound, we propose that $Y_{0.6}U_{0.4}Pd_3$ should be considered as an example of cluster glass system in the concentration range close to the percolation limit for antiferromagnetic ordering.

Search for hybridization gap in the electronic density of states in CeNiSb

Latika Menon, S. K. Dhar, and S. K. Malik
Tata Institute of Fundamental Research, Homi Bhabha Road, Bombay 400 005, India

W. B. Yelon
University of Missouri Research Reactor, Columbia, Missouri 65211

The compounds CeRhSb and CeNiSn show hybridization gap in the electronic density of states. It is of interest to look for a similar gap in a related compound, CeNiSb. We present here the results of the structural, magnetic, and transport studies on CeNiSb. Rietveld analysis of the room-temperature neutron diffraction data reveals that this compound crystallizes in the hexagonal structure (space group $P6_3/mmc$). Magnetization measurements show that this compound is ferromagnetically ordered with a transition temperature of ~4 K. The magnetic susceptibility of CeNiSb follows Curie–Weiss behavior between 10 and 300 K with effective paramagnetic moment close to that of Ce^{3+} ion. The heat capacity of CeNiSb shows a rise at about 4 K due to the ferromagnetic ordering and a moderately large value of γ is obtained. Its electrical resistivity shows a weak shallow minima at 15 K which is a characteristic feature of Kondo lattice systems. However, no rise in the resistivity at low temperatures, as seen in CeRhSb and CeNiSn, is observed in CeNiSb.
 [S0021-8979(96)26008-2]

I. INTRODUCTION

The compound CeRhSb[1,2] is one of the very few Ce-based intermetallic compounds to show an insulating/semiconducting ground state. This compound crystallizes in the orthorhombic ϵ-TiNiSi-type structure (space group *Pnma*). Its susceptibility shows a broad maxima, typical of mixed-valent Ce-based compounds. In such mixed-valent systems, as a result of the strong hybridization between the conduction electrons and the $4f$ electrons, a gap can occur at low temperatures in the electronic density of states. The electrical resistivity of this compound, though metal-like at higher temperatures, indeed shows a sharp rise at low temperature (below 8 K), which is thought to be a manifestation of the gap in the electronic density of states. The gap energy has been estimated to be about 4 K from these measurements. Another Ce-based compound, CeNiSn,[3] isostructural to CeRhSb, also shows similar gap formation.

In view of the above-mentioned results, it is interesting to study the system, CeNiSb, which may be thought to be derived from CeRhSb by substitution of Ni at the Rh site or from CeNiSn by substitution of Sb at the Sn site and to look for gap formation in this compound. We have, therefore, carried out electrical resistivity, magnetic susceptibility, and heat capacity measurements on this compound. Our measurements reveal that the Ce ions in CeNiSb are in a nearly trivalent state. There is a weak Kondo lattice nature and also a ferromagnetic ordering in this compound below 4 K. However, low-temperature resistivity rise is not seen in this compound.

II. EXPERIMENTAL DETAILS

The RNiSb (R=La and Ce) samples were prepared by arc melting of stoichiometric amounts of the constituent elements under a continuous flow of Argon gas. If the loss in weight is attributed to the volatile nature of Sb, the resulting composition of the Ce compound is $CeNiSb_{0.9}$ (which will be referred to as CeNiSb). We have carried out neutron diffraction measurements on this compound to study its crystal structure and various site occupancies. In order to look for gap formation, heat capacity, resistivity, and magnetic susceptibility measurements were carried out. For heat capacity measurements the adiabatic technique was used in the low temperature range of 2–20 K. (For details on resistivity and susceptibility measurements, see Ref. 4.)

III. RESULTS AND DISCUSSIONS

Preliminary x-ray measurements had shown that CeNiSb crystallizes in the hexagonal structure unlike CeRhSb while the nonmagnetic analogs, LaNiSb and YNiSb appeared to be isostructural to CeRhSb. However, a more detailed analysis shows that the crystal structure of all the three RNiSb compounds mentioned above can be refined assuming a hexagonal lattice with space group $P6_3/mmc$. The observed and fitted neutron diffraction pattern of CeNiSb is shown in Fig. 1. The GSAS program based on Rietveld analysis was used to refine its crystal structure.[5] The scattering cross sections (in

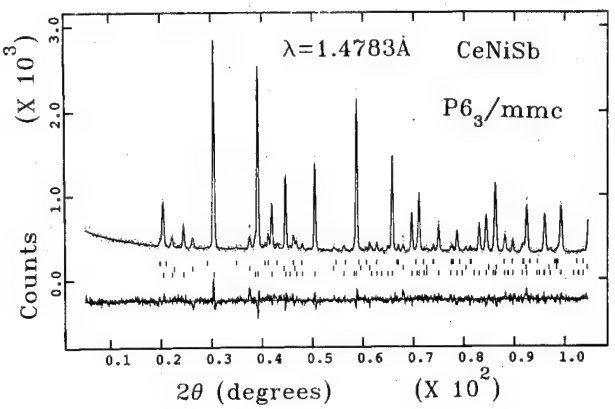

FIG. 1. Observed and fitted neutron diffraction pattern for CeNiSb. The line positions marked below the pattern are for $CeNi_5$, CeSb, and CeNiSb, respectively.

 0021-8979/96/79(8)/6367/3/$10.00

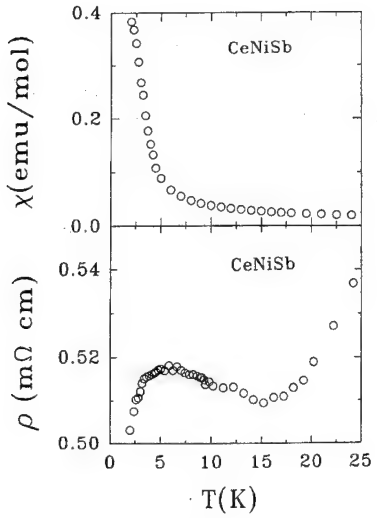

FIG. 2. (a) Plot of magnetic susceptibility χ vs temperature T for CeNiSb. (b) Plot of electrical resistivity ρ vs temperature T for CeNiSb showing the Kondo minimum.

units of 10^{-12} cm) used were Ce(0.484), Ni(1.030), and Sb(0.564). The line shapes were approximated by pseudo-Voigt type function. A reasonably good fit to the data is obtained in the hexagonal structure, (space group $P6_3/mmc$) with two formula units per unit cell in which Ce is at the $2a$ site at (0,0,0), Ni at the $2c$ site at (0.33,0.66,0.25), and Sb at the $2d$ site at (0.33,0.66,0.75). The refinement also included secondary phases CeSb (3%) and $CeNi_5$ (6%). From the refinement, the values of lattice parameters obtained for CeNiSb are a=4.3935(1) Å and c=8.2375(3) Å. The bond distances obtained are d_{Ce-Ce}=4.119 Å, d_{Ce-Sb}=3.266 Å, d_{Ce-Ni}=3.266 Å, and d_{Ni-Sb}=2.536 Å. The reduced χ^2 value for the fit is 1.598, wR_p=5.9% and R_p=4.6%. The refined fractional site occupancies for the sites are Ce: 1 (fixed), Sb: 1.047(18), and Ni: 0.937(14). Since Ni has a higher neutron scattering cross section than Sb, the obtained site occupancies for Ni and Sb in the context of starting composition may be taken to imply some Ni/Sb disordering.

On fitting the x-ray pattern of LaNiSb and YNiSb to a hexagonal structure with space group $P6_3/mmc$ the following lattice parameters are obtained. For YNiSb a=4.312(2) Å, c=7.778(3) Å and for LaNiSb a=4.385(1) Å, c=8.476(1) Å.

Figure 2(a) shows a plot of susceptibility versus temperature for CeNiSb. The rise in susceptibility observed below 5 K is due to impending magnetic ordering. From detailed magnetization measurements on this compound,[4] the ordering is surmised to be of ferromagnetic in nature. Figure 2(b) shows a plot of the electrical resistivity versus temperature. A broad minimum at 15 K is observed which probably indicates Kondo lattice behavior in this system. However, it may be mentioned that this feature in resistivity is somewhat sample dependent but may not be due to impurity phases since no sharp drop is seen. At low temperatures, a sharp drop in the resistivity is observed due to onset of magnetic ordering. No rise in the resistivity is observed at low temperature down to 2 K, unlike that seen in CeRhSb.

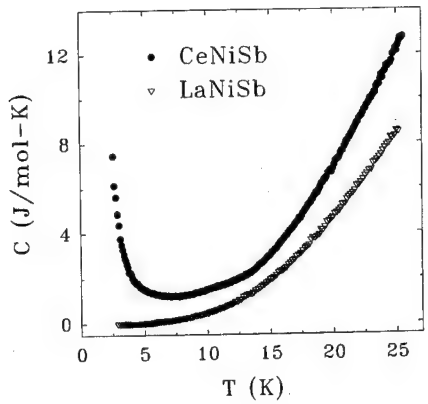

FIG. 3. Plot of heat capacity C vs temperature T for the compounds CeNiSb and LaNiSb in the temperature range 2–26 K.

Figure 3 shows a plot of the heat capacity of CeNiSb and the nonmagnetic analog LaNiSb. The heat capacity of LaNiSb is of the form

$$C=\gamma T+\beta T^3, \tag{1}$$

where γT is the electronic contribution to the heat capacity and βT^3 is the phonon contribution. The value of γ is obtained to be about 1 mJ/mol K^2 which is typical of metallic systems.

In the case of CeNiSb, the heat capacity (C) shows a sharp rise at about 5 K (Fig. 3) which is due to an approach to magnetic ordering. In order to obtain the magnetic or the $4f$ contribution to the heat capacity in CeNiSb, the nonmagnetic contribution has to be subtracted. As a first approximation, we take the nonmagnetic contribution in CeNiSb to be the same as that of LaNiSb. On subtracting the heat capacity of LaNiSb from that of CeNiSb, the obtained magnetic contribution, ΔC, is plotted in Fig. 4. The sharp rise in $\Delta C/T$ vs T^2 plot at 5 K continues to be observed. Above 14 K, the value of $\Delta C/T$ is seen to increase with temperature and on extrapolating $\Delta C/T$ to $T\rightarrow 0$ K, a value of electronic specific heat coefficient, γ of about 60 mJ/mol K^2 is obtained which is quite high compared to that of normal metallic systems. This behavior of the heat capacity of CeNiSb may be compared with that of Ce-based insulators, $Ce_3Bi_4Pt_3$ (Ref. 6)

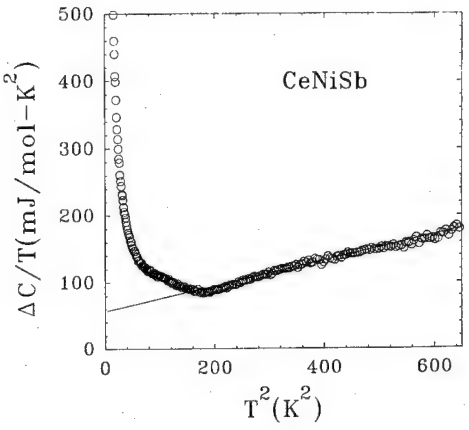

FIG. 4. Plot of $\Delta C/T$ vs T^2 for CeNiSb.

and CeRhSb.[7] In the case of $Ce_3Bi_4Pt_3$, the obtained γ (~3 mJ/mol K^2) is three times smaller than the value for the corresponding La analog. This is indeed expected, since γ is directly proportional to the electronic density of states, and hence for a gapped system (where electronic density of states is very small) the obtained γ too should be small. In CeRhSb, it is observed that below a temperature of about 8 K (i.e., in the gapped state) the heat capacity, though relatively large in comparison with that of LaRhSb, varies linearly with temperature, due to the linear variation of the electronic density of states with temperature in the insulating state. Thus, a large value of γ and the absence of linear variation of $\Delta C/T$ vs T in CeNiSb, suggests that a gap in the electronic density of states of the type seen in CeRhSb and CeNiSn is not observed in this system. This is also consistent with the resistivity behavior of CeNiSb. The large value of $\Delta C/T$ or γ above 14 K is most probably due to the Kondo and crystal field effects.

IV. CONCLUSIONS

In conclusion, CeNiSb is found to crystallize in the hexagonal structure (space group $P6_3/mmc$). Magnetization/susceptibility measurements indicate largely trivalent Ce ions which order magnetically around 4 K. A sharp rise in the heat capacity of CeNiSb is observed at about 5 K consistent with the magnetic ordering in this compound. A moderately large value of γ~60 mJ/mol K^2 is observed, which may be due to the combined effect of crystal field and the Kondo effect. No rise in the low-temperature resistivity is observed, in contrast to the situation in CeRhSb and CeNiSn.

Anisotropy and angular variation of the giant magnetoresistance in magnetic multilayers (invited)

B. Dieny, C. Cowache, and A. Nossov[a)]
CEA/Département de Recherche Fondamentale sur la Matière Condensée, 38054 Grenoble Cedex 9, France

P. Dauguet, J. Chaussy, and P. Gandit
CNRS/Centre de Recherche sur les Très Basses Températures, 38042 Grenoble Cedex 9, France

The giant magnetoresistance (GMR) of magnetic multilayers is usually considered as isotropic, i.e., independent of the direction of the sensing current with respect to the applied field. In spin-valve samples of the form NiFe/Cu/NiFe/FeMn it is possible to accurately determine the amplitude of the GMR (without any contribution from the usual anisotropic magnetoresistance) for various direction of the current with respect to the direction of the magnetization of the two ferromagnetic layers, both in the parallel and antiparallel magnetic configurations. In three series of spin-valve samples of the composition F t_F/Cu t_{Cu}/NiFe/FeMn, we have observed that the GMR amplitude is larger when the current is perpendicular to the magnetizations than when it is parallel to it. This intrinsic anisotropy in the GMR shows a pronounced maximum (relative amplitude of the anisotropy of the order of 10% at the maximum) for a thickness of the ferromagnetic layer of the order of 150 Å. In contrast, this anisotropy depends very weakly on the nonmagnetic spacer layer thickness. The results are compared with semiclassical calculations of Rijks *et al.* [Phys. Rev. B **51**, 283 (1995)]. On another respect, we have measured the in-plane (CIP) and perpendicular to the plane (CPP) giant magnetoresistance of antiferromagnetically coupled (NiFe/Ag) multilayers. Particular attention has been paid on the variation of resistivity with the angle $\Delta\theta$ between the magnetization in the successive magnetic layers. While the CIP GMR varies almost linearly with $\cos(\Delta\theta)$, the CPP GMR shows strong deviations from linearity especially at large NiFe thicknesses. The results are discussed in terms of relative role of *s*-like and *d*-like electrons in CIP and CPP transport. © *1996 American Institute of Physics.* [S0021-8979(96)56108-X]

I. INTRINSIC ANISOTROPY OF THE GIANT MAGNETORESISTANCE IN MAGNETIC MULTILAYERS

The giant magnetoresistance (GMR) first discovered in (Fe/Cr) multilayers[1] and later observed in a large number of transition-metal-based multilayers or sandwiches[2,3] is often considered as an isotropic phenomenon, i.e., the GMR amplitude is independent on the angle between the applied field and the sensing current.[1] This contrasts to the well-known phenomenon of anisotropic magnetoresistance (AMR)[4] which consists, in single layers of ferromagnetic transition metal, in a variation of the resistivity of the material with the angle between the magnetization and the current. This AMR is ascribed to the spin-orbit coupling which tends to induce an anisotropic spin intermixing of the spin-↓ and spin-↑ *d* subbands. In a previous article, we already reported some preliminary results on spin-valve samples of the composition Si/Co 200 Å/Cu 25 Å/NiFe 50 Å/FeMn 100 Å and on multilayers of the composition Si/(Co 30 Å/Cu 40 Å/NiFe 30 Å/Cu 40 Å)$_{10}$ which clearly demonstrate that the GMR is not isotropic.[5] The GMR amplitude is larger when the magnetizations are perpendicular to the current than when they are parallel to it. In the present experimental study, we measured the anisotropy in GMR (AGMR) on several series of spin-valve sandwiches comprising Co or Ni layers. We studied the variation of the AGMR versus the thickness of the ferromagnetic layers as well as of the nonmagnetic spacer layer. Spin-valve sandwiches are particularly well suited for this type of experiment. In these systems indeed, by applying the field in the direction parallel to the direction of the magnetization in the pinned layer (i.e., NiFe/FeMn), one can change the relative orientation of the magnetic moments in the two ferromagnetic layers from parallel to antiparallel without changing the angle between these moments and the in-plane current, whatever its direction: parallel or perpendicular to the field. A convenient way to proceed is to work on a large sample with a square four-point probe. By permuting the connection of one current and one voltage contact without touching the sample, nor changing the direction of the applied field, it is possible to measure the GMR amplitude both parallel and perpendicular to the current (see the schematic representation of the sample, contacts, and relative orientation of the current, field, and magnetic moments in Fig. 1). In this geometry, one is sure that there is no contribution arising from the usual AMR in the difference of GMR amplitude.

Typical results obtained at room temperature are shown in Figs. 2 and 3 for two spin-valve structures of the composition Si/Co 105 Å/Cu 25 Å/NiFe 50 Å/FeMn 100 Å (Fig. 2)

and Si/Co 400 Å/Cu 25 Å/NiFe 50 Å/FeMn 100 Å (Fig. 3). The shape of these curves is normal for spin-valve sandwiches.[5] It consists of two distinct loops associated with the reversal of the free and pinned magnetic layers. In between these loops, flat plateaux of resistance are observed in which the magnetizations of the two magnetic layers are single domain and parallel or antiparallel to each other. The GMR amplitude is determined by the relative difference in resistance between the saturation in the direction parallel to the exchange field created by the FeMn and the first plateau obtained at decreasing field when the magnetization of the free layer (M_1) has switched in the direction opposite to the magnetization of the pinned layer (M_2). During the reversal of M_1, a contribution from the AMR shows up especially when the thickness of the free layer is large (see Fig. 3). This AMR contribution, however, does not affect the determination of the GMR amplitude.

In all measured samples, we observed that the GMR ratio $\Delta R/R_{sat}$ is larger when the magnetic moments are perpendicular to the current as compared to the situation where they are parallel to it. This confirms our previous observation that the GMR is not fully isotropic.

To go further, we have studied the variation of the AGMR versus the thickness of the magnetic and nonmagnetic layers. The results are shown in Figs. 4–6. When the

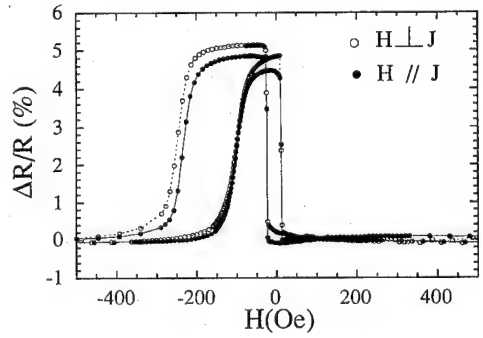

FIG. 2. Magnetoresistance of a spin-valve sample of the composition Si/Co 105 Å/Cu 25 Å/NiFe 50 Å/FeMn 100 Å measured in the two configurations: H parallel to the current [configuration (a) of Fig. 1] and H perpendicular to the current [configuration (b) of Fig. 1].

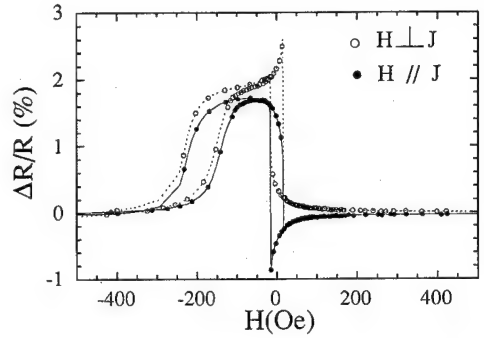

FIG. 3. Magnetoresistance of a spin-valve sample of the composition Si/Co 400 Å/Cu 25 Å/NiFe 50 Å/FeMn 100 Å measured in the two configurations: H parallel to the current [configuration (a) of Fig. 1] and H perpendicular to the current [configuration (b) of Fig. 1].

thickness of the magnetic layers (Co or Ni) is varied (Figs. 4 and 5), the GMR goes through a maximum for an intermediate thickness of the order of 80–100 Å. We define the anisotropy in GMR as

$$\Delta\mathrm{GMR}=\left(\frac{\Delta R}{R_{\mathrm{sat}}}\right)_{\parallel J}-\left(\frac{\Delta R}{R_{\mathrm{sat}}}\right)_{\perp J}$$

(Ref. 6). This quantity is negative for all samples investigated. In absolute value ΔGMR is maximum for an intermediate thickness of the ferromagnetic layers of the same order as the maximum of GMR itself.

In contrast, when the thickness of the nonmagnetic layer is varied, a monotonous decrease in GMR is observed which is usual in this uncoupled sandwich. However, a striking re-

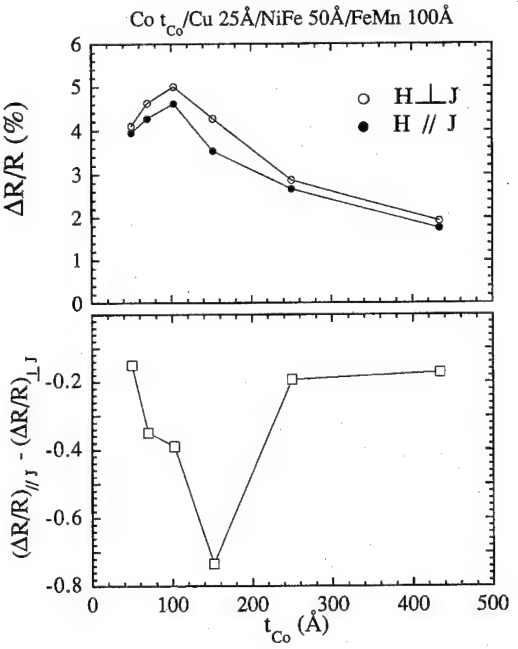

FIG. 4. (a) CIP GMR vs the thickness of the Co layer, measured with the applied field parallel to the current [geometry of Fig. 1(a)] or perpendicular to the current [geometry of Fig. 1(b)] for a series of spin-valve sandwiches of the composition Co t_{Co}/Cu 25 Å/NiFe 50 Å/FeMn 100 Å. (b) Difference in GMR amplitude between the two geometries vs the thickness of the Co layer.

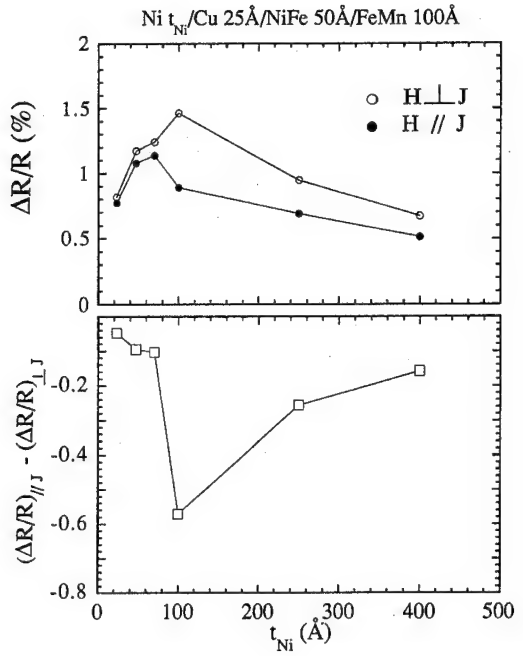

FIG. 5. (a) CIP GMR vs the thickness of the Ni layer, measured with the applied field parallel to the current [geometry of Fig. 1(a)] or perpendicular to the current [geometry of Fig. 1(b)] for a series of spin-valve sandwiches of the composition Ni t_{Ni}/Cu 25 Å/NiFe 50 Å/FeMn 100 Å. (b) Difference in GMR amplitude between the two geometries vs the thickness of the Ni layer.

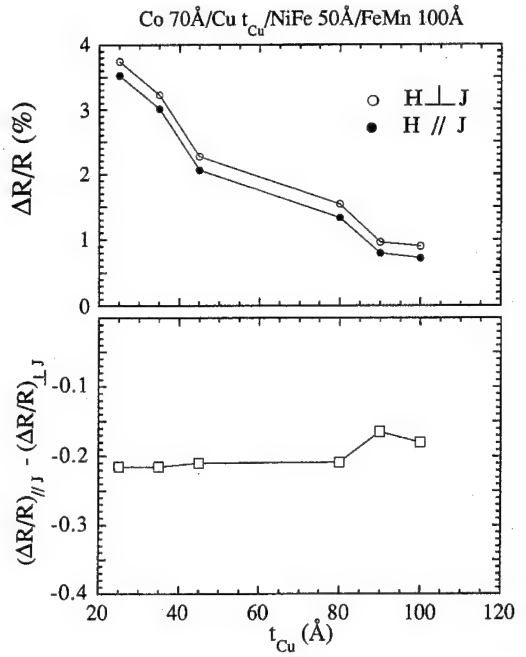

FIG. 6. (a) CIP GMR vs the thickness of the Cu layer, measured with the applied field parallel to the current [geometry of Fig. 1(a)] or perpendicular to the current [geometry of Fig. 1(b)] for a series of spin-valve sandwiches of the composition Co 70 Å/Cu t_{Cu} NiFe 50 Å/FeMn 100 Å. (b) Difference in GMR amplitude between the two geometries vs the thickness of the Cu layers.

sult is that ΔGMR is almost independent of the Cu thickness in the range of thicknesses investigated. These experimental results can be compared with the semiclassical calculations of anisotropic GMR by Rijks *et al.*[6] In these calculations, the authors predicted that the anisotropic GMR could be either negative or positive depending on the thicknesses of the magnetic and nonmagnetic layers. Three effects contribute to the amplitude of this anisotropy,[6] as follows.

(i) It is known that in bulk ferromagnetic transition metals, the resistivity for each spin channel is anisotropic. For instance in $Ni_{80}Fe_{20}$, the resistivities in the direction perpendicular to the current are given by[4] $\rho_{\perp\uparrow}=8.8\ \mu\Omega$ cm, $\rho_{\perp\downarrow}=96\ \mu\Omega$ cm and therefore $\alpha_\perp=\rho_{\perp\downarrow}/\rho_{\perp\uparrow}=10.9$, while the resistivities parallel to the current are: $\rho_{\parallel\uparrow}=10.0\ \mu\Omega$ cm, $\rho_{\parallel\downarrow}=93.9\ \mu\Omega$ cm, leading to $\alpha_\parallel=\rho_{\parallel\downarrow}/\rho_{\parallel\uparrow}=9.4$. Therefore, an anisotropy in the asymmetry ratio of the resistivities of spin-↓ and spin-↑ electrons exists in these materials. Since the amplitude of the GMR is directly related to this ratio of spin-dependent resistivities, an anisotropy in the α ratio naturally leads to an anisotropy in GMR. To our point of view this effect is certainly the most important one.

(ii) When the magnetizations are parallel to the current, the enhanced scattering of the electrons in this direction results in a relatively larger contribution to the current from electrons with a large velocity component perpendicular to the plane of the layers. This results in a positive contribution to ΔGMR.[6] In our experimental results, we do not see the expected change of sign in ΔGMR which would be caused by this contribution, even at large thicknesses of the magnetic layers. This may be due to diffuse scattering occurring not only at outer boundaries but also at inner interfaces.

(iii) The absolute value of ΔGMR is related to the amplitude of the GMR itself.

Qualitatively, our experimental observations fit rather well with the calculations of Rijks *et al.* in the regime of small thicknesses of the magnetic and nonmagnetic layer (lower-left-hand corner of Fig. 10 of Ref. 6). At small thickness of the nonmagnetic layer, as the thickness of the magnetic layer is varied, a minimum in ΔGMR is expected as observed experimentally. In contrast, at fixed thickness of the magnetic layer (of the order of 40–60 Å in Fig. 10 of Ref. 6), a very weak variation in ΔGMR versus the thickness of the nonmagnetic layer is expected despite a rapid decrease in GMR. This agrees also with our observation.

In conclusion, we have observed the existence of an intrinsic anisotropy in the GMR in several series of spin-valve sandwiches. The GMR amplitude is always larger when the magnetizations are perpendicular to the current than when they are parallel to it. Our results qualitatively agree with the semiclassical calculation of Rijks *et al.*[6] The absence of positive anisotropy in our systems is probably due to some interfacial diffuse scattering.

II. ANGULAR VARIATION OF THE CIP AND CPP (GMR) IN (NiFe/Ag) MULTILAYERS

So far, most of the experimental studies of the GMR in magnetic multilayers have focused on the influence of various parameters (thicknesses, conditions of preparation, temperature) on the maximum amplitude of the magnetoresistance, i.e., the change of resistance between the parallel and antiparallel magnetic configurations. In contrast, very few

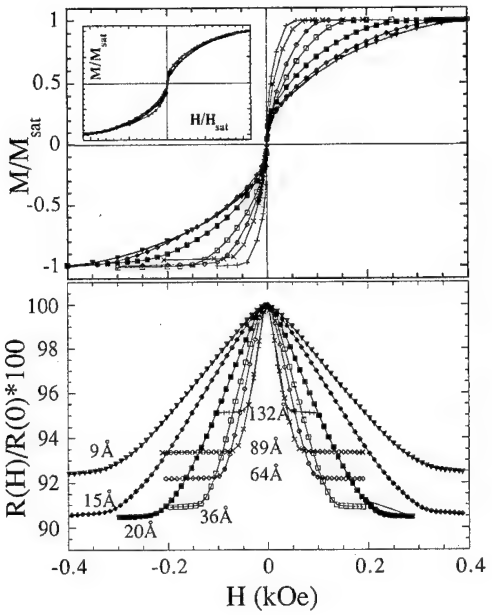

FIG. 7. (a) Magnetization curves at room temperature for a series of multilayers of the composition Si/(NiFe t_{NiFe}/Ag 11 Å)$_{20}$. Inset: Magnetization curves in reduced units of M/M_{sat}, (H/H_{sat}). (b) CIP magnetoresistance for the same set of samples as in (a). The thicknesses of the NiFe layers are labeled in (b).

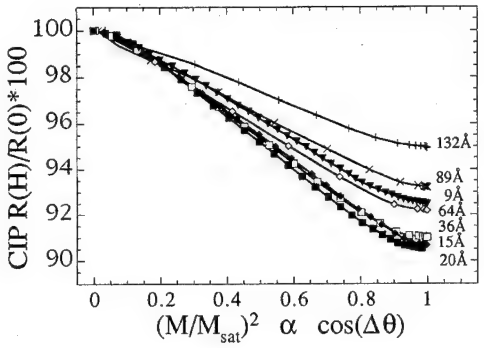

FIG. 8. CIP resistance at room temperature vs $(M/M_{sat})^2$ which is proportional to the cosine of the angle between the magnetization in the successive ferromagnetic layers, for the same series of (NiFe/Ag 11 Å)$_{20}$ multilayers as in Fig. 7.

experimental[7–10] and theoretical studies[11,12] have addressed the variation of resistance versus the angle between the magnetizations in the successive magnetic layers. However, measurements of these angular variations are quite useful since they may provide insights on the role played by the interfacial potential barriers in the GMR mechanism.[11,12] So far, all detailed measurements of the angular variation of CIP GMR have led to a linear variation of resistivity with the cosine of the angle between the magnetizations in the successive magnetic layers.[7–10]

We have carried out a determination of the angular variation of the CIP and CPP GMR in a series of Si/SiO_2/(NiFe t_{NiFe}/Ag 11 Å)$_n$ multilayers prepared by magnetron sputtering. The substrate temperature was maintained at 77 K during deposition in order to obtain a good structural quality with flat Ag layers.[13] For 11 Å of Ag, the NiFe layers are antiferromagnetically coupled. Figure 7(a) shows the magnetization curves for a series of samples with 20 periods. They are reversible with zero remnant magnetization. The saturation field varies as the inverse of the thickness of the NiFe layers. Such variation results from a balance between the volume Zeeman energy ($M_S t_{NiFe} H_{sat}$) and the interlayer coupling energy which is a surface energy J. In reduced units (H/H_{sat}, M/M_{sat}), all curves fit on a single line [see inset of Fig. 7(a)]. The curvature of this line indicates that a biquadratic coupling exists in these multilayers in addition to the antiferromagnetic bilinear coupling.[14] A detailed analysis of these curves will be published in a forthcoming article.[15] Because the interlayer coupling is predominantly antiferromagnetic, the magnetization process occurs via a coherent rotation of the magnetization of the NiFe layers. Since no significant magnetic anisotropy is observed in these multilayers and neglecting the effect due to the finite number of bilayers, one can consider that the magnetic moments of two successive NiFe layers rotate symmetrically with respect to the field. The cosine of the angle between the magnetizations of two successive layers is then proportional to the $(M/M_{sat})^2$. This relationship will be used further to determine the angular variation of the CIP GMR in these multilayers.

The CIP GMR of this series of multilayers is plotted in Fig. 7(b). The amplitude of the CIP GMR is maximum for an intermediate thickness of the NiFe layers of the order of 20 Å. However, since the saturation field monotonously decreases with the thickness of the NiFe layers, the maximum sensitivity $s=\Delta R/R/H_{sat}$ is obtained at large NiFe thicknesses (above 80 Å).

In Fig. 8 the data of Figs. 7(a) and 7(b) have been combined in order to plot the CIP GMR versus $(M/M_{sat})^2$ which represents $\cos(\Delta\theta)$, i.e., the cosine of the angle between the magnetization in the successive NiFe layers. The AMR is rather small in the present multilayers as compared to the CIP GMR (0.5% in the multilayer with the thickest NiFe layers). Therefore, no correction has been made to subtract the contribution from the AMR to the measured magnetoresistance. Within the accuracy of the measurement, a linear variation of $\Delta R/R$ vs $\cos(\Delta\theta)$ is observed in the interval $0.1<(M/M_{sat})^2<0.9$. The deviation from linearity close to saturation can be ascribed to some paramagnetic or superparamagnetic entities at the interfaces. Once the magnetic moments of the NiFe layers have completed their rotation toward the direction of the applied field, these fluctuations still require higher fields to be saturated. They can, therefore, explain the small tails observed in Fig. 8 close to saturation. On the other side, at low fields, one cannot exclude the existence of a small fraction of ferromagnetically coupled regions which would give large change of magnetization without change in resistance. This would lead to a plateau of R vs M^2 as observed in Fig. 8 at low magnetization values; however, the almost linear variation of $R(M^2)$ observed on a large range of angle $\Delta\theta$ means that, according to the theory of Vedyaev *et al.*,[11,12] the electrons which contribute the most to the CIP GMR do not feel interfacial potential barriers and therefore are predominantly s-like electrons.

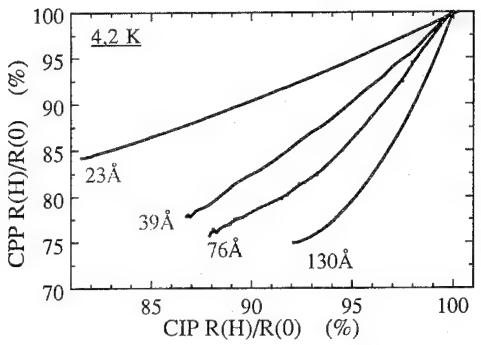

FIG. 9. CPP resistance at 4 K vs the CIP resistance at 4 K for a series of multilayers of the composition (NiFe t_{NiFe}/Ag 11 Å)$_{50}$.

We have also measured the CPP GMR of some of these (NiFe/Ag) multilayers. The technique used is based on the measurements of very low resistance on macroscopic samples sandwiched between superconducting Nb leads,[16] described in detail in Ref. 17. The detailed analysis of the results will be published in a forthcoming article.[18] We want here to focus on the angular variation of the CPP GMR as compared to that of the CIP GMR. In order to extract the angular variation of the CPP GMR in these NiFe/Ag multilayers, we measured the CIP and CPP GMR of a series of antiferromagnetically coupled multilayers of the composition Nb/(NiF$e t_{NiFe}$/Ag11 Å)$_{50}$/Nb. The CIP and CPP measurements are carried out on the same samples at 4 K. However, the part of the sample used for CIP measurements does not have the Nb buffer layer while the CPP part has it. This does not seem to affect the magnetic behavior of the samples since exactly the same saturation fields are obtained in CIP and CPP measurements. As already observed in previous CPP measurements on magnetic multilayers,[16] the CPP GMR amplitude is larger than the CIP amplitude. Contrary to the CIP GMR, the CPP GMR increases monotonously with the thickness of the NiFe layers (from 20% for t_{NiFe}=23 Å to 50% for t_{NiFe}=130 Å). This increase in the CPP GMR can be easily understood in a model of serial resistors which is valid in the present case. The thickness of the Ag layers is indeed much smaller than the spin-flip diffusion length.[19] We then plotted the CPP resistance versus the CIP resistance as a function of the applied field (Fig. 9). According to the discussion of Fig. 8, we assumed that the CIP GMR varies linearly with $\cos(\Delta\theta)$. The plot of Fig. 9 then directly gives a representation of the angular variation of the CPP GMR. It is observed that the angular variation of the CPP GMR is almost linear with $\cos(\Delta\theta)$ at small NiFe thicknesses but shows increasing deviations from linearity at large NiFe thicknesses. These deviations cannot be ascribed to a contribution from the AMR in the CIP measurements since this AMR is quite small as compared to the GMR. The exact meaning of these deviations is not yet clear since no theoretical model of the angular variation of the CPP GMR exists so far. In particular, why are they larger at large NiFe thicknesses than at small thicknesses? This may be related to the role played by the interfacial potential barriers in the CPP transport. Vedyaev *et al.* showed that in CPP transport, a potential step at an interface between two semi-infinite metallic layers leads to spatial oscillations in electric field on both sides of the interface.[20] These oscillations result in an additional interfacial resistance proportional to the square of the barrier height. It may happen that at small NiFe thicknesses, because of the roughness of the layers, interferences between the successive interfaces are smeared out leading to little effect of the potential barriers. In contrast, at large thicknesses, such interferences do not occur so that the potential barriers could play a more effective role.

III. CONCLUSION

In conclusion, we have demonstrated the existence of an intrinsic anisotropy in the CIP GMR of magnetic multilayers which is due to an anisotropy in the $\alpha=\lambda_\uparrow/\lambda_\downarrow$ ratio. This anisotropy has been measured in several series of spin-valve sandwiches comprising Co, Ni, and Cu layers of various thicknesses. The results qualitatively agree with semiclassical calculations of Rijks *et al.*[6]

On another respect, we have determined the angular variation of the CIP and CPP GMR in (NiFe/Ag) multilayers. The CIP GMR is found to vary linearly with the cosine of the angle between the magnetization in the successive magnetic layers while the CPP GMR shows deviations from linearity especially at large NiFe thicknesses. The linearity observed for the CIP GMR indicates that the electrons which contribute the most to the CIP GMR are not sensitive to interfacial potential barriers. The meaning of the deviations in CPP GMR is not yet clear.

Theory of the temperature dependence of giant magnetoresistance (invited)

Hideo Hasegawa[a)]
Department of Physics, Tokyo Gakugei University, Koganei, Tokyo 184, Japan

The temperature dependence of the giant magnetoresistance (GMR) for currents parallel and perpendicular to the multilayer plane is discussed by taking account of the random exchange potentials, phonon scatterings, and spin fluctuations. The effect of spin fluctuations, which plays an important role at finite temperatures, is included by means of the static functional-integral method developed previously by the present author. Our model calculations well explain the observed features of the parallel and perpendicular GMR of Fe/Cr and Co/Cu multilayers recently reported by Gijs *et al.* [Phys. Rev. Lett. **70**, 3343 (1993); Phys. Rev. B **50**, 16 733 (1994)]. © *1996 American Institute of Physics.* [S0021-8979(96)56208-6]

I. INTRODUCTION

The giant magnetoresistance (GMR)[1] in magnetic multilayers is one of the most attractive subjects in current solid-state physics. In recent years much progress has been made in understanding the GMR and its related phenomena.[1] One of the important aspects of the GMR is its temperature dependence. A careful study of the temperature dependence of GMR is not only important in understanding its mechanism but also very useful regarding its realistic applications. Most of the magnetic multilayers are fabricated with transition metals such as Fe, Ni, and Co. It would be instructive to briefly discuss the temperature dependence of the resistivity of bulk transition metals, before we study the temperature dependence of the GMR or of the resistivity of transition-metal multilayers. It has been reported that when the temperature is raised from $T=0$ K, the resistivity of Fe (Ref. 2) or Co (Ref. 3) gradually increases up to the Curie temperature, where it has a cusp (see Fig. 1). This characteristic temperature dependence of the resistivity is interpreted as due to the contributions from impurity, phonon, and magnetic terms. The last contribution is classically discussed as spin-disorder scatterings with the use of the s-d model.[4] Lately, a modern theory on the itinerant-electron magnetism has accounted for it in terms of spin fluctuations.[5]

It has been well known that d electrons in transition metals show both localized and itinerant character. The Curie–Weiss susceptibility and the large specific heat peak near the Curie temperature are easily explained by the localized spin model whereas the nonintegral ground-state moment and the large linear specific heat coefficient favor the band model. It has been realized that the effect of spin fluctuations plays essential roles to reconcile the duality of d electrons.[6] The finite-temperature band theory, which has been proposed by the author,[7] includes the effect of spin fluctuations by means of the static functional-integral method combined with the coherent potential approximation (CPA). Spin fluctuations including spin waves are shown to yield the T^2 contribution to the resistivity at $T\simeq 0$ by several approaches.[8] This type of theory[8] is, however, valid only at very low temperatures. In our finite-temperature theory,[7] spin fluctuations are regarded as localized, static modes with the adopted approximations. This method has proved useful in understanding the overall finite-temperature properties of transition metals, alloy, and multilayers,[9] both below and above the Curie temperature.

By employing the finite-temperature band theory,[7] we discussed in previous articles[10] the temperature dependence of the MR ratio for currents parallel to the multilayer plane. The observed temperature dependences of Fe/Cr (Ref. 11), NiCo/Cu, NiFe/Cu, and CoFe/Cu (Ref. 12) multilayers have been shown to be well explained by our theory. It has been pointed out[10(c)] that a multilayer in which the normal and inverse GMR[13] coexist may have an interesting temperature dependence beneficial for real applications.

One of the purposes of the present article is to generalize our theory[10] to the perpendicular GMR, whose experimental[14–16] and theoretical study[17–19] has been currently performed. The other purpose is to include the phonon contribution to the conductivity calculation, which was neglected in our previous study.[10] The article is organized as follows: In Sec. II, we present our formulation applying our finite-temperature band theory to the GMR. Numerical calculations of the parallel and perpendicular GMR of Fe/Cr and Co/Cu multilayers are reported in Sec. III. Supplementary discussions are given in Sec. IV.

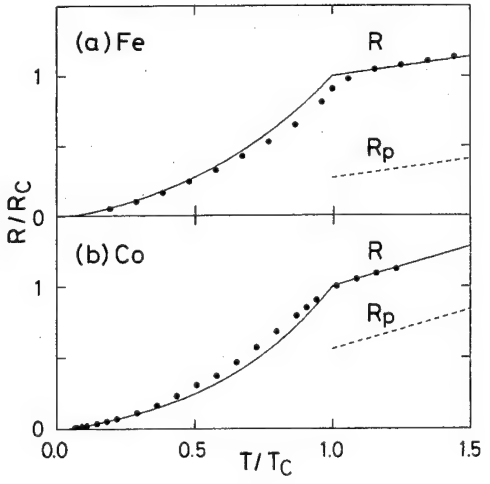

FIG. 1. The temperature dependence of the observed resistivity (circles) of (a) bulk Fe (Ref. 2) and (b) Co (Ref. 3); the calculated resistivity $R(T)$ and its phonon term $R_p(T)$ above T_C are shown by solid and dotted curves, respectively, results being normalized by $R_C=R(T_C)$.

II. CALCULATION METHOD

A. An adopted model and the expression of GMR

We adopt an A/B multilayer consisting of magnetic A and nonmagnetic B atoms with the simple-cubic (001) interface. The layer parallel to the interface is assigned by the index $n(=1-N_f)$, N_f being the thickness of the multilayer. It is assumed that atoms A and B are randomly distributed on layer n with the concentrations of x_n and y_n, respectively $(x_n+y_n=1)$. The multilayer is described by the single-band Hubbard model, in which the atomic potential (the on-site interaction) is assumed to be given by ϵ^{A} and ϵ^{B} (U^{A} and U^{B}) when a given lattice site is occupied by A and B atoms, respectively.

In order to study the finite-temperature properties of the magnetic film, we apply the functional-integral method within the static approximation to the Hubbard Hamiltonian.[7] The partition function is evaluated by calculating the partition function of the effective one-electron Hamiltonian including the random charge and exchange fields with the Gaussian weight. The charge field is included by the saddle-point approximation and the exchange field by the alloy-analogy approximation with the CPA. The energy-dependent coherent potential for an s-spin electron $s(=\uparrow,\downarrow)$ on the layer n, $\Sigma_{ns}(\epsilon)$, is determined by the CPA condition. The coherent potentials, the average of the magnetic moments on the layer n, $\langle M_n\rangle$, and its root-mean-square (rms) value, $\langle (M_n)^2\rangle^{1/2}$, are calculated self-consistently, details having been given in Ref. 7.

When we employ the CPA, the conductivity of the film is given by[19]

$$\sigma_{\xi\eta}=\left(\frac{e}{\hbar}\right)^2\left(\frac{1}{\pi}\right)\int d\epsilon\left(-\frac{\partial f}{\partial\epsilon}\right)\mathrm{Tr}(v_\xi\ \mathrm{Im}\ \mathbf{G}\ v_\eta\ \mathrm{Im}\ \mathbf{G}) \quad (\xi,\eta=x,y,z), \tag{1}$$

provided the vertex correction is neglected. In Eq. (1) v_ξ is the velocity operator and $\mathbf{G}$ is the Green's-function matrix. The conductivities for currents parallel ($\|$) and perpendicular ($\perp$) to the film layer are given by[10,18,19]

$$\sigma^{\|}=\left(\frac{e}{\hbar}\right)^2\int d\epsilon\left(-\frac{\partial f}{\partial\epsilon}\right)\sum_s\ \nu^{\|}(\epsilon)\left(\frac{1}{N_f}\right)\sum_n\ \sum_m\ \frac{a_{nms}\tau_{nms}}{(\Delta_{ns}+\Delta_{ms})}, \tag{2}$$

$$\sigma^{\perp}=\left(\frac{e}{\hbar}\right)^2\int d\epsilon\left(-\frac{\partial f}{\partial\epsilon}\right)\sum_s\ \nu^{\perp}(\epsilon)\left[\left(\frac{1}{N_f}\right)\sum_n\ \Delta_{ns}\right]^{-1}, \tag{3}$$

with

$$\nu^{\lambda}(\epsilon)=\hbar^2\sum_{k_\|}\ v_\lambda^2\delta(\epsilon-\epsilon_{k_\|}) \quad (\lambda=\|,\perp), \tag{4}$$

$$\tau_{nms}=\delta_{nm}+(1-\delta_{nm})\left(\frac{(\Delta_{ns}+\Delta_{ms})^2}{[(\Lambda_{ns}-\Lambda_{ms})^2+(\Delta_{ns}+\Delta_{ms})^2]}\right), \tag{5}$$

where $\Lambda_{ns}=\mathrm{Re}\ \Sigma_{ns}(\epsilon)$, $\Delta_{ns}=|\mathrm{Im}\ \Sigma_{ns}(\epsilon)|$, Σ_{ns} is the coherent potential of an s-spin electron on layer n, and a_{nls} and ν^{λ} are specified by the electronic structure of the film [see Eqs. (19) and (20) in Ref. 10(a)]. Equations (2)–(5) are valid when the thicknesses of the A and B layers are thinner than the mean free path and sufficiently thin compared with the spin diffusion length.[17] Analytic expressions for the conductivity have clear physical meaning. When currents flow parallel to the plane, an s-spin electron propagating successively from a site on layer n to a site on layer m is scattered with the strength proportional to Δ_{ns} and Δ_{ms}, respectively, and its conductivity is given as a sum of such processes with the weight of $a_{nms}\tau_{nms}$.[10] On the contrary, in the case of the perpendicular current, the s-spin conductivity is given as of a series circuit of resistivities on successive layers, each of which is proportional to Δ_{ns}.[18] In both cases, the total conductivity is a sum of the up- and down-spin channels. The so-called spin-flip process is implicitly included through the spin-fluctuation term which is responsible to a decrease in layer magnetization, as will be shown shortly. In the following subsection, we employ our formalism in a semiphenomenological way to discuss the temperature dependence of the MR ratio.

B. A. semiphenomenological study of GMR

We adopt a system consisting of magnetic (M_1,M_2) and nonmagnetic (N_1,N_2) layers, whose thickness are M and N, respectively. For a simplicity of calculation, we take into account only the bulk scattering, although the interface scattering is expected to be also important in magnetic multilayers (related discussion is given in Sec. IV). When magnetic moments on M_1 and M_2 layers are in the antiferromagnetic (AF) configuration, the coherent potentials are assumed to be given by $\Sigma_{ns}=\Delta_s-i\Delta_s$, $\Lambda_{-s}-i\Delta_{-s}$, and $\Lambda_0-i\Delta_0$ for $n\in M_1$, $n\in M_2$ and $n\in N_1$ (or N_2), respectively.[10] Using Eqs. (2)–(5), we get the parallel and perpendicular conductivities given by [10]

$$\sigma^{\mathrm{AF}\|}=\sum_s\left[\frac{2c_{MM}}{(\Delta_s+\Delta_{-s})}+\frac{c_{NN}}{\Delta_0}+4c_{MN}\left(\frac{1}{\Delta_s+\Delta_0}+\frac{1}{\Delta_{-s}+\Delta_0}\right)+d_M\left(\frac{1}{2\Delta_s}+\frac{1}{2\Delta_{-s}}\right)+\frac{d_N}{\Delta_0}\right], \tag{6}$$

$$\sigma^{\mathrm{AF}\perp}=\left(\frac{e}{\hbar}\right)^2\nu^{\perp}N_f\sum_s\left(\frac{1}{M\Delta_s+M\Delta_{-s}+2N\Delta_0}\right), \tag{7}$$

with

$$c_{MM}=N_f^{-1}\left(\frac{e}{\hbar}\right)^2\nu^{\|}\sum_{n\in M_1}\ \sum_{m\in M_2}\ a_{nm}\tau_{nm}, \tag{8}$$

$$d_M=N_f^{-1}\left(\frac{e}{\hbar}\right)^2\nu^{\|}\sum_{n\in M_1}\ \sum_{m\in M_1}\ a_{nm}\tau_{nm}, \tag{9}$$

and c_{NN}, c_{MN}, and d_N are given by similar expressions. We employed the $T=0$ limit of Eqs. (2) and (3) because the relevant temperature is much less than the Fermi energy ϵ_F. In Eqs. (6)–(9) $\nu^{\lambda}=\nu^{\lambda}(\epsilon_F)$, $N_f=2(M+N)$, and the spin dependence in a_{nms} and τ_{nms} is neglected which can be justified within the Born approximation. Subscripts MM, NN, and MN denote the contributions from the interlayer scatterings between magnetic layers, between nonmagnetic layers, and between magnetic and nonmagnetic layers, respectively.

On the contrary, the single subscript $M(N)$ expresses the contribution from the intralayer scatterings within magnetic (nonmagnetic) layers.

On the contrary, when magnetic moments on the subsequent magnetic layers are in the ferromagnetic (F) configuration, the coherent potentials are given by $\Sigma_{ns}=\Lambda_s-i\Delta_s$ and $\Lambda_0-i\Delta_0$ for $n\in M_1$ (or M_2) and $n\in N_1$ (or N_2), respectively.[10] We get the parallel and perpendicular conductivities given by[10]

$$\sigma^{F\parallel}=\sum_s\left(\frac{c_{MM}}{\Delta_s}+\frac{c_{NN}}{\Delta_0}+\frac{8c_{MN}}{(\Delta_s+\Delta_0)}+\frac{d_M}{\Delta_s}+\frac{d_N}{\Delta_0}\right), \tag{10}$$

$$\sigma^{F\perp}=\left(\frac{e}{\hbar}\right)^2\nu^{\perp}N_f\sum_s\left(\frac{1}{2M\Delta_s+2N\Delta_0}\right). \tag{11}$$

The MR ratio $\Delta R/R$ is given from Eqs. (6), (7), (10), and (11) by

$$\left(\frac{\Delta R}{R}\right)^{\lambda}\equiv\frac{(R^{\mathrm{AF}}-R^F)}{R^F}=\frac{(\sigma^F-\sigma^{\mathrm{AF}})}{\sigma^{\mathrm{AF}}}$$

$$=\frac{(\alpha-\beta)^2}{4\alpha\beta}X^{\lambda}\quad(\lambda=\parallel,\perp), \tag{12}$$

with

$$\alpha=\Delta_{\uparrow}/\Delta_0,\quad \beta=\Delta_{\downarrow}/\Delta_0, \tag{13}$$

$$X^{\parallel}=\left[1+g_0\frac{(\alpha+\beta)^2}{\alpha\beta}+g_1\left(\frac{N}{M}\right)(\alpha+\beta)\left(\frac{1}{\alpha+1}+\frac{1}{\beta+1}\right)\right.$$

$$\left.+g_2\left(\frac{N}{M}\right)^2(\alpha+\beta)\right]^{-1}, \tag{14}$$

$$X^{\perp}=\left[1+\left(\frac{N}{M}\right)\left(\frac{1}{\alpha}+\frac{1}{\beta}\right)+\left(\frac{N}{M}\right)^2\left(\frac{1}{\alpha\beta}\right)\right]^{-1}. \tag{15}$$

In Eq. (14) g_0, g_1, and g_2 are defined by[10]

$$\frac{d_M}{4c_{MM}}=g_0,\quad \frac{2c_{MN}}{c_{MM}}=g_1\left(\frac{N}{M}\right),\quad \left(\frac{c_{NN}+d_N}{2c_{MM}}\right)=g_2\left(\frac{N}{M}\right)^2. \tag{16}$$

The expression for $(\Delta R/R)^{\perp}$ given by Eqs. (12) and (15) is just the same as that derived by Edwards and co-workers[20] using the resistor network model and has been employed for an analysis of experimental data on the perpendicular GMR.[14]

The temperature dependence of the GMR arises from those of α and β, which are expressed in terms of the coherent potentials of the film [Eq. (13)]. The imaginary part of the coherent potential in the magnetic (M_1 or M_2) layer is given within the Born approximation by[10]

$$\Delta_s=\Delta_s^r+\Delta_s^s+\Delta_s^p, \tag{17}$$

with

$$\Delta_s^r=\pi\rho_s xy\left[\tilde{\epsilon}^{\mathrm{A}}-\tilde{\epsilon}^{\mathrm{B}}-s\left(\frac{U^{\mathrm{A}}}{2}\right)\langle M^{\mathrm{A}}\rangle\right]^2, \tag{18}$$

$$\Delta_s^s=\pi\rho_s x\left(\frac{U^{\mathrm{A}}}{2}\right)^2[\langle(M^{\mathrm{A}})^2\rangle-\langle M^{\mathrm{A}}\rangle^2], \tag{19}$$

$$\Delta_s^p=P_m\rho_s Z(T/\Theta_m), \tag{20}$$

where $\tilde{\epsilon}^{\mathrm{A}}$ and $\tilde{\epsilon}^{\mathrm{B}}$ are the spin-independent Hartree–Fock potentials and ρ_s is the density of states of an s-spin electron at the Fermi level. The first term (Δ_s^r) in Eq. (17) arises from the scattering due to random Hartree–Fock potentials for an s-spin electron; the second term (Δ_s^s) comes from the effect of spin fluctuations; the third term (Δ_s^p) is introduced for phonon scatterings whose explicit form will be given shortly [Eq. (37)].

On the other hand, the imaginary part of the coherent potential in the nonmagnetic (N_1 or N_2) layer, is given by

$$\Delta_0=\Delta_0^r+P_n\rho_0 Z(T/\Theta_n), \tag{21}$$

where the first and second terms denote the contributions from random potentials and phonons, respectively, and ρ_0 is the density of states at the Fermi level of the nonmagnetic metal. In Eqs. (20) and (21) Θ_m and Θ_n are Debye temperatures, and P_m and P_n are related with the electron–phonon interactions in magnetic and nonmagnetic metals.

Using Eqs. (13) and (17)–(21), we get α and β given by

$$\alpha=A\frac{[1+\gamma(T)]\{xy[B+m(T)]^2+x[\mu(T)^2-m(T)^2]+p_mZ(T/\Theta_m)\}}{[1+p_0Z(T/\Theta_n)]}, \tag{22}$$

$$\beta=A\frac{[1-\gamma(T)]\{xy[B-m(T)]^2+x[\mu(T)^2-m(T)^2]+p_mZ(T/\Theta_m)\}}{[1+p_0Z(T/\Theta_n)]}, \tag{23}$$

with

$$m(T)=\langle M^{\mathrm{A}}\rangle/M_0, \tag{24}$$

$$\mu(T)=\sqrt{\langle(M^{\mathrm{A}})^2\rangle}/M_0, \tag{25}$$

$$\gamma(T)=(\rho_{\uparrow}-\rho_{\downarrow})/(\rho_{\uparrow}+\rho_{\downarrow}), \tag{26}$$

$$A=\pi\rho(U^{\mathrm{A}}M_0/2)^2\Delta_0^r, \tag{27}$$

$$B=(2/U^{\mathrm{A}}M_0)(\tilde{\epsilon}_{\mathrm{B}}-\tilde{\epsilon}_{\mathrm{A}}), \tag{28}$$

$$p_m=P_m/\pi(U^{\mathrm{A}}M_0/2)^2, \tag{29}$$

$$p_0=P_n\rho_0/\Delta_0^r=p_mA(P_n/P_m)(\rho_0/\rho), \tag{30}$$

where $\rho=(1/2)(\rho_{\uparrow}+\rho_{\downarrow})$ and M_0 is the ground-state magnetic moment.

At $T=0$ K where $m(0)=\mu(0)=1$ and $\gamma(0)=\gamma_0$, Eqs. (22) and (23) become

$$\alpha_0=\alpha(T=0)=xyA(1+\gamma_0)(B+1)^2, \tag{31}$$

$$\beta_0=\beta(T=0)=xyA(1-\gamma_0)(B-1)^2, \tag{32}$$

from which the coefficients A and B are expressed in terms of α_0, β_0, and γ_0 as

$$A=\frac{1}{4xy}\left[\left(\frac{\alpha_0}{1+\gamma_0}\right)^{1/2}-\left(\frac{\beta_0}{1-\gamma_0}\right)^{1/2}\right]^2, \tag{33}$$

$$B=\left[\left(\frac{\alpha_0}{1+\gamma_0}\right)^{1/2}+\left(\frac{\beta_0}{1-\gamma_0}\right)^{1/2}\right]\left[\left(\frac{\alpha_0}{1+\gamma_0}\right)^{1/2}-\left(\frac{\beta_0}{1-\gamma_0}\right)^{1/2}\right]^{-1}. \tag{34}$$

The normalized magnetic moment $m(T)$ and its rms value $\mu(T)$ are in principle calculated with the use of the finite-temperature band theory.[9(b)] We here, however, adopt simple, analytic expressions of $m(T)$ and $\mu(T)$ for our model calculation, given by[10]

$$m(T)=\sqrt{1-(T/T_C)^2}, \quad \mu(T)=1. \tag{35}$$

The temperature dependence of the spin asymmetry $\gamma(T)$ defined by Eq. (26) is assumed to be given by

$$\gamma(T)=\gamma_0 m(T). \tag{36}$$

As for the phonon contribution given by $Z(T/\Theta_m)$ in Eqs. (20) and (21), we adopt the simple Grüneisen function,

$$Z\left(\frac{T}{\Theta_m}\right)=\left(\frac{T}{\Theta_m}\right)^5\int_0^{\Theta_m/T}dz\frac{z^5}{(e^z-1)(1-e^{-z})}, \tag{37}$$

which is 124.43 $(T/\Theta_m)^5$ at $T/\Theta_m \ll 1$ and $T/4\Theta_m$ at $T/\Theta_m \gg 1$.

Now we may calculate the MR ratios, $(\Delta R/R)^{\parallel}$ and $(\Delta R/R)^{\perp}$, as a function of temperature with the use of Eqs. (12), (14), (15), (22), (23), (33)–(37), when we treat α_0, β_0, γ_0, g_0, g_1, g_2, T_C, Θ_m, Θ_n, p_m, p_0, and y as input parameters. Our strategy for calculating the temperature-and layer-thickness-dependent MR ratio is as follows: We first determine the parameters α_0, β_0, and γ_0 to be consistent with the band calculation, and also g_0, g_1, and g_2 so as to reproduce the N dependence of the observed, ground-state parallel GMR. Then fixing there six parameters thus determined, we calculate the finite-temperature GMR with the additional parameters T_C, Θ_m, Θ_n, p_m, p_n, and y, which can be properly chosen as is discussed in the model calculations of the following section.

III. MODEL CALCULATIONS

A. Fe/Cr multilayers

Gijs and co-workers have observed both the parallel and perpendicular GMR for a sample of (3 nm Fe+1.0 nm Cr) multilayer, whose results are plotted by circles and squares in Fig. 2, respectively.

First we consider the case of $T=4.2$ K. We determine the value of $\gamma_0=0.4$ from the ground-state band calculation of $\rho_\uparrow/\rho_\downarrow=2.3$.[21] We adopt $\alpha_0=7.9$ and $\beta_0=1.0$, leading to $B=3.38$ [Eq. (34)], which is consistent with the value estimated from Eq. (28) by using the band parameters such as $\tilde{\epsilon}^{\mathrm{Fe}}$, etc. We choose the parameters of $g_0=0.045$, $g_1=0.77$,

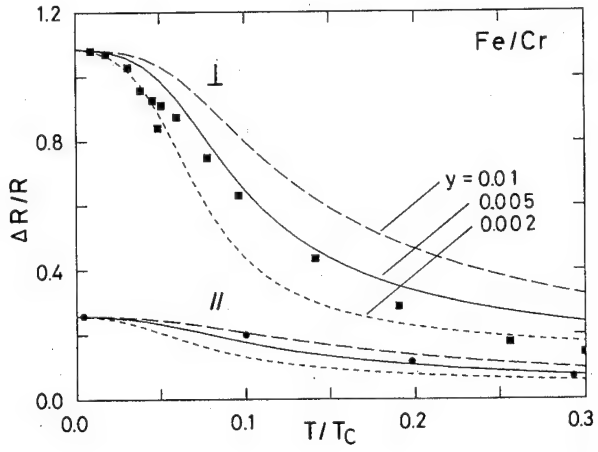

FIG. 2. The temperature dependence of the parallel (∥) and perpendicular $\Delta R/R(\perp)$ of (3 nm Fe+1.0 nm Cr) multilayers. Dotted, solid, and dashed curves denote the calculated results with $y=0.002$, 0.005, and 0.01, respectively, circles (squares) expressing the observed parallel (perpendicular) GMR (Ref. 15).

and $g_2=3.05$, such that we have a good fit to the envelope of the observed layer-thickness (t_N) dependence of parallel GMR in (3 nm Fe+t_N Cr) multilayers.[11]

Next we consider the MR ratio at finite temperatures. We assume the Curie temperature of the multilayer of $T_C=1000$ K because the thickness of the Fe layers of the adopted Fe/Cr multilayers[11,15] is sufficiently thick to sustain the Curie temperature of bulk Fe. The Debye temperatures of Fe and Cr are assumed to be $\Theta_m=\Theta_n=460$ K. The phonon parameters p_m and p_0 can be determined as follows: The total resistivity, R, of a pure, bulk metal is given from Eqs. (2), (3), and (22) by

$$R(T)\propto\left(\sum_s\left\{[1+s\gamma_0 m(T)]\left[\mu(T)^2-m(T)^2+p_m Z\left(\frac{T}{\Theta_m}\right)\right]\right\}^{-1}\right)^{-1}, \tag{38}$$

from which the ratio of the phonon contribution R_p to the total resistivity at $T=T_C$ is given by

$$r_p\equiv R_p(T_C)/R(T_C)=p_m Z(T_C/\Theta_m)/[1+p_m Z(T_C/\Theta_m)].$$

The value of $p_m=0.69$ is chosen from the experimental data of $r_p=0.27$ of bulk Fe [Fig. 1(a)].[2] We calculate p_0 by $p_0=p_m A(\rho_0/\rho)$ derived from Eq. (30) with $P_n=P_m$ and $\rho_0/\rho=0.7$.[21] The solid curve in Fig. 1(a) expresses the resistivity $R(T)$ of bulk Fe calculated by using Eqs. (35), (37), and (38) with $\gamma_0=0.4$ and $p_m=0.69$, which well reproduces the observed data.[2]

The last parameter y, which expresses a concentration of nonmagnetic atoms in the magnetic layer and which depends on a sample employed in an experiment, is treated as an adjustable parameter. The parallel and perpendicular GMR of the Fe/Cr multilayer calculated with $y=0.002$, 0.005, and 0.01 are shown in Fig. 2. Our calculation with $y=0.005$ well explains both the $(\Delta R/R)^{\parallel}$ and $(\Delta R/R)^{\perp}$ observed by Gijs

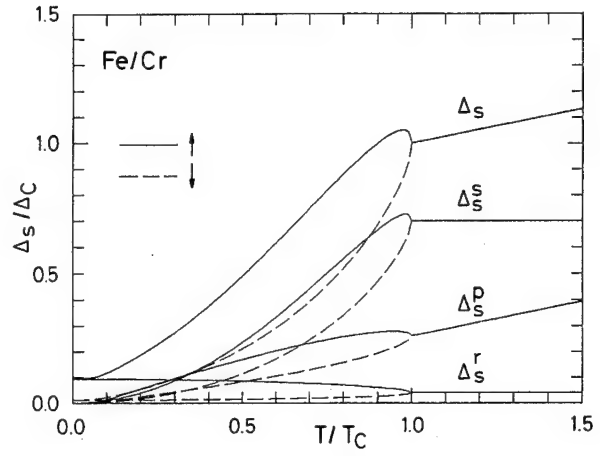

FIG. 3. The temperature dependence of Δ_s of up-spin (solid curves) and down-spin electrons (dashed curves) calculated with $y=0.005$ for the (3 nm Fe+1.0 nm Cr) multilayer. Also shown are their decomposition to various contributions from the random exchange potentials (Δ_s^r), spin fluctuations (Δ_s^s), and phonons (Δ_s^p), the calculated results being normalized by $\Delta_C=\Delta_s(T_C)$.

and co-workers.[15] The strong temperature dependence of GMRs mainly comes from $(\alpha-\beta)^2/4\alpha\beta$ in Eq. (12); that of $X^{\parallel}$ and $X^{\perp}$ is fairly weak.

In order to study the temperature dependence of the GMR in more detail, we show in Fig. 3, Δ_s ($s=\uparrow,\downarrow$) as a function of the temperature. When the temperature is raised, $\Delta_\uparrow$ and $\Delta_\downarrow$ increase because of the contributions from spin fluctuations and phonons. Then the ratio $\Delta_\uparrow/\Delta_\downarrow(=\alpha/\beta)$ changes from 7.9 at $T=0$ to unity at $T\geqslant T_C$. Figure 3 also shows the decomposition of Δ_s to various contributions from random potentials (Δ_s^r), spin fluctuations (Δ_s^s), and phonon (Δ_s^p). We note that at $T=T_C$, $\Delta^s/\Delta=0.70$, $\Delta^p/\Delta=0.26$, and $\Delta^s/\Delta^p=2.65$. This shows a significant spin-fluctuation contribution, as suggested from the resistivity data of bulk Fe.[2]

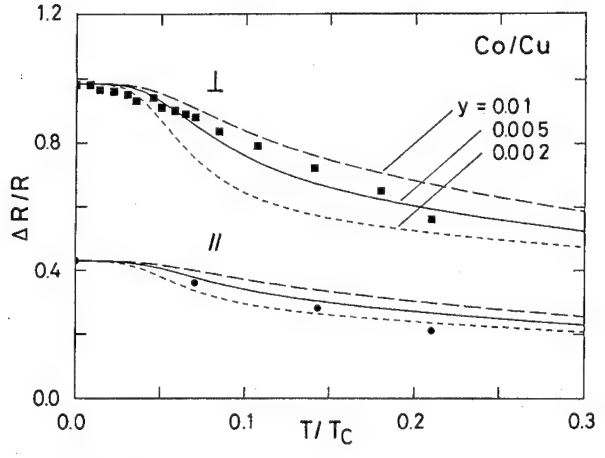

FIG. 4. The temperature dependence of the parallel (||) and perpendicualr $\Delta R/R(\perp)$ of (1.2 nm Co+1.1 nm Cu) multilayers. Dotted, solid, and dashed curves denote the calculated results with $y=0.002$, 0.005, and 0.01, respectively, circles (squares) expressing the observed parallel (perpendicular) GMR (Ref. 16).

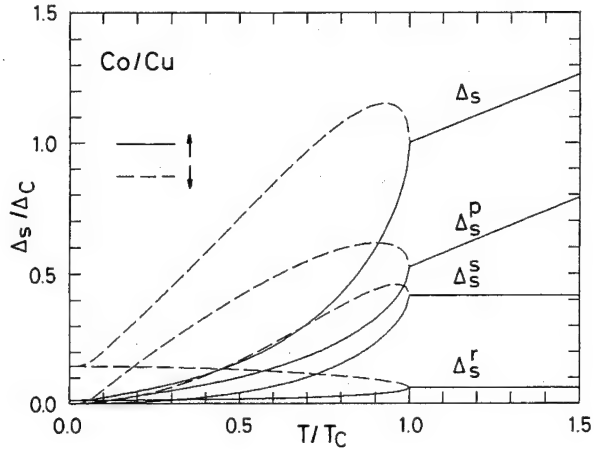

FIG. 5. The temperature dependence of Δ_s of up-spin (solid curves) and down-spin electrons (dashed curves) calculated with $y=0.005$ for the (1.2 nm Co+1.1 nm Cu) multilayer, (see caption of Fig. 3).

B. Co/Cu multilayers

We have performed a similar calculation to explain the temperature dependence of parallel and perpendicular GMR of the (1.2 nm Co+1.1 nm Cu) multilayer observed by Gijs *et al.*[16] We adopt $\alpha_0=0.7$, $\beta_0=8.4$ $(\beta_0/\alpha_0=14)$,[16] and $\gamma_0=-0.7$, which comes from the ground-state band calculation of $\rho_\uparrow/\rho_\downarrow\sim0.15$ of bulk Co.[21] We cannot determine the values of g_0, g_1, and g_2 because the layer-thickness dependence of the parallel GMR of this series of samples has not been reported. Then we tentatively adopt $g_0=0.13$, $g_1=0.39$, and $g_2=0.11$ by scaling the data of similar Co/Cu multilayer[22] as to reproduce the observed ground-state value of $(\Delta R/R)^{\parallel}=0.43$.[16] The Curie and Debye temperatures are taken to be $T_C=1400$ K and $\Theta_m=\Theta_n=445$ K. We adopt $p_m=1.62$ from the observed ratio of $r_p=0.56$ for bulk Co [Fig. 1(b)],[3] and $\rho_0/\rho=0.3$.[21] The solid curve in Fig. 1(b) denotes the temperature-dependent resistivity of bulk Co calculated by using Eqs. (35), (37), and (38) with $\gamma_0=-0.7$ and $p_m=1.62$.

The calculated $(\Delta R/R)^{\parallel}$ and $\Delta R/R)^{\perp}$ of the Co/Cu multilayer are shown in Fig. 4, where y is treated as an adjustable parameter. Both the parallel and perpendicular GMR observed by Gijs *et al.*[16] are fairly well explained by our calculation with $y=0.005$.

Figure 5 expresses the temperature dependence of Δ_s and its components Δ_s^r, Δ_s^s, and Δ_s^p, which shows that at $T=T_C$, $\Delta^s/\Delta=0.42$, $\Delta^p/\Delta=0.53$, and $\Delta^s/\Delta^p=0.79$. Comparing these figures with the corresponding ones of Fe/Cr systems, we note that the spin-fluctuation contribution in Co/Cu multilayer is less significant than in the Fe/Cr multilayer. This fact is expected to be the main reason why the observed temperature dependence of the GMR in Co/Cu multilayer is less considerable than that in the Fe/Cr multilayers.

IV. CONCLUSION AND DISCUSSION

We have discussed the temperature dependence of the GMR for currents parallel and perpendicular to the multilayer plane, including the random exchange potentials,

spin fluctuations, and phonons. Our model calculations have accounted for the following features of the observed GMR:[11,15,16]

(1) Both the parallel and perpendicular GMR are significantly more temperature dependent than the (average) layer moment;
(2) $(\Delta R/R)^{\perp}$ is larger than $(\Delta R/R)^{\parallel}$;
(3) the temperature dependence of $(\Delta R/R)^{\perp}$ is more significant than that of $(\Delta R/R)^{\parallel}$; and
(4) the temperature dependence of GMR in Co/Cu multilayers is less considerable than that in Fe/Cr multilayers.

The effect of spin fluctuations plays an important role to account for these items whereas phonons play a secondary role. In fact, items (1)–(3) can be explained without invoking phonons.[10] Item (2) can be understood as follows: Setting $N=0$ in Eqs. (12)–(15) for simplicity of explanation, we get

$$\left(\frac{\Delta R}{R}\right)^{\parallel}=\frac{(\alpha-\beta)^2}{4\alpha\beta[1+g_0(\alpha+\beta)^2/\alpha\beta]}, \tag{39}$$

$$\left(\frac{\Delta R}{R}\right)^{\perp}=\frac{(\alpha-\beta)^2}{4\alpha\beta}, \tag{40}$$

and the ratio of the parallel GMR to the perpendicular one is given by

$$(\Delta R/R)^{\parallel}/(\Delta R/R)^{\perp}=[1+g_0(a+1)^2/a]^{-1}\leqslant 1$$

$$(a=\alpha/\beta).$$

When electrons flow perpendicularly to the layer plane, all electrons pass through the adjacent two magnetic layers. On the contrary, this is not the case for currents parallel to the plane; some electrons go through only the one of the magnetic layers without probing the other magnetic layer. The g_0 term of the denominator of Eq. (39) [and of Eq. (14)] denotes this contribution. Itoh and co-workers[19] claim that the anisotropy of the velocity operator $v^{\parallel}/v^{\perp}\geqslant 1$ is the main mechanism leading to $(\Delta R/R)^{\parallel}\leqslant(\Delta R/R)^{\perp}$. The factor, $v^{\parallel}$ or $v^{\perp}$, is not, however, relevant because it is cancelled out when the MR ratio given by Eq. (12) is calculated.

In our phenomenological analysis given in Sec. II B we have included only the bulk scattering, neglecting the interface scattering whose importance has been pointed out by several experiments. We can extend our analysis as to take into account both the interface and bulk scatterings.[23] Numerical calculations using the generalized expressions for GMR which evitably include many parameters are in progress and will be reported in a separate article.[23]

Currents at angle to the planes of the layers (abstract)

A new class of *corrugated* multilayers has been grown on silicon substrates which have (111) faceted grooves etched on their surface.[1] These structures can be probed by conventional means with current at an *angle* to the plane of layers (CAP) as well as CIP. This angle is fixed by: the depth to width ratio of the grooves (which determines the angle θ), and the angle ϕ of the current probes with respect to the grooves. We have prepared multilayers of [Co(12 Å) Cu(t)NiFe(12 Å) Cu(t)]$_y$ with t=58 and 116 Å, and y=167 and 91 repeats, respectively; and have varied ϕ from 0 and 90° while θ is held fixed at 54.7°. We find the data is very well fit to the theoretical expression for CAP resistivity in terms of the more conventional CIP and CPP resistivities.[2] From measurements of the CIP and CAP–MR's on these corrugated multilayers we are able to *predict* the CPP–MR for these structures. © *1996 American Institute of Physics.* [S0021-8979(96)61908-6]

Oblique electron transport in the presence of collinear and noncollinear magnetizations

Horacio E. Camblong
Department of Physics, University of San Francisco, San Francisco, California 94117

The nonlocal real-space Kubo approach to electron transport in magnetic multilayers is applied to a new geometry, "oblique transport," whose complexity is traced back to a combination of the layering, of the nonlocal character of the linear response, and of the oblique direction transport in this new geometry. The problem is dealt with by applying a condition on the average current density vector or on the average electric-field vector, depending upon the external driving conditions. Its solution exhibits a characteristic anisotropy and it yields the global oblique conductance and magnetoresistance as simple trigonometric expressions in terms of the in-plane and vertical conductances and magnetoresistances, for arbitrary noncollinear-magnetization configurations. © *1996 American Institute of Physics.*[S0021-8979(96)56308-8]

Electrical transport in metallic multilayers is fairly well understood and its applications to giant magnetoresistance have confirmed the validity of the various models that have been used, namely, the quasiclassical approach[1] (based on the Boltzmann equation) and the Kubo approach.[2–5]

Previous theoretical analyses of magnetotransport in multilayers have only dealt with the special cases of in-plane transport (CIP) and vertical transport (CPP). Of course, there is a continuum of alternative geometries with the current neither in the plane of the layers nor perpendicular to the plane of the layers. Any such geometry is referred to as "oblique transport." The electric-field and current patterns for oblique transport are more involved than for CIP or CPP because variations in the local resistivity give rise to changes in the directions of the fields and currents from layer to layer. Actually, a version of this new geometry has been recently explored experimentally[6] using a corrugated metallic multilayered structure.[7]

A typical oblique-transport scenario is shown in Fig. 1, where z is a coordinate along the multilayer axis (or growth direction) and ζ is a coordinate along the "external driving direction," which I define as the direction of the average "driving field" $\mathbf{V}$. In practice, the driving field $\mathbf{V}$ will be either the current density $\mathbf{j}$ or the electric field $\mathbf{E}$; this leads to two outstanding boundary conditions: a "current-injection condition," when the direction of $\langle \mathbf{j} \rangle$ is externally fixed (for example, by proper insertion of current probes), and a "voltage condition," when the direction of $\langle \mathbf{E} \rangle$ is externally controlled. The parameter α, which is defined as the angle between the axes z and ζ (with $0° \leqslant \alpha \leqslant 90°$) measures the deviation of a particular oblique-transport geometry from either CIP ($\alpha=90°$), or CPP ($\alpha=0°$). These two coordinates are related via $\zeta = z \cos\alpha$, with a suitable choice of origin for both. Correspondingly, unit vectors along the external driving direction $\mathbf{e}_\zeta$, along the growth direction $\mathbf{e}_z$, and along the in-plane direction $\mathbf{e}_x$ satisfy the relations $\mathbf{e}_\zeta \cdot \mathbf{e}_z = \cos\alpha$ and $\mathbf{e}_\zeta \cdot \mathbf{e}_x = \sin\alpha$. In addition, it is clear that averages over z and over ζ of z-dependent quantities are identical, i.e.,

$$\langle f(z) \rangle_z = \langle f(\zeta/\cos\alpha) \rangle_\zeta . \tag{1}$$

As a consequence of the relations above, it follows that the component $A_\zeta(z)$ of any vector $\mathbf{A}(z)$ that is only z dependent (for example, the current densities or the internal fields) has an average [cf. Eq. (1)]

$$\langle A_\zeta(z) \rangle = \sin\alpha A_\parallel + \cos\alpha A_\perp . \tag{2}$$

The analysis presented in this article is based on Eqs. (1) and (2), which are of interest when the relevant physical quantities (fields and currents) are essentially only z dependent. Of course, this assumption breaks down near the external boundaries. Thus, for the computation of global properties, the analysis is valid when edge effects are globally unimportant.

The resulting transport behavior can be described most easily by using the real-space Kubo approach,[3,4] wherein the general nonlocal linear relationship between the currents $\mathbf{j}_{\alpha\beta}(z)$ and the fields $\mathbf{E}_{\gamma\delta}(z')$ can be written as

$$\mathbf{j}_{\alpha\beta}(z) = \int dz' \sigma_{\alpha\beta,\gamma\delta}(z,z') \mathbf{E}_{\gamma\delta}(z'), \tag{3}$$

where the Greek indices label the two spin channels ($\alpha = \uparrow, \downarrow$), $\sigma_{\alpha\beta,\gamma\delta}(z,z')$ is the spin-dependent two-point conductivity, and Einstein's summation convention for repeated indices has been applied. In Eq. (3) the complex structure of

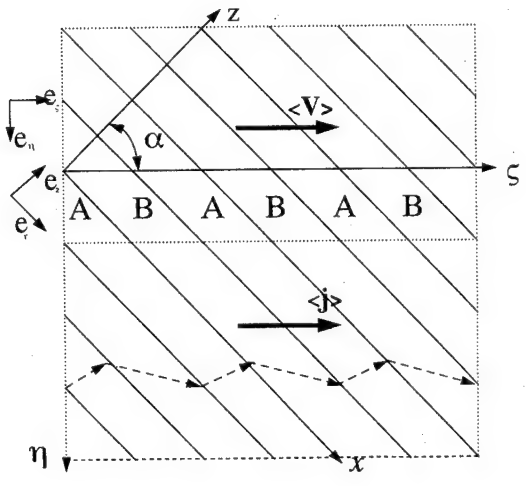

FIG. 1. Schematic representation of the oblique-transport geometry for a binary A/B superlattice grown along the z direction. The dotted lines represent the bounds of a typical region; it is assumed that the system extends to infinity in both directions along the η axis and that, if drawn to scale, many more layers would be encountered along the ζ axis. The lower part of the figure gives a graphical representation in terms of current lines of the current-injection condition (with $\sigma_A < \sigma_B$); the voltage-condition construction is not shown as it is more convoluted.

 0021-8979/96/79(8)/6383/3/$10.00

spin indices is a convenient way of dealing with noncollinear magnetizations. In this framework the internal fields $\mathbf{E}_{\alpha\beta}(z)$ absorb the vertex corrections[4] that correspond to long-range diffusion processes and acquire a spin dependence that can be thought of as arising from electrochemical potentials.[8,9]

The geometries studied so far are simple in that either the current or the fields are essentially uniform: For CIP the external fields $\mathbf{E}_{\gamma\delta}(z)$ are constant (if a uniform external electric field is applied) and for CPP the current densities $\mathbf{j}_{\alpha\beta}(z)$ are constant. Instead, for oblique transport, both the currents and the fields are position dependent (even for a uniform external electric field) and their directions are not fixed in space. This complexity can be tackled by resolving all vector fields into components parallel (∥) and perpendicular (⊥) to the plane of the layers. This construction is useful due to the fact that geometrical symmetries associated with the multilayered system reduce both the spatial dependence and the vector structure of the two-point conductivity to a simple form. In effect, if edge effects are neglected, the two-point conductivity is only a function of z (twice) and that it admits the resolution into irreducible components: an in-plane or CIP component, $\sigma^{(\parallel)}_{\alpha\beta,\gamma\delta}(z,z')$, and a vertical or CPP component, $\sigma^{(\perp)}_{\alpha\beta,\gamma\delta}(z,z')$. Explicitly,

$$\sigma_{\alpha\beta,\gamma\delta}(z,z')=\mathbb{1}_{\parallel}\sigma^{(\parallel)}_{\alpha\beta,\gamma\delta}(z,z')+\mathbf{e}_z\mathbf{e}_z\sigma^{(\perp)}_{\alpha\beta,\gamma\delta}(z,z'), \tag{4}$$

where $\mathbb{1}_{\parallel}$ is the unit tensor in the plane of the layers, and $\mathbf{e}_z$ is the unit vector in the z direction. The approach of Refs. 3 and 4 yields the components of the two-point conductivity, $\sigma^{(r)}_{\alpha\beta,\gamma\delta}(z,z')$ (with $r=\parallel,\perp$), whose nonlocal spatial dependence is governed by the inverse length $\xi(z)$, that is proportional to $\Delta(z)$, the local scattering strength (imaginary part of the self-energy). Then, the resolution of the two-point conductivity into irreducible components, which is expressed by Eq. (4), leads to two independent problems. The CIP problem,

$$j^{(\parallel)}_{\alpha\beta}(z)=\sigma^{(\parallel)}_{\alpha\beta,\gamma\delta}(z)E^{(\parallel)}_{\gamma\delta}, \tag{5}$$

has an apparent local character that is just an artifact generated by the uniformity of the externally applied electric field; in fact, Eq. (5) is formulated in terms of the one-point conductivity[2,3] $\sigma^{(\parallel)}_{\alpha\beta,\gamma\delta}(z)$, which is the integral of the two-point conductivity with respect to z' and it governs the characteristic CIP exponential size effects (nonlocal effects), a result that is in agreement with experiments [see Eq.(8)]. On the other hand, the CPP problem,

$$E^{(\perp)}_{\alpha\beta}(z)=\rho_{\alpha\gamma}(z)j^{(\perp)}_{\gamma\delta}, \tag{6}$$

is formulated in terms of the local resistivity[4,9] $\rho^{(\perp)}_{\alpha\beta}(z)=C_D^{-1}\xi_{\alpha\beta}(z)$, which is a completely local quantity determined by the local scattering rate; this problem has the remarkable feature that the global conductance has no exponential size effects and is wholly determined by the so-called series resistor model or the average scattering,[9–11] a prediction that has been found to be in impressive agreement with experimental results.[12]

In summary, the problems formulated by Eqs. (5) and (6) solve specifically in-plane and vertical transport. In addition, they can be used as the building blocks for oblique transport, as shown below.

For oblique transport it is necessary to consider the "matching" boundary conditions satisfied by the internal fields and the currents across the interfaces: namely, continuity of the tangential components of the fields $\mathbf{E}^{(\parallel)}_{\alpha\beta}$ and continuity of the normal components of the currents $\mathbf{j}^{(\perp)}_{\alpha\beta}$. The condition on the internal fields follows from their irrotational character when defined in terms of the vertex corrections to the conductivity,[4] whereas the condition on the currents expresses the independence of the spin channels, i.e., the two-independent current model, an approximation that is valid when the spin-diffusion length is large (compared to the relevant scales for multilayers).[4]

Let us now investigate the variation in the directions of the fields and currents from layer to layer. The relationship between the fields and currents is indeed given by the nonlocal Eq. (3). However, from Eqs. (4)–(6), it follows explicitly that for a uniform externally applied electric field the corresponding internal fields are

$$\mathbf{E}_{\alpha\beta}(z)=\mathbf{e}_z\rho_{\alpha\gamma}(z)j^{(\perp)}_{\gamma\beta}+\mathbf{e}_{\parallel}\rho^{(\parallel)}_{\alpha\beta,\gamma\delta}(z)j^{(\parallel)}_{\gamma\delta}(z), \tag{7}$$

where $\rho^{(\parallel)}_{\alpha\beta,\gamma\delta}(z)$ is the matrix inverse with respect to $\gamma\delta$ of the one-point conductivity $\sigma_{\alpha\beta,\gamma\delta}(z)$. The interfacial boundary conditions further imply that $j^{(\perp)}$ and $E^{(\parallel)}$ (second term) are constant. The two terms in Eq. (7) behave very differently because $\rho_{\alpha\gamma}(z)$ is a purely local quantity whereas $\rho^{(\parallel)}_{\alpha\beta,\gamma\delta}(z)$ has a nonlocal dependence through the local mean free paths. Let us see the limiting forms of $\rho^{(\parallel)}_{\alpha\beta,\gamma\delta}(z)$: In the local limit (short mean free paths compared with layer thicknesses) it is asymptotically a tensor with components given by various rearrangements of indices of $\rho_{\alpha\gamma}(z)$, whereas in the homogeneous limit (long mean free paths compared with layer thicknesses) it is asymptotically given by $C_D^{-1}\bar{\xi}$. These different limiting behaviors indicate that, in the local limit, $\mathbf{E}$ is locally parallel to $\mathbf{j}$ but globally nonparallel, whereas in the homogeneous limit, $\mathbf{E}$ is globally parallel to $\mathbf{j}$ but locally nonparallel. In other words, the geometrical anisotropy associated with the layering prevents the currents and fields from being parallel to each other; thus, the medium behaves phenomenologically in an anisotropic way both locally and globally, a result that can be understood in terms of charge accumulation: Charges accumulate on the various interfaces to respect the various interfacial boundary conditions.

Averaging Eqs. (5) and (6) over the external-direction axis ζ gives

$$\langle j^{(\parallel)}\rangle=\sigma_{\mathrm{CIP}}E^{(\parallel)} \tag{8}$$

and

$$\langle E^{(\perp)}\rangle=\rho_{\mathrm{CPP}}j^{(\perp)}, \tag{9}$$

where the averages are with respect to either z or ζ [see Eq. (1)]. In Eq. (8)

$$\sigma_{\mathrm{CIP}}=\langle\sigma^{(\perp)}_{\alpha\alpha,\gamma\gamma}(z)\rangle \tag{10}$$

(with Einstein's summation convention for repeated indices) is the CIP global conductivity[4] and in Eq. (9)

$$\rho_{\mathrm{CPP}}=(\sigma_{\mathrm{CPP}})^{-1}=C_D^{-1}\,[\mathrm{Tr}(\bar{\xi}^{-1})]^{-1} \tag{11}$$

is the global CPP resistivity, with $\bar{\xi}=\langle\xi\rangle$ being proportional to the average scattering.[4]

The directly measurable quantities are the total voltage per unit length across the sample in the external driving direction,

$$\frac{V}{L}=\frac{1}{L}\int \mathbf{E}\cdot d\mathbf{r}=\langle E_\zeta\rangle=\sin\,\alpha E^{(\parallel)}+\cos\,\alpha\langle E^{(\perp)}\rangle, \tag{12}$$

[where L is the length of the sample along the external-driving direction, see Eq. (2)], and the average current density along the driving direction,

$$\langle j_\zeta\rangle=\sin\,\alpha\langle j^{(\parallel)}\rangle+\cos\alpha j^{(\perp)}. \tag{13}$$

In order to extract a global or measurable resistance from Eqs. (12) and (13), it is necessary to apply the external boundary conditions (see Fig. 1): either the current-injection condition, which is defined by

$$\langle\mathbf{j}\rangle=\mathbf{e}_\zeta\langle j_\zeta\rangle, \tag{14}$$

or the voltage condition, which is defined by

$$\langle\mathbf{E}\rangle=\mathbf{e}_\zeta\langle E_\zeta\rangle. \tag{15}$$

Definition of the global resistivity as

$$\rho=\frac{\langle E_\zeta\rangle}{\langle j_\zeta\rangle} \tag{16}$$

leads to the following results:

$$\rho_1=\rho_{\mathrm{CIP}}\sin^2\,\alpha+\rho_{\mathrm{CPP}}\cos^2\,\alpha, \tag{17}$$

for current-injection conditions, and

$$\sigma_2=\sigma_{\mathrm{CIP}}\sin^2\,\alpha+\sigma_{\mathrm{CPP}}\cos^2\,\alpha. \tag{18}$$

for external-voltage conditions. Equations (17) and (18) are the main results of this article. They reduce to the familiar expressions $\rho(\alpha=90°)=\rho_{\mathrm{CIP}}$ and $\rho(\alpha=0°)=\rho_{\mathrm{CPP}}$, and they have the characteristic angular dependence of a quadratic form, i.e., they amount to the existence of a global resistivity tensor

$$\boldsymbol{\rho}_1=\mathbb{1}_\parallel\rho_{\mathrm{CIP}}+\mathbf{e}_z\mathbf{e}_z\rho_{\mathrm{CPP}} \tag{19}$$

(such that $\rho=\mathbf{e}_\zeta\cdot\boldsymbol{\rho}\cdot\mathbf{e}_\zeta$) for current-injection conditions and to the existence of a global conductivity tensor

$$\boldsymbol{\sigma}_2=\mathbb{1}_\parallel\sigma_{\mathrm{CIP}}+\mathbf{e}_z\mathbf{e}_z\sigma_{\mathrm{CPP}} \tag{20}$$

(such that $\sigma=\mathbf{e}_\zeta\cdot\boldsymbol{\sigma}\cdot\mathbf{e}_\zeta$) for external-voltage conditions.

The angular dependence of the magnetoresistance with respect to α can be derived straightforwardly from Eqs. (17) and (18). The main consequence stemming from this analysis for the resistivity and magnetoresistance is that the oblique-transport values are in between those for CIP and CPP, with the CPP values being the largest; this is because CPP is exactly self-averaging.[4]

In conclusion, I have calculated the oblique-transport electrical resistivity/conductivity and found that, as a consequence of the layering and if edge effects are unimportant, it is given as a quadratic form in the orientation of the external-driving direction, with an anisotropic resistivity/conductivity tensor composed of the global CIP and CPP resistivities/conductivities, for current-driving/external-voltage conditions. These results may be of help in the implementation of detailed phenomenological analyses of magnetotransport in magnetic multilayers.

The effects of magnetostatic interactions on the giant magnetoresistive (GMR) response of NiFe/Cu/NiFe spin valves are studied using an analytical model. The model is applicable to devices small enough for the magnetic layers to exhibit single-domain behavior. Devices having lengths in the track-width direction of 10 μm and interlayer separations of 4.5 nm are studied. Stripe heights are varied from 0.5 to 2 μm. The magnetization of one magnetic layer is pinned by a transverse pinning field that is varied from 0 to 24 kA/m (300 Oe). GMR curves for transverse fields are calculated. At zero external field the magnetization of the layers shows a tendency to align themselves antiparallel in the transverse direction. This results in an offset from the ideal biasing of the device. Broadening of the curves due to shape anisotropy occurs with decreasing stripe height and increasing magnetic layer thickness, and the magnetization in the pinned layer becomes less stable. © *1996 American Institute of Physics.* [S0021-8979(96)56408-X]

INTRODUCTION

Spin valves[1] are being actively investigated as promising read-head materials in ultrahigh-denisty magnetic recording. This is because of their relatively simple structure and high sensitivity to external fields. In this work, spin valves are studied using an analytical model that is an extension to two layers of a Stoner–Wohlfarth single-layer model.[2,3] Our model differs from other analytical spin-valve models,[4] by including interlayer magnetostatic interaction effects and the ability to model magnetic layers using general ellipsoidal shapes.

The micromagnetic model is applicable to devices that are small enough in size for the magnetic layers to exhibit single-domain behavior. The transition width of a Néel domain wall in a magnetic thin film increases with decreasing film thickness. For a small enough sample, the transition width exceeds the film dimensions, so that the film is no longer capable of sustaining domain walls. The film then becomes single domain. In Ref. 2, single-domain behavior was observed in magnetoresistive NiFe films having stripe heights less than 2 μm and film thicknesses less than 10 nm.

Figure 1 shows schematically the three-layer spin-valve structure studied in this work. Two NiFe layers of length l, stripe height w, and thickness t are separated by a Cu spacer layer of thickness d. Current I flows longitudinally through the device. The magnetization **M** of the top NiFe layer is exchange pinned transversely by an antiferromagnetic overcoat layer (not shown in the figure), while the magnetization of the bottom layer is free to rotate. The device is ideally biased if, in the absence of an external field, the magnetization of the layers orient perpendicular to each other in the plane of the film, as shown in Fig. 1(a). Figure 1(b) shows the giant magnetoresistance (GMR) response curve of an ideally biased spin valve. A description of the micromagnetic model is given in the following section. The model is used in a systematic study of the dependence of GMR response on stripe height and pinning-field strength.

MODEL OF SPIN VALVE

The magnetic layers of a spin valve are treated as single-domain films, and their magnetic behaviors are modeled using the Stoner–Wohlfarth coherent rotation model of the magnetization reversal of a uniformly magnetized ellipsoid. Brown[5] showed that the magnetic behavior of any uniformly

FIG. 2. (a) GMR response curves as a function pinning field H_p, for devices with stripe height $w=2$ μm and magnetic layer thickness $t=10$ nm. The curves are displaced vertically from each other for clarity; (b) magnetization states at zero field of the devices in the pinned layer (top arrows) and free layer (bottom arrows).

magnetized body could be modeled as that of an appropriate equivalent ellipsoid, which has the same principal axes and volume as the actual body. For a body in the form of a rectangular film the demagnetizing factors of the equivalent ellipsoid along the principal axes are equal to the magnitudes of the volume-average demagnetizing fields per unit magnetization inside the film, when it is magnetized along its principal axes. The field sources of a uniformly magnetized film are the surface magnetic charges formed on its bounding faces. The field due to such a face can be expressed in closed form.[6]

The free energy density of the pinned magnetic layer, consisting of the self-demagnetization and the applied field terms, is given by the expression

$$W=\tfrac{1}{2}M_s^2(N_x\alpha^2+N_y\beta^2+N_z\gamma^2) - |\mathbf{H_o}+\mathbf{H_p}+\mathbf{H_m}(M_s')|M_s(l\alpha+m\beta+n\gamma), \quad (1)$$

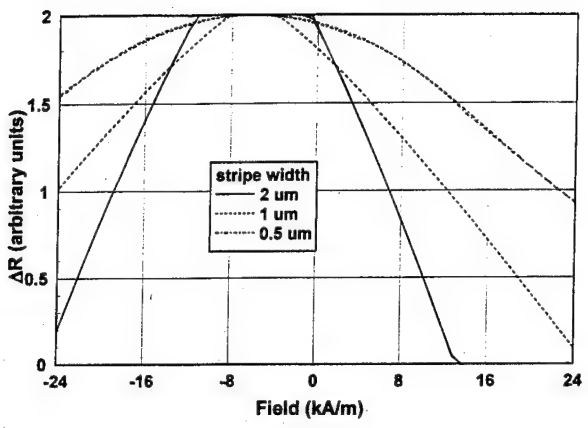
where $\mathbf{H}_o$ is the externally applied field; $\mathbf{H}_p$ is the pinning field; $\mathbf{H}_m(M_s')$ is the interlayer magnetostatic interaction field, and is equal to the volume-average field acting on the film due to the magnetization M_s' of the free layer; α, β, and γ are the direction cosines of the magnetization of the film M_s; l, m, and n are the direction cosines of the total field $\mathbf{H}_o+\mathbf{H}_p+\mathbf{H}_m(Ms_s')$, and N_x, N_y, and $N_z(N_x+N_y+N_z=1)$ are the demagnetizing factors along the three principal axes of the film.

Surface charges on the boundaries of the actual rectangular geometry of the magnetic film are the field sources used in calculating $\mathbf{H}_m$. Other fields, such as the self-field due to current flowing through the device, and possible effective exchange interaction field between the magnetic layers, may be included in the applied-field term in Eq. (1) if needed. These additional field terms were not considered in this work. An expression similar to Eq. (1) follows for the energy density of the free layer, by interchanging the roles of M_s and M_s' and omitting the pinning field term. For the free layer, $\mathbf{H}_m$ is the interlayer magnetostatic interaction field acting on it due to the magnetization of the pinned layer.

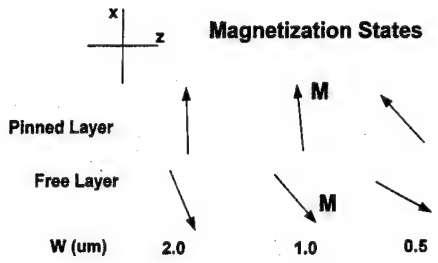
The direction cosines α, β, and γ are related to the azimuthal and polar angular coordinates θ_M, ϕ_M of the magnetization vector, by $\alpha=\sin\theta_M\cos\phi_M$, $\beta=\sin\theta_M\sin\phi_M$, and $\gamma=\cos\theta_M$. The spin valve is subjected to a uniform external field that is varied step-wise. The magnetization dependence of $\mathbf{H}_m$ necessitates the use of iterative methods in minimizing the energy of the interacting magnetic layers. The expression in parenthesis in the self-demagnetization term of Eq. (1) is precomputed and stored as a function of the angular coordinates. These values are calculated only for one quadrant of space; the values for other quadrants can be found by symmetry. Beginning from an initial magnetization state of the layers, the stored values are used to compute the energy functional $W(\theta_M,\phi_M)$ according to Eq. (1) in each of the magnetic layers. The angular coordinates corresponding to the minima of $W(\theta_M,\phi_M)$ in the magnetic layers are found and used to obtain the first approximations of the magnetization of the layers. These approximations are used to recalculate $\mathbf{H}_m$ and a new energy functional, from which the next approximation to the magnetization is obtained. This procedure is repeated until the magnetization of the layers converges to equilibrium. During iteration, the $(l\alpha+m\beta+n\gamma)$ term continually changes as $\mathbf{H}_m$ changes with the magnetization of the layers. The initial magnetization states used at the beginning of the iteration are the solution states from the preceding external field. The first solution when the external field is initially applied is obtained by assuming that the magnetization of the layers are initially pointing in the positive z direction. The solution space for the magnetization of a single layer depends on the history of the magnetization process, and the search for possible solutions having angular coordinate $\theta_M=0$ requires special treatment. The switching of the magnetization of each layer occurs as its free energy reaches an unstable threshold, changing from a minimum to maximum energy state. These issues are described in detail in Ref. 3. The change in the magnetoresistance of the spin valve is calculated using the expression $\Delta R=1-\cos\theta$, where θ is the angle between the magnetization vectors of the layers.

SIMULATION RESULTS

The spin valves simulated in this work have length $l=10$ μm, nonmagnetic spacer thickness $d=4.5$ nm, and magnetic layers with magnetization $M=800$ kA/m. The GMR response curves for the devices are calculated for an external transverse field (acting along x axis in Fig. 1) that is cycled between ± 24 kA/m (300 Oe). GMR response curves calculated



(a)



(b)

FIG. 3. (a) GMR response curves as a function of stripe width w, for devices with magnetic layer thickness $t=10$ nm and pinning field $H_p=12$ kA/m; (b) magnetization states at zero field of the devices in the pinning (top arrows) and free (bottom arrows) layers.

using different pinning fields, for devices having stripe height $w=2$ μm and magnetic layer thickness $t=10$ nm, are plotted in Fig. 2(a). The zero-field magnetization states of the devices given by the orientations of the magnetization vectors in the pinned and free layers are shown in Fig. 2(b). The shape anisotropy of the magnetic layers causes the magnetization vectors to lie completely in the plane of the magnetic films. For moderately pinned devices ($H_p \leqslant 4$ kA/m), self-demagnetizing fields in the pinned layer result in considerable canting, away from the transverse direction, of the magnetization vectors at zero field. Pinning is improved as H_p is increased.

Magnetostatic coupling between the magnetic layers favors the antiparallel orientation of the magnetization of the layers. This antiparallel orientation is pronounced in moderately pinned devices. In strongly pinned devices ($H_p=12$ and 24 kA/m), the rotation of the free layer is opposed by the self-demagnetization of the layer. Interlayer magnetostatic interaction thus results in the deviation of the GMR responses of the spin valves from that of the ideal biased state of Fig. 1. The positive saturation fields of the GMR curves decrease slightly as the pinning field is increased. This is due to a reduction in the work required to rotate the magnetization of both magnetic layers toward parallel alignment in the transverse direction against the interlayer magnetostatic interactions opposing this rotation. The peaks of the GMR curves get broader and flatter as the pinning field is increased, and the negative saturation fields increase.

Self-demagnetization effects in the devices increase as stripe heights are made smaller. The effect of decreasing the stripe height on the GMR response and magnetization states of the devices is shown in Fig. 3. The figure was obtained for devices with magnetic layer thickness of 10 nm and pinning field 12 kA/m. Decreasing the stripe height increases the canting of the magnetization of the pinned layers and increases the broadening of the GMR curves.

DISCUSSION

An analytical micromagnetic model of interacting single-domain films was used in this work to study the dependence on device sizes and pinning field strengths of the GMR responses of spin valves having identical magnetic layers. The calculation of self-demagnetizing and magnetostatic fields can be modified to take into account nonuniform magnetization in the magnetic layers.[7] The simulations show offsets in the ideal biasing of devices due to interlayer magnetostatic interaction. The GMR curves broaden as the self-demagnetization in the magnetic layers increases as the stripe height is decreased. Thus, for moderately pinned devices, self-demagnetization results in the canting of the magnetization of the pinned layers. The behavior of the devices is sensitive to their linear dimensions; the offset in biasing can be corrected by the judicious choice of device dimensions. For example, if the free layer is made thicker than the pinned layer, the self-demagnetization will oppose the antiparallel rotation of the magnetization, resulting in better biasing.

The model can be extended in a straightforward manner to simulate devices with three or more magnetic layers, and to include interlayer ferromagnetic, antiferromagnetic, and biquadratic exchange interactions between adjacent magnetic layers. More exotic devices can thus be simulated and studied both by selectively applying these interactions among the magnetic layers and by making use of magnetic layers with different magnetic properties and linear dimensions. Self-fields due to current flow in the device can be modeled by adding an appropriate field to the applied field free energy density term of Eq. (1).

We have grown epitaxial NiO {111} films of thicknesses ranging from 60 to 1200 Å, deposited 45 Å NiFe films on these NiO substrates, and made measurements of exchange field and coercivity, of the effective uniaxial anisotropy, of rotational hysteresis, and of the training effect on these films. We find that the large coercive fields, ~500 Oe, observed in these epitaxial systems can be understood using a model in which the magnetization reversal process is by rotation, with the coercive field determined by the effective uniaxial anisotropy of the system. This effective anisotropy is in turn determined by the anisotropy of the NiO and depends on NiO thickness.
 [S0021-8979(96)56508-9]

I. INTRODUCTION

The anisotropic exchange interaction between Permalloy ($Ni_{0.8}Fe_{0.2}$) and NiO has drawn a lot of attention[1] because of the potential usage of NiO as a biasing layer in magnetoresistance (MR) heads or spin valves.[2] Previous investigations of the NiFe–NiO exchange interaction have involved sputtered polycrystalline NiO and NiFe.[1–3] Generally, it is more difficult to characterize quantitatively the exchange anisotropy interaction in polycrystalline systems because of the random orientations involved. In recent work[4] we demonstrated the epitaxial growth of NiO {111} and {100} by metalorganic chemical-vapor deposition (MOCVD), making a quantitative study of the NiFe–NiO interaction feasible. The coercivity we observed in our NiFe–NiO {111} systems was anomalously large as compared to that observed in polycrystalline systems. We report here further investigation of the physical origins of the large coercive fields observed in the NiFe–NiO {111} films. We have deposited NiFe on NiO {111} films of various thicknesses, and report here the dependence upon the NiO thickness of the exchange field H_e, the coercivity H_c, and the magnetic training effect. Torque measurements were made to determine magnetic anisotropy and rotational hysteresis observed to help understand the magnetization process. An attempt was made to change the anisotropy of NiO by doping with 2% strontium (Sr^{2+}) and the effect of the doping upon H_e and H_c was observed.

II. EXPERIMENTAL PROCEDURES

Epitaxial NiO films ranging in thickness from 60 to 1200 Å were grown on {0001} Al_2O_3 using a solid source MOCVD technique at a growth temperature of about 510 °C. The Sr-doped films were made by putting 2 at. % Sr^{2+} into the solid source $Ni(THD)_2$. NiFe films 45 Å thick were deposited on the epitaxial NiO {111} films by dc magnetron sputtering in the presence of a magnetic field of 275 Oe. 50 Å of Ta was used as a capping layer. Electron probe microanalysis (EPMA) was used to determine the chemical compositions and the thickness of the films. The hysteresis loops were taken at room temperature using the magneto-optical Kerr effect (MOKE). To observe the magnetic training effect, the first five cycles were recorded individually and the stabilized loop was taken after 50 field cycles. The in-plane torque measurements were executed at room temperature from 100 Oe up to 10 kOe after the hysteresis loops had been stabilized.

III. RESULTS

In Fig. 1 we show the changes in stabilized (after training) H_c and H_e of the NiFe–NiO system as the thickness of NiO is varied from 60 to 1200 Å. As the thickness of the NiO, t_{af}, is increased, there is a critical thickness, 150 Å, at which H_e first appears. H_e then increases gradually to a maximum of 70 Oe at t_{af}=400 Å. This behavior is to be contrasted with the sharp rise of H_e with t_{af} usual for the NiFe–FeMn system.[5] The coercivity for our NiFe–NiO films rises from about 35 Oe at t_{af}=60 Å to a maximum of 510 Oe at 275 Å. H_e and H_c are almost unchanged for thicknesses of NiO between 400 and 1200 Å.

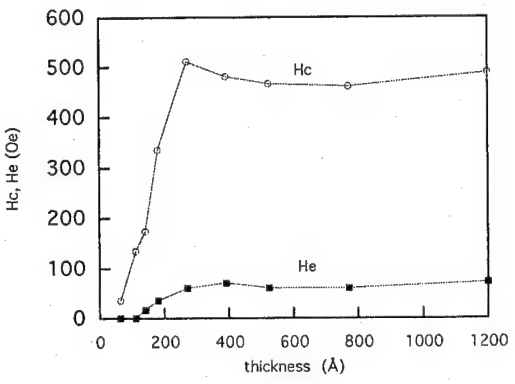

FIG. 1. NiO {111} thickness dependence of the coercivity H_c and the exchange field H_e for 50 Å Ta/45 Å $Ni_{0.8}Fe_{0.2}$/60–1200 Å NiO.

 0021-8979/96/79(8)/6389/3/$10.00

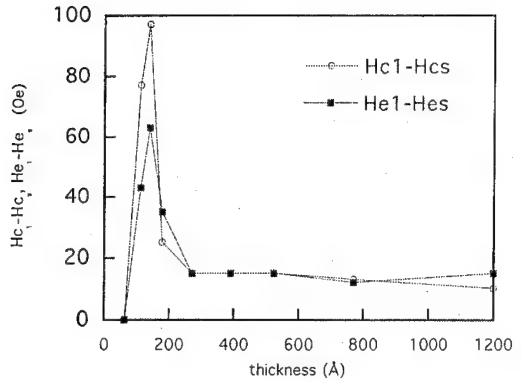

FIG. 2. NiO {111} thickness dependence of the trainable components ($H_{c_1} - H_{c_s}$) and ($H_{e_1} - H_{e_s}$) for 50 Å Ta/45 Å $Ni_{0.8}Fe_{0.2}$/60–1200 Å NiO. H_{c_1} and H_{e_1} (H_{c_s} and H_{e_s}) are the coercivity and the exchange field of the first hysteresis loop (of the stabilized hysteresis loop).

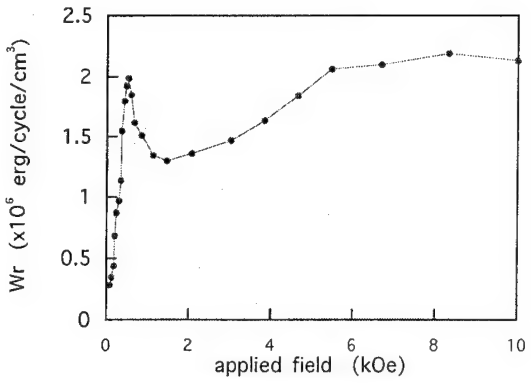

FIG. 4. Field dependence of rotational hysteresis loss W_r for 50 Å Ta/45 Å $Ni_{0.8}Fe_{0.2}$/275 Å NiO.

NiO films having a 2% Sr^{2+} doping with thickness of 400 and 550 Å were prepared. NiFe films deposited on the Sr-doped NiO films showed reductions of H_c, 45% and 21%, respectively, and a 20% increase of H_e, compared to NiFe deposited on pure NiO of same thicknesses.

The magnetic training effect, the gradual reduction in H_e and H_c during the first several hysteresis loop cycles,[6,7] varies with the thickness of the NiO as shown in Fig. 2. The trainable components of H_e and H_c, the difference between the values for the first loop (H_{e_1},H_{c_1}) and the stabilized loop (H_{e_s},H_{c_s}), are zero at t_{af}=60 Å, rise to a sharp peak at the critical thickness of NiO, 150 Å, and return to a small, almost constant, value for t_{af}>275 Å.

To determine the anisotropy in the film and to help understand the magnetization process, torque measurements were conducted on each sample. A typical torque curve in this NiFe–NiO system is shown in Fig. 3. A skewed sin 2θ curve indicates that the uniaxial anisotropy dominates in NiFe–NiO films. In addition, a large rotational hysteresis, $W_r=\frac{1}{2}\int_0^{2\pi} L\, d\theta$ (L:torque), exists even at a high field. If we assume the energy per unit volume for the NiFe to be $E=-K_e' \cos\theta+K_u \sin^2\theta$ (θ is the angle between the magnetization and easy axis of the NiFe), K_u, the effective uniaxial anisotropy constant, can be deduced from the amplitude of the sin 2θ component. (The cos θ term arises from the interaction of the anisotropic interfacial exchange with NiO.) The anisotropy field H_k of the NiFe film is equal to $2K_u/M_s$, assuming rotation of a single domain. In this specific sample, 50 Å Ta/45 Å NiFe/275 Å NiO, $K_u=2.2\times10^5$erg/cm^3 and $M_s=780$ emu/cm^3, giving H_k=569 Oe. Comparing this H_k to the H_c measured from MOKE, we find H_k differs from H_c by only 10%. This approximate equality of H_k from torque measurements and H_c from the hysteresis loops held for all our samples with NiO thicknesses greater than 275 Å. This result strongly suggests the magnetization process in the NiFe films coupled to NiO {111} is a pure rotation process.

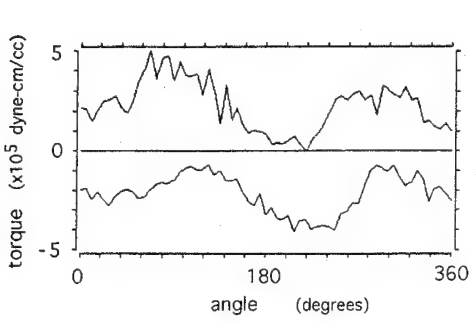

FIG. 3. In-plane torque curve for 50 Å Ta/45 Å $Ni_{0.8}Fe_{0.2}$/275 Å NiO. The applied field is 2000 Oe.

The typical dependence of rotational hysteresis upon magnetic field that we observed is shown in Fig. 4. The nonvanishing rotational hysteresis at a high field is one of the distinguishing characteristics of coupled ferro-antiferromagnetic systems.[8] The rotational hysteresis rises to a sharp peak at the coercive field, 510 Oe, and then increases again at high field.

IV. DISCUSSION

Following the analysis of Meiklejohn,[9] the magnetic energy of a ferromagnetic layer (f) coupled to an antiferromagnetic layer (af) can be expressed in a simple model. The energy E per unit area of the interface can be written as follows:

$$E=-HM_s t_f \cos(\theta-\theta_f)+K_{af}t_{af} \times\sin^2\theta_{af}-K_e\cos(\theta_f-\theta_{af}), \quad (1)$$

where M_s and H are the saturation magnetization and applied field magnitude, respectively, t_f (t_{af}) are the thicknesses of NiFe (NiO), θ is the angle of the applied field to the anisotropy axis, θ_f (θ_{af}) is the angle of the magnetization (the sublattice magnetization for the NiO) to the anisotropy axis, K_e is the interfacial coupling constant, and K_{af} is the uniaxial crystalline anisotropy of the NiO.

From this model, the condition

$$K_{af}t_{af}>K_e \quad (2)$$

is required for a shift of the hysteresis loop. In principle, if there are well-defined single values for K_{af} and K_e, there should exist a sharp onset of H_e. A wide distribution of

blocking temperatures has been reported for the NiFe–NiO system.[10] It was suggested that a variety of exchange paths across the interface existed due to interfacial disorder and fluctuating atomic arrangements. Further, the anisotropy of NiO strongly depends on strain[9] and stochiometry.[11] As a result, it is reasonable to assume a wide distribution of $K_e/(K_{af}t_{af})$ across the films because of local microscopic inhomogeneities. Because of this wide distribution of $K_e/(K_{af}t_{af})$, H_e increases gradually for NiO from 150 to 400 Å thick. When the thickness of NiO is less than 150 Å, there is no loop shift observed; however, nonvanishing rotational hysteresis still appears, which indicates that the exchange interaction between NiFe and NiO exists even for the t_{af} less than critical thickness. The existence of rotational hysteresis below the critical t_{af} implies that the superparamagnetic model[12] is not valid for this system with t_{af} less than the critical thickness.

For simplicity, we can divide the interface area into two categories:

(1) $K_e/(K_{af}t_{af}) \geq 1$ and
(2) $K_e/(K_{af}t_{af}) < 1$.

In the area belonging to the first category, the anisotropy of the NiO is too weak to pin the spins in the NiFe; therefore, this area cannot contribute to loop shift, H_e. When the magnetization of the NiFe rotates, the spins of the NiO rotate irreversibly, causing an increase in H_c. In the area belonging to the second category, the NiO can effectively block rotation of the spins in the NiFe and contribute to the observed H_e. If we can increase the anisotropy of the NiO, we should observe increased H_e and reduced H_c. In fact, this was observed in the NiFe coupled to the NiO doped with 2 at. % Sr^{2+}. It has been well established that the anisotropy of NiO in the {111} plane is small[13] but sensitive to strain.[9] The large ion, Sr^{2+}, probably introduces local strain into the NiO, resulting in a larger local anisotropy and increasing the portion of the film area with $K_e/(K_{af}t_{af}) < 1$.

The torque measurements give us an explanation of the anomalously high H_c observed for the epitaxial NiFe–NiO {111} films. Since the coercive field, H_c is very nearly equal to H_k, we believe that the magnetization process is dominated by pure rotation. For normal NiFe films uncoupled to an antiferromagnet, magnetization reversal proceeds by nucleation and propagation of domains of reversed magnetization, with the resulting H_c much smaller than H_k. For NiFe films coupled to NiO, coupling through interfacial exchange makes the nucleation of reversed magnetization energetically unfavorable. Further, this coupling makes the effective anisotropy K_u of NiFe films much larger than the intrinsic value for NiFe alone.

Based on Meiklejohn's calculations,[9] the rotational hysteresis loss shows a sharp peak at the threshold field, $H=J_k/M_s$ (J_k: anisotropy energy per unit volume) at which the spins of the antiferromagnet rotate. In our samples the field at which the rotational hysteresis loss peaks very nearly equals the coercive field H_c. This result reinforces our proposal that the coercivity in the NiFe/NiO {111} system is the field required to rotate the spins in NiO. Further, the existing rotational hysteresis loss at the field less than the threshold field is another indication of distribution of $K_e/(K_{af}t_{af})$. In addition, the increase of the rotational hysteresis loss at high field is probably due to the direct interaction between the applied field and NiO.[14]

We propose also a tentative model of the training effect consistent with the above picture and consistent with the model of Paccard *et al.*[7] in which the training effect is attributed to reorientation of the spins in the antiferromagnet with magnetization reversal in the ferromagnet. For thin NiO films ($t_{af}<60$ Å), the anisotropy resident in the NiO film per unit area is much less than K_e, so the NiO spins follow the NiFe spins on all cycles and there is no training effect. For thick NiO films ($t_{af}>200$ Å) the anisotropy per unit area in the NiO is large so that the local spin axes are mostly unchanged after the field cycles; therefore, the training effect is small. For intermediate NiO thicknesses, the local uniaxial anisotropy directions in the NiO are affected through K_e and are shifted during early magnetic cycles to directions favoring the external applied field. The training effect is therefore greatest in this domain of NiO thicknesses.

V. CONCLUSIONS

We believe we have shown, through measurements of H_c and H_e as a function of the thickness of the NiO and through measurements of torque and rotational hysteresis in epitaxial NiFe–NiO {111} films, that the magnetization process in such coupled film systems is rotational, that the coercive field is determined by the effective uniaxial anisotropy of the system, and that this effective anisotropy is in turn determined by the anisotropy in the antiferromagnetic NiO film. We present also a model of the magnetic training effect consistent with this picture.

ACKNOWLEDGMENTS

We are grateful to Professor R. S. Feigelson for the MOCVD growth, and to Dr. M. Lu for assistance with the torque measurements.

Change of magnetoresistance characteristic and crystal structure by ion bombardment to interfaces in [$Ni_{81}Fe_{19}$/Cu] multilayers (abstract)

Y. Miyamoto, T. Yoshitani, S. Nakagawa, and M. Naoe
Department of Physical Electronics, Tokyo Institute of Technology, Meguro, Tokyo 152, Japan

Many practical applications using giant magnetoresistance (GMR) have been developed, such as read-out heads and spin valve devices; however, the origin of GMR is not still fully understood. The GMR effect seems to be originated from the spin scattering mechanism whether at the interfaces or at the layer bodies.[1] Therefore, it is necessary to investigate the spin scattering behaviors at the interfaces in GMR multilayers. It is regarded that the mixing and the diffusion of atoms at the interfaces in multilayers can be well promoted by ion bombardment to the interfaces at proper energy in dual ion beam sputtering (DIBS) method. In this study, change of magnetoresistance (MR) and crystallographic characteristics induced by interfacial mixing of atoms were investigated. Specimen films were deposited by DIBS. Additional ion bombardment to the growing surfaces arranges the mixing effect at the interfaces between Ni-Fe and Cu layers. Acceleration voltage of sputtering ion source V_{mg} were set at 500 V and that of bombarding ion source V_{sg} was varied in the range of 0–300 V. Si wafers were used as substrates. Ni–Fe/Cu multilayers with GMR were deposited on 50 Å thick Fe buffer layers. Only two monolayers at the interfaces in Ni–Fe/Cu multilayers were exposed to ion bombardment to cause the local interfacial mixing. X-ray diffraction diagrams, showed that (111) orientations of Ni–Fe and Cu crystallites are obtained at V_{sg} below 200 V and that, on the contrary, (100) orientation became dominant in the films deposited at V_{sg} above 200 V. There is no apparent differences in MR ratio with increase of V_{sg}. However, the field sensitivity and saturation field properties were drastically degraded at V_{sg} above 200 V, while the crystal structure seemed to be changed. These results indicate that spin scattering were mainly occurred at the layer bodies in Ni–Fe/Cu multilayers. These results implied that the interfacial mixing is not so effective for changing MR ratio of Ni–Fe/Cu multilayers. However, the behavior of magnetization vectors are much influenced by change of local structure at the interfaces. These results seem to confirm the proposed theory; i.e., the spin scattering in layer bodies is the dominant mechanism on GMR in Ni–Fe/Cu multilayers.

Structural comparisons of ion beam and dc magnetron sputtered spin valves by high-resolution transmission electron microscopy

William E. Bailey, Nan-Chang Zhu, Robert Sinclair, Shan X. Wang
Department of Materials Science and Engineering, Stanford University, Stanford, California 94305-2205

We have used high-resolution transmission electron microscopy to compare the nanostructures of ion-beam and dc magnetron sputter-deposited giant magnetoresistive (GMR) spin valves and to correlate nanostructure with magnetic properties. Very low coercivities and strong exchange bias (<8 Oe, 125 Oe) were achieved in ion-beam-deposited spin valves of the form NiFe(50)/Co(20)/Cu(>25)/Co(20)/NiFe(50)/FeMn(150)/Ta(30 Å); these were compared with typical dc magnetron deposited structures of the same kind, both with and without a Ta seed layer, which exhibited similar and poorer exchange biasing but superior GMR ratios (to 8%.) Cross-sectional and plane-view samples were prepared of all three structures and examined by high-resolution electron microscopy. Near-perfect (111)-textured fcc metal and *c*-axis hcp Co columnar grains were revealed in the ion beam deposited sample, while some (10°) dispersion of this texture and random grain orientations were observed in the Ta-seeded and unseeded dc magnetron sputter-deposited samples, respectively. No amount of the α-FeMn (A12) phase was observed in any of the films. Exchange bias strengths and coercivity of the top Co/NiFe/FeMn layers thus correlate strongly with the degree of (111) texture. © *1996 American Institute of Physics.* [S0021-8979(96)56608-1]

I. INTRODUCTION

Magnetically soft giant magnetoresistance (GMR) spin value structures of the form $Ni_{80}Fe_{20}/Cu/Ni_{80}Fe_{20}/Fe_{50}Mn_{50}$ are widely recognized to be important to the next generation of magnetic recording systems. Their sensitive change in resistance with applied field[1] is attractive for use in the read element of a recording head; with the addition of thin Co layers at the $Ni_{80}Fe_{20}$/Cu interfaces,[2] resistance changes as great as 9.2% over 50 Oe (Ref. 3) have been demonstrated. Also important among the advantages of GMR spin valves over AMR sensors is the far wider range of applied fields for which the MR response is linear.[4] High coercivities in the pinned ferromagnetic layer can encroach upon this linear range, so the lowest possible pinned-layer coercivities, along with high GMR ratios and strong exchange bias, are sought by developers.

While the overwhelming majority of spin valves have been deposited by rf or dc magnetron sputtering, ion-beam deposition (IBD) is a promising technique, as it offers some greater control over the microstructure of the film and is amenable to *in situ* characterization.[5] Microstructural control and characterization are critical to the properties of these devices, due to the atomic scale of the thin films involved. *Ex situ*, then, high-resolution transmission electron microscopy (HREM) is well suited to characterizing the structure of these thin metallic layers. While HREM has been used to study Co/Cu multilayers[6,7] and some amount of work has been done on the $Ni_{80}Fe_{20}/Fe_{50}Mn_{50}$ couples,[8] there is a lack of HREM data available for full spin valves, with some exceptions.[9] Understanding of structure-properties relations in spin valves remains incomplete.

In the current work we have used HREM to study the microstructure of NiFe/Co/Cu/Co/NiFe spin valves created by ion-beam deposition. These have been compared with spin valves formed by conventional dc magnetron sputtering, and the relationship of microstructure to pinned layer biasing and coercivity has been explored.

II. EXPERIMENTAL METHOD

A series of nominal $Si(111)/SiO_2$(30 Å)/NiFe(50 Å)/Co(20 Å)/Cu(t_{nm})/Co(20 Å)/NiFe(50 Å)/FeMn(150 Å)/Ta(20 Å) spin valve heterostructures, for t_{nm} = 15, 20, 25, 30, and 35 Å, was deposited by IBD. Depositions were carried out on the native oxide of the Si wafer, using 300 V beam voltages and 1×10^{-4} Torr working pressures. Permanent magnet biasing was used during deposition and rotated by 90° between ferromagnetic layers; the rotation was carried out in air, with 20 Å of Co sputter-etched back before proceeding. Two comparison structures, nominally [Ta (60 Å)/] NiFe(60 Å)/Co(20 Å)/Cu(28 Å)/Co(20 Å)/NiFe(30 Å)/FeMn(120 Å)/Ta(50 Å) were deposited by dc magnetron sputtering on thermally oxidized (100) Si coated by 1500 Å Al_2O_3. To examine the effect on microstructure, one was deposited with and the other without the Ta underlayer. Further information on the sputter-deposition conditions can be obtained elsewhere.[3] The magnetic and magnetotransport properties of the layers were examined using $B-H$ looper magnetometry and four-point probe analysis. These results are summarized in Table I and are discussed in the following section.

Cross-sectional and plane-view TEM specimens were prepared of all three samples using standard methods;[10] low-angle (~6°) ion milling was used on the cross-sectional samples. High-resolution images were obtained using a Phillips EM430 (300 kV) transmission electron microscope, which has ~1.9 Å point-to-point resolution. Additional structural information was gathered using standard bright- and dark-field imaging and selected-area diffraction techniques.

III. RESULTS

The IBD spin valves show excellent exchange biasing and extremely low pinned layer coercivity (see Table I). Compared by the exchange product $H_E^*(M_s t_f)$,[11] the IBD

 0021-8979/96/79(8)/6393/3/$10.00

TABLE I. Magnetic and magnetotransport properties of the spin valves. Note the extremely low pinned layer coercivity (H_{c_2}) and strong exchange biasing (K_u) of the ion-beam-deposited sample.

Deposition method	$(\Delta R/R)$	H_{c_2} (Oe)	Exchange bias H_E (Oe)	K_u (merg/cm^2)
Ion beam	2.8%	7.7	125.0	89.3
dc magnetron				
no Ta seed	8.1%	28.5	73.4	39.8
Ta seed layer	6.7%	29.9	170.0	92.2

sample shows only 3% smaller biasing strength than the Ta-seeded sputtered sample. The pinned layer coercivity of the ion-beam-deposited sample, on the other hand, is approximately a factor of 4 less than that of the Ta-seeded sputter-deposited sample: only 8 Oe. This is far lower than values typically found for sputter-deposited spin valves. The exchange biasing of the unseeded sputter-deposited spin valve was weaker than either of the others and about half that of the IBD sample, with coercivity roughly equal to that of the Ta-seeded structure.

The plane-view diffraction patterns of all three samples (Fig. 1) show fcc crystallization of the metals with a range of lattice parameters between 3.54 and 3.66 Å, with differences in texture and the amount of hcp Co present. These lattice parameters are in good agreement with reported bulk values for fcc Co, Cu, $Ni_{80}Fe_{20}$, and thin-film γ-$Fe_{50}Mn_{50}$ (a = 3.54, 3.62, 3.55, and 3.64, respectively).[9,12]

Highly perfect (111) fcc and (0002) Co textures are observed in the IBD spin valve. In the plane-view diffraction pattern (Fig. 1), note the high intensity of the (220) and (422) fcc and $(3\bar{3}00)$ Co rings, along with the sharp intensity of the innermost $(1\bar{1}00)$ Co ring. Zero diffracted intensity is observed from the (200) or (111) reflections, so no (100)- or (110)-oriented grains are present. The unseeded dc magnetron-sputtered sample shows much weaker diffraction overall, and purely random fcc polycrystalline orientations. No intensity is observed for hcp Co at the $(1\bar{1}00)$ reflection.

With the addition of the Ta seed layer, predominant (111) and c-axis texture begins to emerge from dc magnetron deposition, although significant amounts of random orientations are still present. The diffraction rings thus represent a midway point between the textural extremes of the ion-beam-deposited and unseeded dc magnetron-sputtered samples. Strong (220) and weaker (111) and (200) diffracted intensities are present here, as are (111) and (200) fcc orientations. A weak but distinct amount of $(1\bar{1}00)$ Co diffraction discernible inside the fcc (111) ring.

No amount of the α-FeMn (A12) phase is observed in any of the samples. In many TEM specimens (not shown here), extra rings appear which index to a fcc phase with a = 4.2 Å. The source of this is uncertain although it may be an artifact of the specimen preparation.

Conclusions about the degree of texturing in the oriented films are supported by the cross-sectional diffraction patterns (insets, Figs. 2 and 3). While the IBD spin valve shows $<1°$ of angular dispersion in the perfect (111) fiber

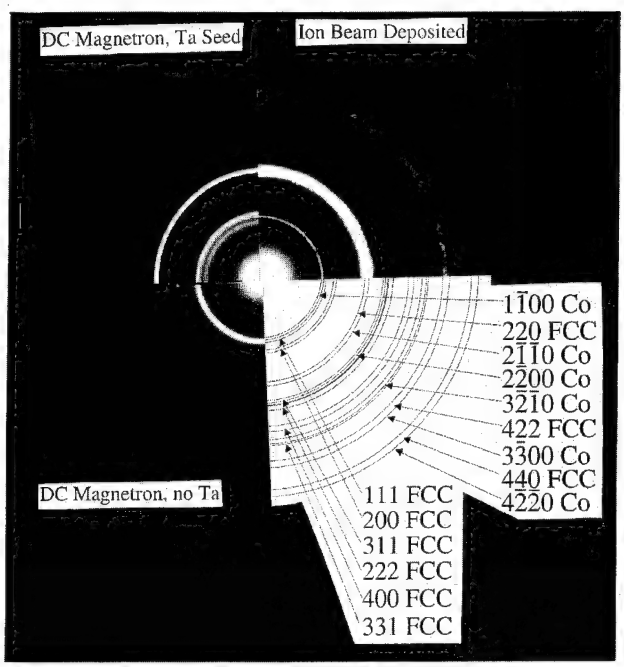

FIG. 1. Selected-area-diffraction patterns of the three plane-view samples. Upper right-hand side: perfect (111) fcc metal and c-axis Co texture in the IBD sample. Upper left-hand side: strong (111) and c-axis texture, with significant (200) fcc and random grain orientations, for the Ta-seeded sputtered sample. Lower left-hand side: completely random fcc grain orientations for the unseeded sputtered sample.

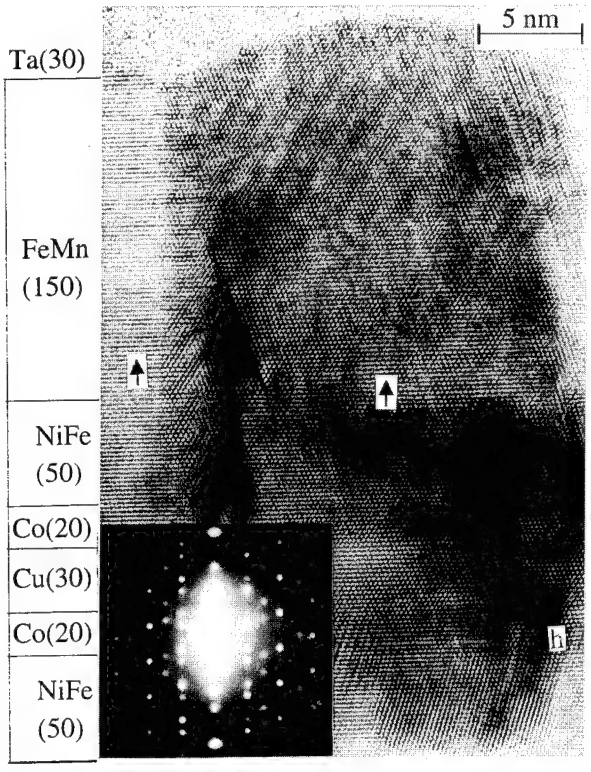

FIG. 2. High-resolution cross-sectional image of the ion-beam-deposited spin valve. Inset: selected-area-diffraction pattern illustrating the $<1°$ variation in (111) texture; arrows indicate the (111) directions on the image. A region of hcp Co is indicated by "h." Nominal interface positions are shown on the left-hand side.

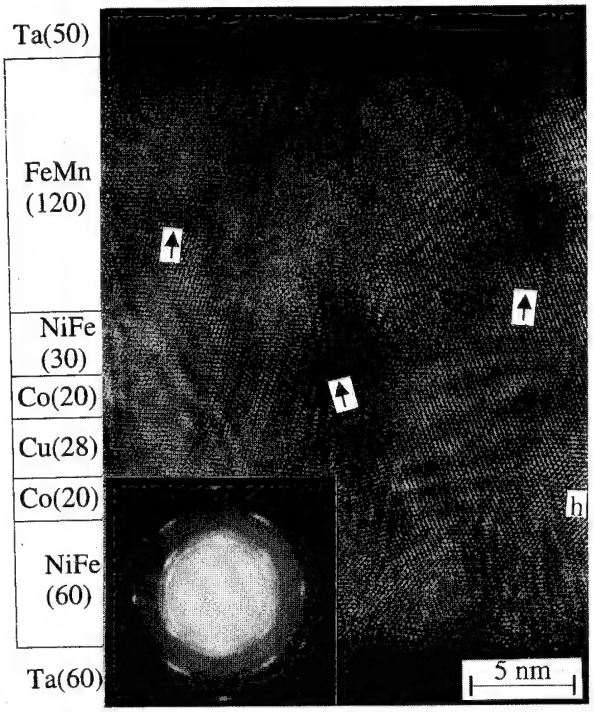

FIG. 3. High-resolution cross-sectional image of the sputtered, Ta seeded spin valve. Inset: selected-area-diffraction pattern illustrating the ~10° variation in (111) texture.

texture, the Ta-seeded, sputter-deposited spin valve shows approximately 10° dispersion. The perfect texturing is apparent from the cross-sectional high-resolution image (Fig. 2) as well. Here, the horizontal (111) stacking planes extend even over distances much greater than the grain size with little undulation. In the dc magnetron-deposited film (Fig. 3), the stacking planes waver by 10° over 50 Å length scales or less. Some regions of c-axis-textured hcp Co crystallization, indicated by "h," are visible in both spin valves. These coexist with a great amount of fcc Co, also visible.

The average grain sizes in the spin valves were found from HREM images of the plane-view samples (not shown). Average grain sizes were larger in the IBD films (120 Å) than in the dc magnetron sputtered films and roughly the same size in the seeded as in the unseeded sputtered films (50 Å), though grains in the latter are equiaxed rather than columnar. The cross-sectional images show that full epitaxial growth throughout a grain, typical in the ion-beam-deposited film, is not operative in the Ta-seeded dc magnetron-sputtered film. Thus, the grains tend to extend through all the layers only in the ion-beam-deposited sample, although they may traverse multiple layers in the dc magnetron-sputtered film. Likely related to this difference in growth mode, however, is the development of a convex growth front at the top of the grains of FeMn, on the order of 25 Å, terminating at the grain boundaries. The sputter-deposited samples show a more uniform FeMn surface morphology.

IV. DISCUSSION

Some relationships between microstructure and spin valve properties can be drawn out from the foregoing results. First, the strength of exchange biasing was seen to depend in large part upon the degree of texture throughout the layers. Strongly textured Co/NiFe(111)/FeMn(111), deposited by either ion-beam or dc magnetron sputtering, provided more than twice the exchange biasing than that of randomly oriented grains. This is in good agreement with studies done on molecular-beam-epitaxy-deposited NiFe/FeMn bilayers in various orientations, in which the (111)-oriented samples were seen to provide some 50% stronger biasing than (100) and (110) orientations.[13] Furthermore, it provides some confirmation for the near-linear relationship between XRD intensity in the (111) peak and H_E found in ion-beam deposited NiFe/Cu/NiFe/FeMn spin valves with various buffer layers.[12]

The pinned layer coercivity is likely to correlate with the homogeneity of crystal orientations at the F/AF interface. In our work, the waviness of the (111) planes, clearly visible in the Ta-seeded sputter-deposited sample, is completely absent in the ion-beam-deposited sample and accompanied by a fourfold drop in H_{c_2}. A coercivity dependence on textural dispersion may be expected to the extent that variations in texture introduce local inhomogeneities in the energetics of exchange biasing, and is consistent with the similarly low values of H_{c_2} and high values of H_E reached by molecular-beam epitaxial deposition of NiFe(111)/FeMn(111) on Cu(111).[12]

ACKNOWLEDGMENTS

Thanks are due to Ann Marshall for expert assistance with TEM, Thomas Anthony at Hewlett–Packard for providing the dc magnetron deposited samples, and Stephen Michael at Commonwealth Scientific for assistance with the ion-beam deposition. As a result of combined magnetization, specific heat, electrical resistivity, and neutron-scattering studies on single crystals, we present a complex magnetic phase diagram of UNiGa that exhibits several antiferromagnetic (AF) phases below $T_N = 39$ K. A relatively low magnetic field (~1–1.5 T) applied along the c-axis induces metamagnetic transitions from the zero-field AF structures to an uncompensated AF and/or to a ferromagnetic (F) phase. All the magnetic structures are collinear (uranium magnetic moments parallel to the c-axis of the hexagonal structure). They consist of F basal-plane sheets which are coupled along c in various ways. The strongly anisotropic magnetism in UNiGa causes anisotropy of the electrical resistivity. The magnetic phase transitions are reflected in pronounced resistivity anomalies especially for current along the c-axis. The metamagnetic transitions are accompanied by giant magnetoresistance (GMR) effects which can be correlated with respective changes of the magnetic periodicity. This implies an important feature of the mechanism responsible for GMR phenomena in UNiGa. The strong resistance enhancement in the paramagnetic range when approaching T_N is connected with AF short-range ordering with propagation along the c-axis. © *1996 American Institute of Physics.* [S0021-8979(96)56708-7]

UNiGa is one of uranium ternary compounds UTX (T =transition metal, X=p metal) which crystallize in the hexagonal ZrNiAl-type structure.[1] This structure consists of the U–T and T–X basal-plane layers alternating along the c axis. The huge uniaxial magnetocrystalline anisotropy in these materials locks the uranium magnetic moments along the c axis which leads to an Ising-like behavior. The anisotropy is due to considerable uranium $5f$-orbital moments and in the strong bonding of $5f$-states in the U–T planes.

The bonding implies the anisotropic $5f$-ligand hybridization which mediates anisotropic exchange interactions between the U moments. The strong F exchange interaction within the U–T planes yields magnetic structures built up of F basal-plane sheets (with $\mu_U \| c$). The interaction along the c-axis is, as a rule, considerably weaker but it plays an important role in determining the type of magnetic ordering, because it provides the coupling between the F sheets.

We present the magnetic phase diagram of UNiGa deduced from results of magnetization,[2] electrical resistivity and magnetoresistance,[3] specific heat,[4] and neutron-scattering studies performed on single crystals. Results involving application of magnetic fields have been obtained in fields parallel to the c-axis, which is the easy magnetization direction. The huge uniaxial anisotropy prevents perpendicular magnetic fields (at least up to 35 T) from affecting the magnetic state of UNiGa.

All experiments were performed on samples originating from two single crystals grown in a Czochralski tri-arc equipment of the FOM ALMOS at the University of Amsterdam. Both crystals were checked by the electron microprobe and found to be stoichiometric within the experimental accuracy of the method. Other details on sample preparation can be found in Ref. 5. The low-field magnetization was measured in the field of 1.2 mT in a SQUID magnetometer. The resistivity, specific-heat,[4] and magnetization[2] results were taken from our previous work where experimental details can be found. Neutron-scattering studies were carried out at temperatures between 2 and 80 K and in magnetic fields up to 2 T on double-axis spectrometers in CEN Grenoble and HMI Berlin. We also present additional neutron-scattering data obtained in zero magnetic on a triple-axis spectrometer at LLB operating in elastic mode.

In Fig. 1 we present the detailed magnetic phase diagram of UNiGa ($B-T$ diagram for $\mathbf{B} \| c$). In zero magnetic field, four antiferromagnetic phases can be observed below T_N within about 5 K. The effects of the magnetic phase transitions on the resistivity, specific heat, magnetization, and peak intensities of characteristic magnetic reflections in the neutron-diffraction experiment are plotted in Fig. 2, from which one can also deduce the temperature ranges of stability of the AF phases.[1–4]

Magnetic ordering in UNiGa appears through a second-order phase transition around 39 K, where the resistivity and low-field magnetization display only faint anomalies. The appearance of satellite reflections $h,k,l+\delta$ with δ=0.36–0.37 gives a clear evidence of an incommensurate antiferromagnetic (IAF) structure with the wave vector $\mathbf{q}=(0,0,\delta)$. The transition temperature can be best defined from the maximum critical scattering anomaly measured for $\mathbf{Q}$=1,1,0.378 (Fig. 3). Since previous estimates[2–4] of T_N from bulk properties had a relatively large scatter due to weakness of the respective anomalies, we consider the present value, $T_N = 39$ K to be the most reliable.

The IAF phase is stable down to 37.3 K (the δ value is

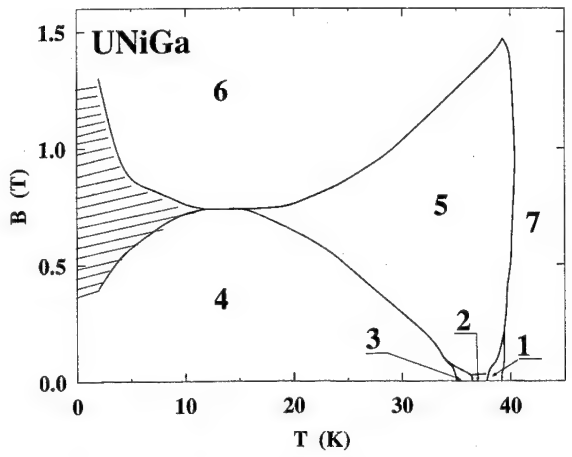

FIG. 1. Magnetic phase diagram of UNiGa for magnetic fields applied along the c axis: (1) incommensurate AF structure, $\mathbf{q}=\pm(0,0,\delta)$,$\delta\sim0.36$; (2) AF phase with $\mathbf{q}=\pm(0,0,1/3)$, e.g., the structure with frustrated "paramagnetic" moments in each third U–T plane, i.e., $(+0-)$; (3) AF phase with the $(++-+--+-)$ stacking, $\mathbf{q}=\pm(0,0,1/8)$, $\pm(0,0,3/8)$; (4) AF phase with the $(++-+--)$ stacking, $\mathbf{q}=\pm(0,0,1/2)$, $\pm(0,0,1/3)$, $\pm(0,0,1/6)$; (5) uncompensated AF phase with the stacking $(++-)$, $\mathbf{q}=\pm(0,0,1/3)$; (6) ferromagnetic phase, $\mathbf{q}=\pm(0,0,0)$; (7) paramagnetic phase.

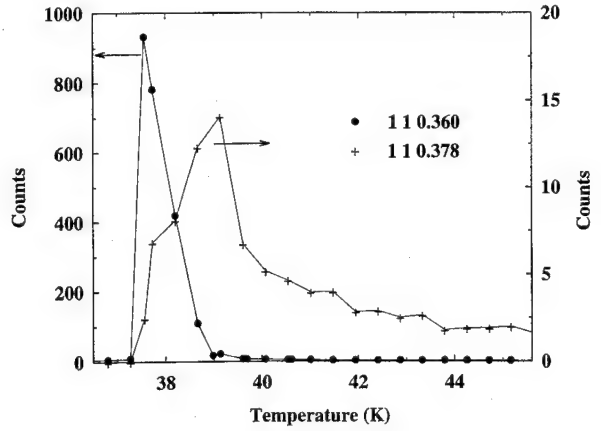

FIG. 3. Temperature dependence of the peak intensity of the magnetic Bragg reflection $\mathbf{Q}=1,1,0.36$ (●) and intensity of the magnetic scattering at $\mathbf{Q}=1,1,0.378$ (+), normalized to the same monitor measured at zero energy transfer on a triple-axis spectrometer.

varying between 0.37 at T_N to 0.36 at 37.5 K), where it transforms to the phase 2 through a first-order transition. This phase has the periodicity $3c$, but zero spontaneous magnetization. This may be conceived with a stacking sequence $+0-$, where 0 means the basal-plane layer of uranium atoms with the zero-ordered magnetic moment. Such a situation can appear in the case of a balanced AF interaction between nearest-neighbor and next-nearest-neighbor uranium planes. The resistivity drops by several percent at this transition.

With further decreasing temperature, gradual transformation of the magnetic structure to the ground-state AF phase 4 with the stacking $(++-+--)$ via the "intermediate" phase $3(++-+--+-)$ was observed. While the $2\rightarrow3$ is associated with a substantial increase of the resistivity, the other $(3\rightarrow4)$ yields a somewhat smaller decrease. As evidenced by the neutron-diffraction results, both transitions are characterized by a coexistence of neighboring phases over a certain critical region which can be more than 1 K wide (the transition $3\leftrightarrow4$).

The uranium moment, which is $\sim1.4\ \mu_B$ at 2 K, does not decrease substantially with increasing temperature up to almost 35 K, where it retains more than 90% of its low-temperature value. This behavior seems to be more general for the UTX compounds which exhibit high anisotropy yielding an Ising-like behavior.

The line $7\leftrightarrow5$ in fields between ~0.2 and 1 T in Fig. 1 marks the first-order transitions in contrast to the second-order transitions $7\leftrightarrow1$ in lower fields. Also the transitions $4\leftrightarrow5\leftrightarrow6$ above 14 K are second-order transitions. The phases 1, 2, and 3 are stable only in very low fields. The propagation vector $\mathbf{q}$ of the IAF phase gets slightly reduced under application of field (by less than 0.01 in 100 mT).

The hatched area in the magnetic phase diagram below 14 K represents the B–T region in which magnetic history phenomena have been observed by the bulk measurements.[2] These effects are reflected also on the microscopic scale including the relaxation phenomena, as follows.

(a) For T=const for sweeping the applied magnetic field the upper (lower) line in Fig. 1. Marks the $4\rightarrow6$ $(6\rightarrow4)$ transition. This fact is well documented by the large hysteresis of the field dependence of the magnetization, magnetoresistance and magnetic reflection displayed in Fig. 4. The hatched region represents the hysteresis, which increases progressively

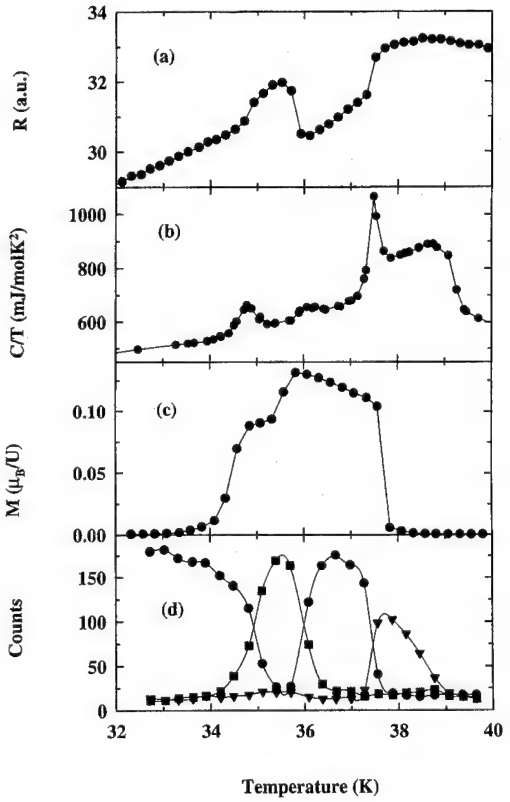

FIG. 2. Temperature dependence of the (a) specific heat, (b) electrical resistivity, (c) magnetization in a field 1.2 mT parallel to the c axis, and (d) the peak intensity of neutron-diffraction magnetic reflections (●) 1,1,4/3, (■) 1,1,11/8, and (▼) 1,1,0.36 in zero magnetic field measured on UNiGa in the temperature range 30–40 K.

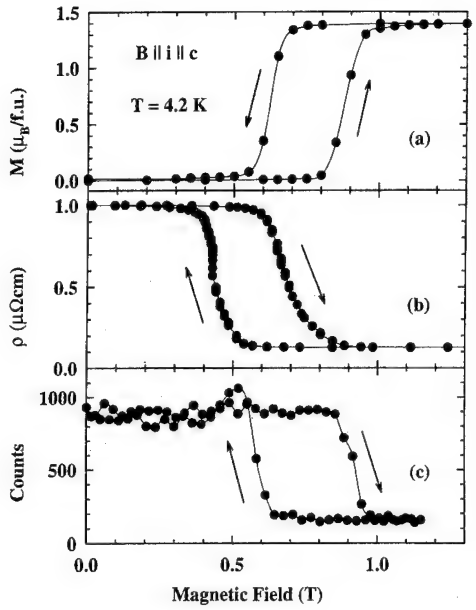

FIG. 4. Field dependence of the (a) magnetization, (b) reduced electrical resistivity, and (c) the peak intensity of the neutron diffraction reflection 1,1,4/3 measured on UNiGa single crystal at 4.2 K in magnetic field applied along the c axis. The offsets in critical fields are due to different demagnetization fields (different sample shapes) in particular experiments.

with lowering temperature. The metamagnetic transitions below 14 K are first order and only one phase (either 6 or 4) is present dependent on the direction of a field sweep. The same holds for the transitions 4→6 and 6→4 with varying temperature.

(b) B=const ~0.73 T: By cooling from higher temperatures (phase 5) down to the "hysteresis region" we reach a mixed state consisting of phases 4 and 6. This is clear from the simultaneous observations of magnetic intensities characteristic for each phase (4 and 6), and from bulk properties,[2–4] as well. The 4+6 phase mixture, which we observe also in the magnetoresistance and magnetization, seems to be stable, at least on the time scale of minutes.

As we have mentioned before, the metamagnetic transitions 4↔6 and 4↔5↔6 are inducing giant resistance changes. For example, the effect displayed in Fig. 4 represents almost 90% reduction of the resistance [$\Delta\rho/\rho(0T) \sim -0.9$] when we change from the AF structure with $\mathbf{q}$=0,0,1/6 (magnetic periodicity $6c$) to the F phase 6 ($\mathbf{q}$ =0,0,0; periodicity $1c$). Above 14 K, the transition from the phase 4 to 6 is realized by two steps via the uncompensated AF phase 5 ($\mathbf{q}$=0,0,1/3, magnetic periodicity $3c$) yielding the spontaneous magnetization of $\frac{1}{3}M_s$ (M_s is the magnetization in the F phase). The magnetoresistance also shows two transitions,[3] and the resistivity change between phases 4 and 5 is also approximately 1/3 of that between phases 4 and 6.

All the magnetoresistance changes connected with the metamagnetic transitions between various phases in UNiGa are qualitatively correlating with the change in the periodicity of corresponding magnetic structures. The increase of the magnetic periodicity is followed by a positive resistivity change. This observed systematic behavior points to the possible following scenario based on the high-resistivity state in antiferromagnets appearing due to superzone boundary formation (Fermi-level gapping). Thus, the additional magnetic periodicity yields the reduction of the carrier concentration and consequently enhances the resistivity. In the gapping model of Elliot and Wedgwood,[6] the resistivity in the local-moment AF state can be described by

$$\rho = \frac{\rho_0 + \rho_{e-p} + \rho_{spd}}{1 - g m(T)}, \tag{1}$$

where $m(T)$ is the normalized sublattice (staggered) magnetization, ρ_0 the residual resistivity, ρ_{e-p} the contribution of electron–phonon scattering, and ρ_{spd} is the magnetic contribution (spin-disorder scattering). The truncation parameter g characterizes the effective reduction of the number of conduction electrons due to the Fermi-level gapping. The difference between the resistance in the F and AF state depends on the width in the electron energy spectrum, which scales with the exchange coupling parameter between the local moments and conduction electrons. The exchange coupling parameter can be significantly enhanced in case of U local moments connected with the $5f$ states forming a narrow band at E_F. A more detailed discussion of magnetoresistance in UTX compounds will be published elsewhere.[7]

The last point we want to discuss is the anomalous temperature behavior of the resistivity for the current along the c axis ($i \| c$), i.e., sensing the AF coupling between uranium moments. Below 80 K, the resistivity starts to increase with decreasing temperature. The increase becomes gradually more pronounced when approaching T_N. The fact that this increase can be suppressed by applied fields corroborates the idea that the negative $d\rho/dT$ above T_N is due to incipient AF correlations.[2,5] The fact that a non-negligible neutron scattering (elastic) intensity at $\mathbf{Q}$=1,1,0.378 (see Fig. 3) can be detected far above the Néel temperature indicates that at least part of the enhanced resistance should be due to short-range AF ordering, which probably persists up to 2 T_N. A more detailed account of the diffuse scattering at T_N will be a subject of a forthcoming article.

This work was sponsored by the Dutch "Stichting voor Fundamenteel Onderzoek der Materie" (FOM) and the Grant Agency of the Czech Republic (Project No. 202/94/0454). The neutron scattering experiments at HMI Berlin and LLB Saclay were financially supported from the EU programs "Go West" (V.S.) and "HCM–Large Facilities+PECO" (K.P. and V.S.).

Spin-valve structures with a magnetic material buffer layer, CoNbZr/NiFe/$Co_{90}Fe_{10}$/Cu/$Co_{90}Fe_{10}$/$Fe_{50}Mn_{50}$, were prepared on a oxidized Si substrate. From x-ray diffraction analysis, it was shown that the CoNbZr/NiFe buffer layer enhances the fcc (111) orientation of the spin-valve structure on oxidized Si. After annealing, the giant magnetoresistance (GMR) ratio of $\Delta\rho/\rho=8\%$ and the soft magnetic properties of $H_c=0.1$ Oe and $H_k=2.8$ Oe were obtained. The sensitivity of GMR, $\Delta(\Delta\rho/\rho)/\Delta H$, of 1.4%/Oe is achieved. © *1996 American Institute of Physics.* [S0021-8979(96)56808-4]

I. INTRODUCTION

In recent years, the giant magnetoresistance (GMR) in spin-valve structure is attracting much attention.[1–4] In the spin-valve structures, large antiferromagnetic coupling between two magnetic layers across the intervening nonmagnetic layer is not needed, because one of the ferromagnetic layers is biased by exchange coupling from the antiferromagnetic layer. Therefore it is easy to obtain good soft magnetic properties and this makes the spin valve structure very interesting for sensor applications such as the MR head in high-density magnetic recording. For such applications, a high MR ratio and good thermal stability are required. The Co/Cu spin-valve structure satisfies this requirement, but it is difficult to obtain good soft magnetic properties with this structure.

On the other hand, the $Co_{90}Fe_{10}$ film with low magnetostriction is expected to show soft magnetic properties because an fcc phase is, according to its equilibrium phase diagram, stable in the presence of Fe, and an (111)-oriented fcc phase suppresses the softness deterioration due to magnetocrystalline anisotropy. In the previous article, we reported that the $Co_{90}Fe_{10}$/Cu spin-valve structure prepared on the sapphire substrate showed a good (111) orientation and an MR ratio of about 13% with a hysteresis of less than 1 Oe for the magnetization rotation mode.[5] However, the spin-valve structure prepared on the oxidized Si substrate showed a weak (111) orientation and an MR ratio less than 9% with a large hysteresis loop. From technological viewpoints, it is very important to obtain good spin-valve properties on the oxidized Si substrate.

In this article, we investigated a magnetic material buffer layer CoNbZr (100 Å)/NiFe (20 Å). This buffer layer is expected to enhance the (111) orientation of the spin-valve structure, because the surface of this buffer layer is composed of the NiFe (111) plane with high orientation. Moreover, this buffer layer is also expected to enhance soft magnetic properties of the spin-valve structure by its own good soft magnetic properties. We also studied the annealing effect of the proposed spin-valve structure.

II. EXPERIMENTAL

The spin-valve structure of $Co_{90}Fe_{10}$ (47 Å)/Cu (22 Å)/$Co_{90}Fe_{10}$ (47 Å)/$Fe_{50}Mn_{50}$ (150 Å) was prepared on oxidized Si (hereafter called "SiO_2 sample") and c-axis oriented sapphire substrates (hereafter called "sapphire sample") by conventional magnetron sputtering. A magnetic field was applied on the film plane during deposition, in order to induce a unidirectional bias field to the CoFe layer in contact with the FeMn layer. The spin-valve structure with a magnetic material buffer layer, CoNbZr (100 Å)/NiFe (20 Å)/$Co_{90}Fe_{10}$ (49 Å)/Cu (28 Å)/$Co_{90}Fe_{10}$ (49 Å)/$Fe_{50}Mn_{50}$ (80 Å), was prepared on oxidized Si substrates (hereafter called "buffer sample"). First, the CoNbZr and NiFe layers were prepared by ion beam sputtering. Then, the prepared sample was exposed to the atmosphere, and brought into another sputtering chamber. The buffer layer was not cleaned by sputter etching after introduction to the deposition chamber, because a sputter etching will cause the surface roughness. So the surface of the buffer layer should be shallow oxidized. Then, the $Co_{90}Fe_{10}$/Cu/$Co_{90}Fe_{10}Fe_{50}Mn_{50}$ layer was prepared on the buffer layer as describe above.

The magnetoresistance ratio was measured by the four-point method at room temperature by applying a magnetic field to the unidirectional bias field. Magnetization curves were measured with a vibrating sample magnetometer. The crystal structure was measured by x-ray diffraction θ-2θ method with the Cu $K\alpha$ line.

III. RESULTS

A. Crystal structure

Figure 1 shows x-ray diffraction patterns around the fcc (111) peak of representative samples. In case of the sapphire sample, some well-separated peaks with large intensity were observed. On the other hand, the patterns of the SiO_2 sample show a single broad peak around the (111) peak with small intensity. Figure 1 also shows the patterns of a buffered sample. Some clear peaks are observed and their intensity is larger than the SiO_2 sample. This result shows that the buffer layer enhances the (111) orientation of the spin-valve structure.

In order to clarify if these peaks are attributable to the multilayered structure with the preferred (111) orientation, calculations on the x-ray diffraction patterns were carried out by the kinematic theory including interfacial disorder.[6,7] We assume that the spin-valve structure is composed by four

 0021-8979/96/79(8)/6399/3/$10.00

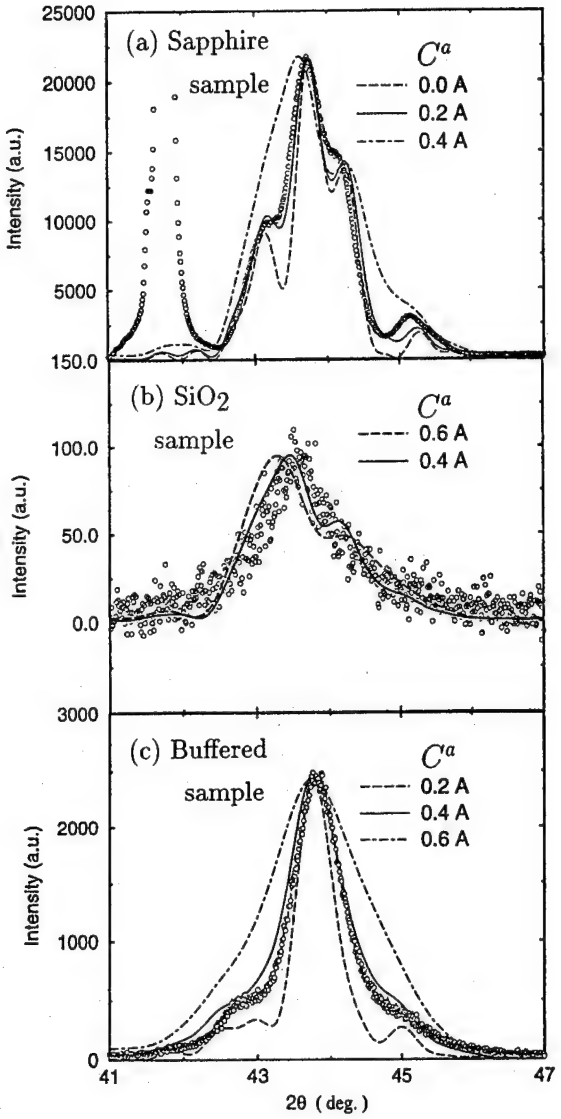

FIG. 1. X-ray diffraction patterns of CoFe/Cu spin-valve structures with calculated x-ray diffraction patterns. Circles and lines represent experimental values and calculation results, respectively. (a) $Co_{90}Fe_{10}$ (47 Å)/Cu (22 Å)/$Co_{90}Fe_{10}$ (47 Å)/$Fe_{50}Mn_{50}$ (150 Å) spin valve prepared on sapphire substrate (sapphire sample). (b) $Co_{90}Fe_{10}$ (47 Å)/Cu (22 Å)/$Co_{90}Fe_{10}$ (47 Å)/$Fe_{50}Mn_{50}$ (150 Å) spin valve prepared on oxidized Si substrate (SiO_2 sample). (c) CoNbZr (100 Å)/NiFe (20 Å)/$Co_{90}Fe_{10}$ (49 Å)/Cu (28 Å)/$Co_{90}Fe_{10}$ (49 Å)/$Fe_{50}Mn_{50}$(80 Å) prepared on oxidized Si substrate (buffered sample).

crystalline layers, each layer has materials, lattice stacking N_i with lattice spacing d_i and interfacial distance between the adjacent layers is a_i. The d_i and a_i values have Gaussian distribution of widths c_i^d and c_i^a, respectively. Then the x-ray profiles are described as

$$I(Q)=\langle F(Q)\cdot F^*(Q)\rangle, \tag{1}$$

where $F(Q)$ is the structure factor and the symbols $\langle\ \rangle$ denote averaging by integrating over all real interface distance. The structure factor $F(Q)$ can be written as

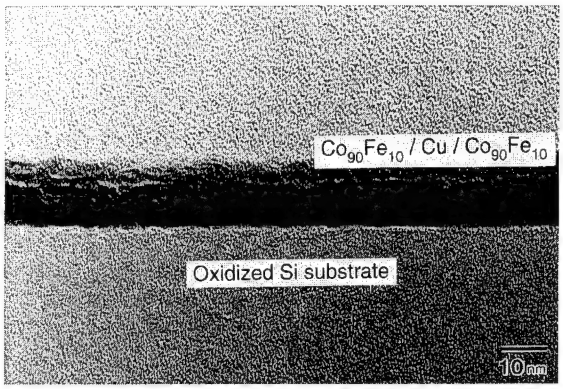

FIG. 2. Cross-sectional view of $Co_{90}Fe_{10}$ (50 Å)/Cu (30 Å)/$Co_{90}Fe_{10}$ (50 Å) sandwich structure prepared on oxidized Si substrate.

$$F(Q)=\sum_l \left[\left\langle \sum_n \left\{ \sum_m M_n^m f_m(Q)\right\} \exp(iQnd_l)\right\rangle \times\left\langle iQ\cdot\sum_{j=0}^{l-1}(a_j+N_jd_j)\right\rangle\right], \tag{2}$$

where M_n^m is atomic density for atom m (Co, Fe, Mn, and Cu) in the nth atomic layer and $f_m(Q)$ is the atomic scattering factor of atom m.

Fitting was carried out on the following assumptions: (1) the $Fe_{50}Mn_{50}$ layer is oxidized very easily. Therefore we assume a surface oxidized layer having an amorphous structure, and its thickness is determined by fitting. (2) all c_i^d values are equal to zero. This means that all layers have almost the same fluctuation, because the lattice spacing fluctuation value does not affect the shape of the profiles, if all layers take the same c_i^d value. (3) All c_i^a values are equal to c^a, and can be determined by fitting.

The fitting does not include the effect of interlayer diffusion or substrate roughness. The values of c^a did not mean the widths of the interfacial region, but mean the interface fluctuation.

Figure 1 shows the experimental and calculated x-ray diffraction profile. The calculated profile of sapphire sample agrees well with the experimental one if c^a is assumed to be 0.2 Å. On the other hand, the calculated profile of SiO_2 sample agrees well with the experiment with the assumption c^a=0.4–0.6 Å. Further, the best agreement was obtained for the profile of buffered sample with c^a=0.4 Å.

These results show that the interface fluctuation of buffered sample is still larger than that of the sapphire sample and at the same level with that of the SiO_2 sample, although the preferred (111) orientation is enhanced by the buffer layer.

The x-ray diffraction θ-2θ method detects the crystal structure perpendicular to the substrate. In order to clarify the in-plane crystal structure, we observed by transmission electron micrography the cross-section view of the $Co_{90}Fe_{10}$ (50 Å)/Cu (30 Å)/$Co_{90}Fe_{10}$ (50 Å) sandwich structure prepared on the oxidized Si substrate. Figure 2 shows that the structure has very rough and undulating interfaces. The sample seems to have the columnar structure.

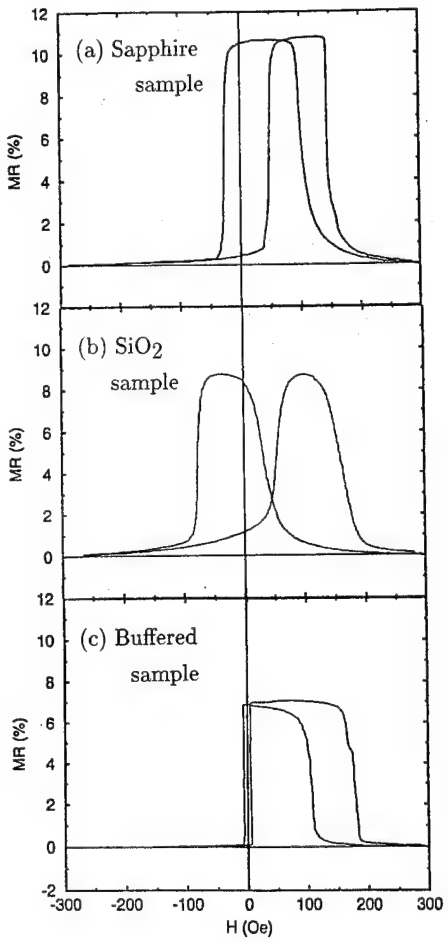

FIG. 3. Magnetoresistance curve of CoFe/Cu spin-valve structures: (a) $Co_{90}Fe_{10}$ (47 Å)/Cu (22 Å)/$Co_{90}Fe_{10}$ (47 Å)/$Fe_{50}Mn_{50}$ (150 Å) prepared on sapphire substrate (sapphire sample). (b) $Co_{90}Fe_{10}$ (47 Å)/Cu (22 Å)/$Co_{90}Fe_{10}$ (47 Å)/$Fe_{50}Mn_{50}$ (150 Å) prepared on oxidized Si substrate (SiO_2 sample). (c) CoNbZr (100 Å)/NiFe (20 Å)/$Co_{90}Fe_{10}$ (49 Å)/Cu (28 Å)/$Co_{90}Fe_{10}$ (49 Å)/$Fe_{50}Mn_{50}$(80 Å) prepared on oxidized Si substrate (buffered sample).

B. GMR characteristics

Figure 3 shows the magnetic field dependence of the MR ratio of three samples. The typical characteristic of spin-valve magnetoresistance is observed. The MR ratio of the sapphire sample is 10.8%. On the SiO_2 sample, on the other hand, the MR ratio is 8.5%, and the MR ratio of the buffered sample is 7.0%. Because there is a short current by the buffer layer in buffered sample, the MR ratio of buffered sample is essentially comparable with the SiO_2 sample. It is suggested by the x-ray diffraction analysis that buffered sample has the (111) preferred orientation, but the interface coherency is the same as the SiO_2 sample. The MR ratio of the spin-valve structure will be affected by interface coherency.

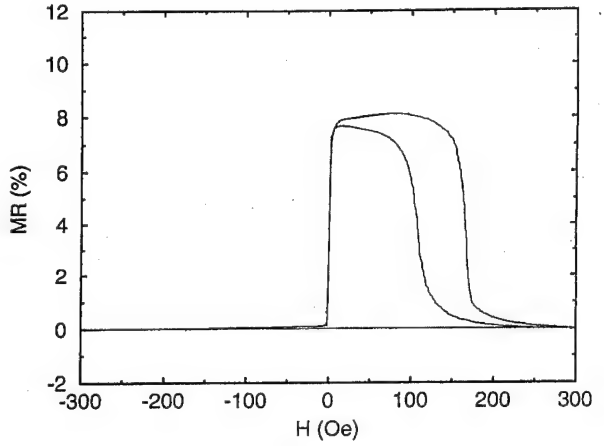

FIG. 4. Magnetoresistance curve of CoNbZr (100 Å)/NiFe (20 Å)/$Co_{90}Fe_{10}$ (49 Å)/Cu (28 Å)/$Co_{90}Fe_{10}$ (49 Å)/$Fe_{50}Mn_{50}$ (80 Å) after annealing.

On the other hand, hysteresis loop of buffered sample is very small. This is a result of the enhancement of (111) preferred orientation. The H_c value was successfully lowered from 66 Oe of SiO_2 sample to 5 Oe of buffer sample. This decrease of H_c comes partially from good soft magnetic properties of the buffer layer.

To improve soft magnetic properties, we annealed the buffered sample. In annealing, the temperature was increased to 250 °C and kept in magnetic field. In cooling process, the applied magnetic field was rotated 90°. Because only the unidirectional bias field rotates at low temperatures, the free $Co_{90}Fe_{10}$ layer's easy axis becomes almost orthogonal to that of the exchange-biased $Co_{90}Fe_{10}$ layer. Figure 4 shows the magnetic field dependence of the MR ratio after annealing. The MR ratio were enhanced by annealing and reached 8%. Soft magnetic properties were enhanced and H_c=0.1 Oe and H_k=2.8 Oe. The sensitivity of GMR, $\Delta(\Delta\rho/\rho)/\Delta H$, became 1.4%/Oe.

Giant magnetoresistance effect in multilayered wire arrays

Minoru Kume, Atsushi Maeda, Toshio Tanuma, and Kazuhiko Kuroki
New Materials Research Center, SANYO Electric Co., Ltd, 1-1 Dainichi-higashimachi, Moriguchi, Osaka 570, Japan

Three wire arrays, each comprised of a different type of giant magnetoresistive (GMR) multilayer, were fabricated by high-resolution electron-beam lithography and lift-off techniques. With a GMR multilayer of the biquadratic-coupling type, a magnetic field applied parallel to the wires produced a larger MR change and higher response than in the corresponding unpatterned multilayered film; however, the wire structures worsened the MR characteristics of two other types of GMR multilayers. © *1996 American Institute of Physics.* [S0021-8979(96)56908-0]

I. INTRODUCTION

There is considerable interest in the physical properties of microfabricated materials, in which the geometry and spacing are well defined. To date, the authors have observed unique magnetic and microwave absorption characteristics in submicron-size $Ni_{80}Fe_{20}$ or Co wire and box arrays.[1–4] As one application of these laterally artificial structures, the present study looks at multilayered wire arrays prepared with the goal of obtaining superior magnetoresistance (MR) characteristics.

Various multilayered materials display a giant MR (GMR) when the moments of ferromagnetic layers separated by a nonmagnetic layer are turned from parallel to antiparallel.[5–7] However, there is evidence that the magnetization states never reach fully antiparallel and parallel alignments because of the domain structures in the plane.[8] Inducing strong shape anisotropy by fabricating the micron-size magnetic wires is expected to be effective in overcoming the involvement of the magnetic domains. Consequently, the antiparallel and parallel alignments should be improved in the multilayered wires, and therefore the MR should be larger than that of corresponding unpatterned multilayered films. In addition, the shape anisotropy is expected to restrain Barkhausen noise which is a serious problem in device applications. The above-mentioned ideas motivated us to prepare multilayered wire structures.

"Array" samples were considered because they have an advantage in the study of microfabricated materials; using array samples including a large number of wires makes it possible to apply conventional techniques to characterize physical properties.

We report here the results of an investigation on the MR and magnetic characteristics of wire arrays comprised of three types of GMR multilayers.

II. EXPERIMENT

The wire arrays were fabricated by high-resolution electron-beam lithography and lift-off techniques. Resist films of 1-μm-thick polymethyl methacrylate (PMMA) coated on Si(100) wafers were directly exposed to an electron beam whose acceleration voltage ranged between 25 and 50 kV. The typical exposure area (equivalent to the sample size) was 8×8 mm^2. The wire width and spacing were varied from 0.6 to 10.0 μm. After baking at 473 K under a nitrogen atmosphere for 20 min, the samples were developed using methylisobutyl ketone. Next, various GMR multilayers were prepared on the lithographic resist mask by ion-beam sputtering at room temperature. All the samples possessed only one period. Ar gas pressure was held constant at 4.2×10^{-5} Torr during deposition. The remaining resist material was removed with an acetone lift-off process. A thin Au film was evaporated on both ends of the wires to serve as electrodes. The distance between the Au electrodes was held constant at 1 mm. Thus, the aspect ratio in the multilayered wires ranged from 100 to 1700, resulting in strong shape anisotropy.

The artificial structures of the arrays that were prepared were observed by scanning electron microscopy (SEM). The MR was measured at room temperature in a four-terminal geometry with a direct current. A magnetic field H up to 250 G was applied parallel to the array plane and at a variable angle to the axes of the wires. In the present study the MR ratio was determined as follows:

$$\text{MR ratio}=\Delta R/R(H_{\max}), \tag{1}$$

where ΔR is the MR change [that is, $R_{\max}-R(H_{\max})$] and $R(H_{\max})$ is the MR at the maximum measuring field. Magnetization M and hysteresis loops were measured at room temperature using a vibrating sample magnetometer.

III. RESULTS AND DISCUSSION

Figure 1 shows the SEM image of an $Fe_{50}Mn_{50}$ (7.0 nm)/$Ni_{80}Fe_{20}$ (3.4 nm)/Co (0.6 nm)/Cu (2.8 nm)/Co (0.6 nm)/$Ni_{80}Fe_{20}$ (5.4 nm) wire array with widths and spacings of 0.9 μm. The measured widths were equal to the spacings, as

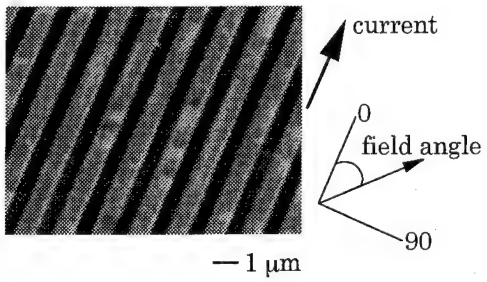

FIG. 1. SEM image of $Fe_{50}Mn_{50}$ (7.0 nm)/$Ni_{80}Fe_{20}$ (3.4 nm)/Co (0.6 nm)/Cu (2.8 nm)/Co (0.6 nm)/$Ni_{80}Fe_{20}$ (5.4 nm) wire array with widths and spacings of 0.9 μm.

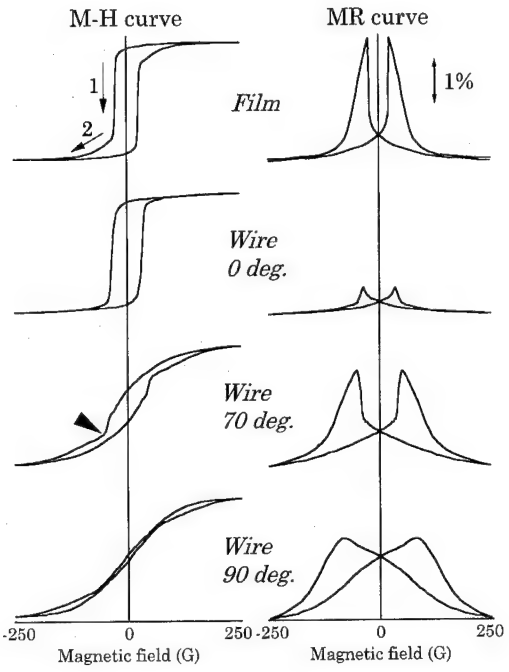

FIG. 2. Angular dependence of magnetization and MR curves for Fe (5.0 nm)/$Ni_{80}Fe_{20}$ (4.0 nm)/Co (0.6 nm)/Cu (4.0 nm)/Co (4.0 nm) multilayered film and wire array with widths of 2.6 μm and spacings of 1.2 μm.

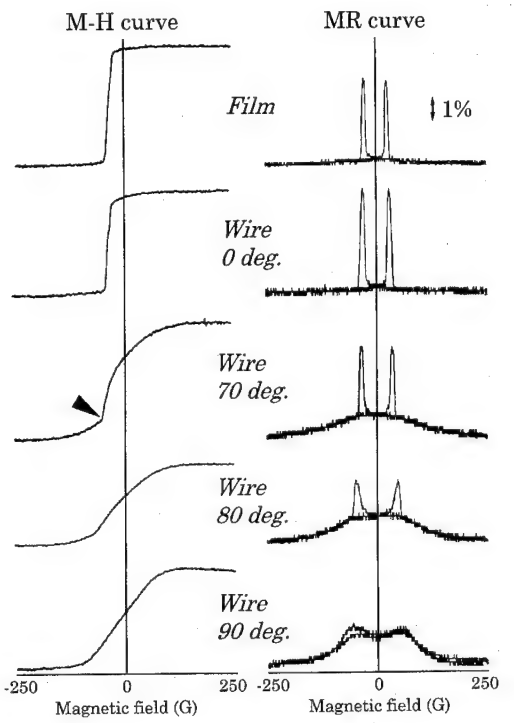

FIG. 3. Angular dependence of magnetization and MR curves for $Ni_{80}Fe_{20}$ (6.0 nm)/Co (0.6 nm)/Cu (4.0 nm)/Co (4.0 nm) multilayered film and wire array with widths of 2.6 μm and spacings of 1.2 μm.

designed. The linearity of each wire was good enough to allow for the following meaningful discussion of the physical properties. The other GMR multilayers exhibited similar SEM images.

Figure 2 shows the angular dependence of the $M-H$ and MR curves of an Fe (5.0 nm)/$Ni_{80}Fe_{20}$ (4.0 nm) /Co (0.6 nm)/Cu (4.0 nm)/Co (4.0 nm) multilayered film with no pattern and a wire array with widths of 2.6 μm and spacings of 1.2 μm. Here, an ultrathin Co layer was added to the $Ni_{80}Fe_{20}$ layer to enhance the interfacial spin-dependent scattering.[9] In this measurement, we defined the field angle to be 0° when the magnetic field was applied parallel to the stripes. The film sample displayed an isotropic magnetization switching process associated with the different coercive fields H_c. Namely, the magnetic moments of Fe/$Ni_{80}Fe_{20}$/Co, with the smaller H_c, initially rotated with decreasing field (arrow 1). Next, magnetization switching of the Co layer, with the larger H_c, gradually occurred as indicated by arrow 2. In the figure, the features of the MR curve correspond well with those of the $M-H$ curve. The MR ratio was 2.89%, being less than that observed in similar films with a few tens of periods.[6] The $M-H$ curve along the easy axis of the wire array (0°) showed a rectangular loop with indistinct steps. This suggests that strong shape anisotropy reduces the difference in the coercive field between the Fe/$Ni_{80}Fe_{20}$/Co and Co layers. As a result, only partial antiparallel alignment is achieved and the MR was negligibly small. At the field angle of 70° the magnetization process became spread over larger field range. This behavior can be qualitatively modeled by assuming the existence and properties of a demagnetizing field. Here, it is important to note that the step as shown by the arrow is present in the $M-H$ curve, indicating the appearance of the difference in the coercive field. Thus, the MR curves that were observed around this angle possessed the same shape as those of the film sample, though broader. In the hard axis (90°), the magnetic and MR characteristics were strongly affected by a demagnetization field; however, the MR change was large, suggesting that the difference in the coercive field was maintained in the multilayered wires. In summary, the MR characteristics of the Fe/$Ni_{80}Fe_{20}$/Co/Cu/Co multilayered wire arrays along the easy axis were not improved, as expected, because the coercivities are equalized by the shape anisotropy.

Next, we discuss wire arrays fabricated from biquadratic-coupled multilayers. Since the magnetization states of these materials is controlled by "exchange coupling," the effect of the shape on the MR characteristics seems to be small. Figure 3 shows the angular dependence of the $M-H$ and MR curves of a $Ni_{80}Fe_{20}$ (6.0 nm)/Co (0.6 nm)/Cu (4.0 nm)/Co (4.0 nm) multilayered unpatterned film and a wire array with widths of 2.6 μm and spacings of 1.2 μm. The film sample displayed a steep MR change. We consider that biquadratic coupling between the $Ni_{80}Fe_{20}$/Co and Co layers is responsible for this behavior.[10–13] The MR ratio was 3.47%, being less than that of similar films with several periods.[14] Along the wire axes of the array sample (0°) it is worth noting that the MR is increased in the wire structure sample compared with the unpatterned sample. The increase in the MR ratio from 3.47% to 4.13% is probably due to the fact that the shape anisotropy improved the magnetic alignments in the multilayers. The improvement in sensitivity is attributable to the steep magnetization switching without the

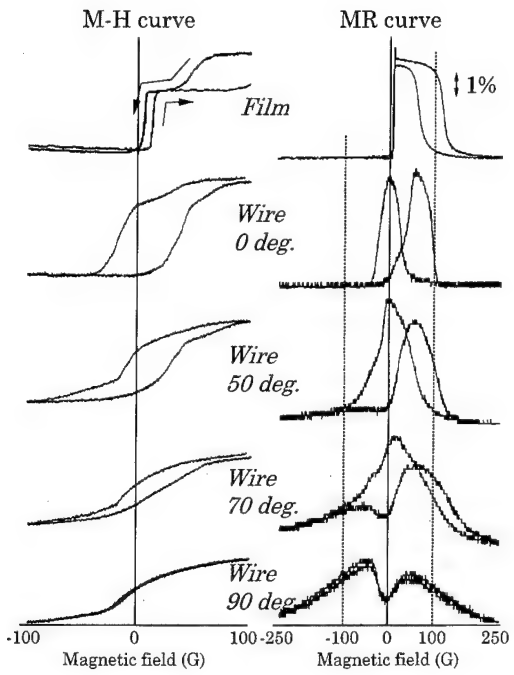

FIG. 4. Angular dependence of magnetization and MR curves for $Fe_{50}Mn_{50}$ (7.0 nm)/$Ni_{80}Fe_{20}$ (3.4 nm)/Co (0.6 nm)/Cu (2.8 nm)/Co (0.6 nm)/$Ni_{80}Fe_{20}$ (5.4 nm) multilayered film and wire array with widths and spacings of 0.9 μm.

involvement of domain structures in the easy axis. Similar experimental results were observed in the other $Ni_{80}Fe_{20}$ (6.0 nm)/Co (0.6 nm)/Cu (4.0 nm)/Co (4.0 nm) multilayered wire arrays with micron-size widths and spacings. This result indicates that the magnetization states controlled by the biquadratic coupling was maintained in the wire arrays. For multilayered wire arrays of this type, the optimal combination of wire width and spacing to obtain superior MR characteristics is currently under investigation. As shown in Fig. 3, the steep MR change was gradually buried in the broad component with increasing field angle. This is due to the demagnetizing field arising from a narrow width. The step in the $M-H$ curve that was observed at 70° indicates the difference in the coercive field between the $Ni_{80}Fe_{20}$/Co and Co layers. This indicates the coexistence of two kinds of mechanisms that control the magnetization orientation, i.e., biquadratic coupling and different intrinsic coercive fields.

Finally, the physical properties of wire arrays comprised of an exchange-coupled spin-valve multilayer, i.e., $Fe_{50}Mn_{50}$ (7.0 nm)/$Ni_{80}Fe_{20}$ (3.4 nm)/Co (0.6 nm)/Cu (2.8 nm)/Co (0.6 nm)/$Ni_{80}Fe_{20}$ (5.4 nm) are discussed. Figure 4 shows the $M-H$ and MR curves of the film and wire array. Here, the MR curves of the array sample are minor loops measured between −100 and 100 G. The wire widths and spacings were both 0.9 μm. In comparison with the film, the physical properties of the wire array can be characterized as follows:

(1) broader MR curves;
(2) weaker pinning effect by the $Fe_{50}Mn_{50}$ layer; and
(3) weaker coupling between the $Ni_{80}Fe_{20}$/Co and Co/$Ni_{80}Fe_{20}$ layers separated by the Cu layer.

Analyzing the angular dependence, the maximum MR ratio of 4.67% was observed at 50°. This value was larger than that in the unpatterned film and was similar to that in the spin-valve films with a Ta underlayer.[15] In addition, the magnetic response, which is estimated as maximum MR change per 1 Oe, became worse with increasing field angle. Among the results presented in Fig. 4, the MR data obtained in the easy axis (0°) were contrary to our model because the effects of the pinning which control the magnetization states were not expected to be influenced by the shape anisotropy, such as with the biquadratic coupling. To provide further insight into this experimental result, magnetic measurements on samples with various widths and spacings are presently being made.

IV. SUMMARY

Micron-size multilayered wire arrays comprised of various GMR materials were successfully fabricated by high-resolution electron-beam lithography and lift-off techniques. For some GMR multilayers with biquadratic coupling, when the magnetic field was applied parallel to the stripes, a larger MR and magnetic response were observed in comparison with the corresponding multilayered film having no patterns. These features are attributable to the strong shape anisotropy and provide additional opportunities for technological applications. In contrast, the wire structures worsened the MR characteristics of different-coercive-fields-type and spin-valve-type GMR multilayers.

Superconductivity and structural transformation in HfV_2 and Nb-doped HfV_2

F. Chu
Center for Materials Science, Los Alamos National Laboratory, Los Alamos, New Mexico 87545

Z. W. Chen,[a] C. J. Fuller, C. L. Lin, and T. Mihalisin
Department of Physics, Temple University, Philadelphia, Pennsylvania 19122

The temperature dependence of the specific heat shows that the strong electron-phonon coupling system HfV_2 undergoes a structural transformation at 116 K and becomes superconducting around 9 K. The structural instability can be interpreted in terms of a strong electron-phonon coupling and Fermi surface nesting. The structural transformation shifts to lower temperatures with very dilute Nb substitution in HfV_2, and completely disappears with only 5 at. % Nb. The low-temperature specific heat of HfV_2 shows a large density of states at the Fermi level. These experimental results are consistent with predictions from band-structure calculations. © *1996 American Institute of Physics.* [S0021-8979(96)26108-9]

A15 and C15 compounds have attracted much interest because of a variety of striking phenomena.[1–8] For example, some compounds, e.g., Nb_3Sn, V_3Si, HfV_2, and ZrV_2, undergo a structural transformation[1–4] at a low temperature and become superconducting[5,6] at an even lower temperature. These compounds show[5,6] an enhanced electronic specific heat coefficient γ which implies a high density of states at the Fermi level. The ratio of A, the coefficient of the T^2 term in the resistivity, to the γ value for these compounds shows a universal behavior[7] which is similar to that of the Ce- and U-based heavy fermion systems. Among the binary C15 Laves phase compounds, HfV_2 has the highest superconducting transition temperature ($T_{sc}\approx 9$ K) and undergoes a structural transformation around $T_{st}=116$ K. In addition, it has been shown[9–11] that T_{sc} does not vary significantly with dilute substitution of Ta or Nb for Hf in HfV_2 and has nearly the same value for the equi-ternary compounds Hf-V-T with T=Zr, Nb, Ta, and Cr. Some controversial issues remain unresolved. For instance, the specific heat of HfV_2 and ZrV_2 (Refs. 4 and 9) shows a broad λ-type second-order transition, instead of the more common first-order structural transformation. Moreover, the effects of substitution on the structural transformation have not been studied systematically. To address these issues, we have prepared samples of HfV_2, and Nb-doped HfV_2, having the C15 Laves phase structure, and have measured the temperature dependence of the specific heat of these compounds. The results are presented and discussed with predictions of theoretical band-structure calculations.[12]

The ternary Hf-V-Nb equilibrium phase diagram has been established recently[13] and shows that the C15 Laves phase exists in a broad region for this ternary system. The binary HfV_2 and the Nb-doped ternary with 0.5, 1.0, 2.0, and 5.0 at. % Nb polycrystalline samples having the C15 cubic structure were prepared by melting stochiometric ratios of the constituents in a conventional inert atmosphere arc furnace. The nominal purities of the elemental Hf and V were 99.99 at. % and that of Nb was 99.7 at. %. The samples were annealed under high vacuum at 1200 °C for 120 h. Powder x-ray diffraction studies were used to check the homogeneity and the structure of the samples. No evidence for a second phase was found. The specific heat was measured using a semiadabatic heat pulse method using a He^4 probe from 1.2 to 20 K, and using a closed-cycle refrigerator system from 15 to 150 K.

The specific heat of the binary HfV_2 for the region from 110 to 125 K is shown in Fig. 1. One can see that in the vicinity of 116 K the specific heat jumps dramatically from about 70 to 250 J/mole K and that the full width at half maximum of this anomaly is very narrow (about 0.5 K). This drastic change in the magnitude and the narrow width of the anomaly may indicate that the transition is in fact first order

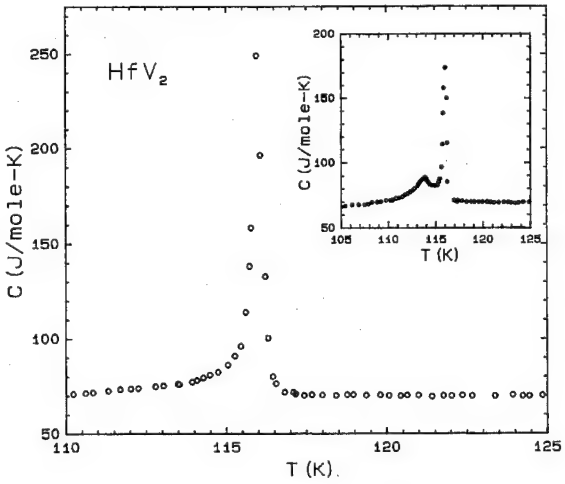

FIG. 1. The temperature dependence of the specific heat of HfV_2. Inset: The $C(T)$ data for an off-stochiometric HfV_2 sample.

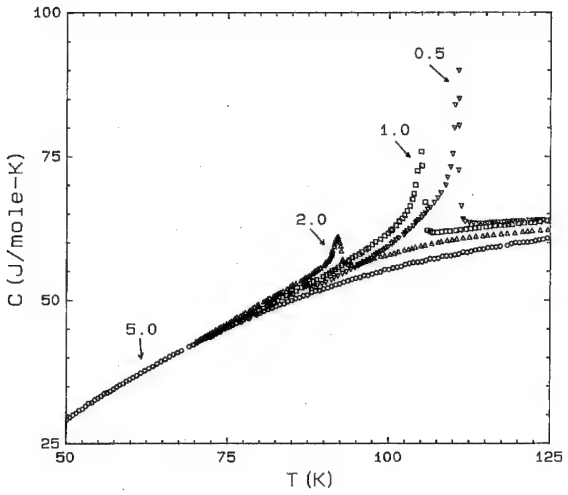

FIG. 2. The $C(T)$ data for the Nb-doped HfV_2 ternary system with 0.5, 1.0, 2.0, and 5.0 at. % Nb.

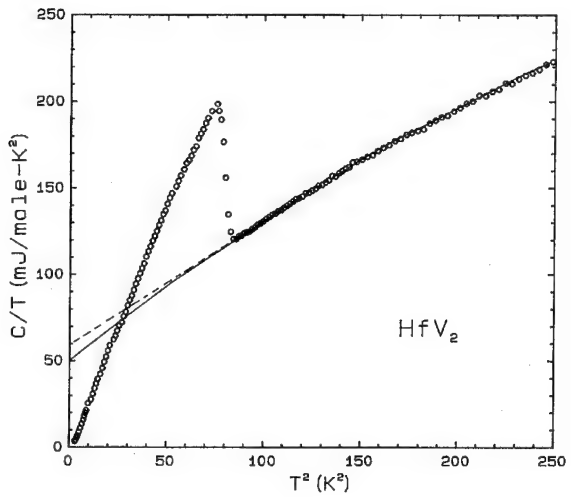

FIG. 3. C/T vs T^2 for HfV_2 at low temperatures. The dash line is the $C/T=\gamma+\beta T^2$ fit to the experimental data from T^2=90 to 120 K^2. The solid curve is the $C/T=\gamma+\beta T^2+\alpha T^4+\delta T^6$ fit to the experimental data from T^2=90 to 250 K^2.

and that a latent heat measurement should be done rather than a specific heat measurement. A first-order structural transformation from a high-temperature cubic structure to a tetragonal structure below 116 K has been reported.[13,14] The value of 116 K is consistent with that previously published by Hafstrom *et al.*[9] and Kimura.[4] However, in both these reports, the specific heat anomaly starts to swing up at about 110 K and reaches a maximum at 118 K. In both cases, the anomaly has a much broader width (about 3 K) and exhibits a λ-type transition. This difference could be due to the limited number of data points taken with large temperature changes ΔT around the transition temperature and/or samples that were off-stochiometry. We have also measured the specific heat of a HfV_2 sample with a slight off-stochiometry Hf to V ratio. The data for this sample are shown in the inset of Fig. 1. The specific heat of this sample starts to increase and deviate from the background at 110 K and shows two anomalies. We believe that the second smaller specific heat anomaly at 114 K can be attributed to a phase separation which follows the structural transformation at 116 K as the sample is cooled to low temperatures.

In order to study the alloying effect on the structural transformation, we have measured the specific heat of the Nb-doped HfV_2 ternary system. Shown in Fig. 2 are the specific heat curves for 0.5, 1.0, 2.0, and 5.0 at. % Nb. Note that the magnitude of the specific heat anomaly is significantly reduced from 180 J/mole K for the binary HfV_2 to 25 J/mole K for the 0.5 at. % Nb sample and the structural transformation temperature shifts down to 110 K. On careful examination one can see that the shape of the anomaly for the 0.5 at. % Nb sample begins to resemble that of a λ-type transition. The reason for the change from the very narrow transition for the pure HfV_2 to a λ-type transition for the case of very dilute Nb doping could be the one alluded to just above. For the 5.0 at. % Nb sample, a specific heat anomaly is not visible for temperatures down to 15 K, implying no structural phase transformation for this sample. The effect of substitution on the structural transformation described above is stronger than that observed previously in similar systems, e.g., T_{st} is about 78 K for 7% Ta doping in $Hf_{1-x}Ta_xV_2$ (Ref. 9) and a structural transformation occurs across the entire series for the case of $Hf_{1-x}Zr_xV_2$.[15] This point is discussed in more detail later.

We have also made measurements of the specific heat at lower temperatures in the region of the superconducting transition. Shown in Fig. 3 is a plot of C/T vs T^2 for the binary HfV_2. Note that the HfV_2 sample undergoes a superconducting transition at T_{sc}=9 K which is determined at the midpoint of the specific heat anomaly. The C/T data above T_{sc} exhibit a slight downward curvature (instead of being a straight line), so that it is difficult to extract the electronic specific heat coefficient γ. We can estimate the γ value for the binary HfV_2 using two different approaches. First we can use $C/T=\gamma+\beta T^2$ to fit the experimental data for a narrow temperature range from T=9.5 to 11 K, i.e., T^2=90 to 120 K^2. This method gives γ=60 mJ/mole K^2. Or we can use $C/T=\gamma+\beta T^2+\alpha T^4+\delta T^6$ which results from a consideration of the entropy balance between the normal and superconducting states for the wider temperature range from 9.5 to 16 K, i.e., T^2=90–250 K^2. This method gives γ=50 mJ/mole K^2. These T_{sc} and γ values are in good agreement with those previously published.[5,6] Note that either estimate for γ is larger than that for a typical weak electron-phonon coupling superconductor or for normal metals. This larger value indicates a large density of states at the Fermi surface in the case of HfV_2.

Shown in Fig. 4 is a plot of C/T vs T^2 for 5.0% Nb-doped HfV_2. Note that this sample does not transform from the cubic to the tetragonal phase at low temperatures. The T_c value increases slightly to 9.6 K. The γ values are also 50% higher than those for pure HfV_2, i.e., 90 and 75 mJ/mole K^2 obtained from using $C/T=\gamma+\beta T^2$ and $C/T=\gamma+\beta T^2+\alpha T^4+\delta T^6$, respectively. The estimated values of $\Delta C/\gamma T_{sc}$ are 1.8–2.0 for both pure HfV_2 and 5.0% Nb doping in HfV_2. These values are larger than the value of 1.43 given by the BCS theory. The larger γ and $\Delta C/\gamma T_{sc}$ values have been explained in terms of strong electron-phonon coupling effects.[5,6]

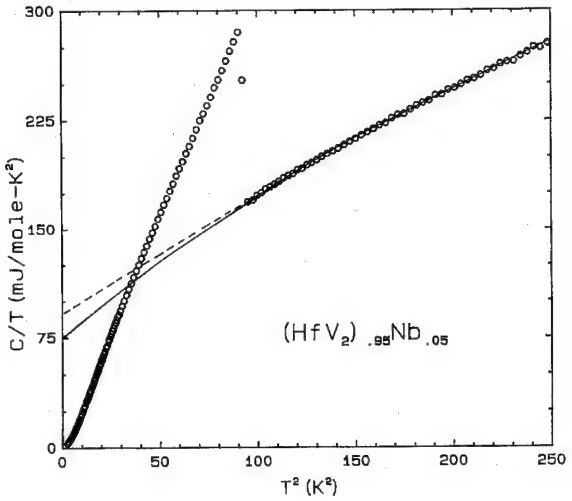

FIG. 4. C/T vs T^2 for the 5.0% Nb-doped HfV_2 sample. The dash line is the $C/T=\gamma+\beta T^2$ fit to the experimental data from T^2=90 to 120 K^2. The solid curve is the $C/T=\gamma+\beta T^2+\alpha T^4+\delta T^6$ fit to the experimental data from T^2=90 to 250 K^2.

The band-structure calculations for the C15 HfV_2 have been carried out[12] recently using the linear-muffin-tin-orbital (LMTO) method.[16] The results show a narrow peak close to the Fermi energy, indicating a large density of states $N(E_f)$. This behavior is similar to that calculated for the Ce- and U-based f-electron systems.[17] The measured γ value of 50 mJ/mole K^2 for HfV_2 is in qualitative agreement with these calculations. Note that the value of γ was measured in the tetragonal phase (at low temperatures) for HfV_2 and the cubic phase for 5.0% Nb-doped HfV_2, whereas the $N(E_f)$ value was calculated for the C15 cubic phase.

It has been shown previously that a narrow peak at E_f, and a large $N(E_f)$, can lead to a very strong electron-phonon coupling,[18–20] which serves as a necessary (but not sufficient) condition for structural instabilities at low temperatures.[9,19,21,22] The band-structure calculations[12] for HfV_2 also show that there are large areas of the Fermi surface which are parallel or nearly parallel, leading to a so-called Fermi surface nesting, with a nesting vector $\mathbf{q}$ parallel to $\langle 001\rangle$. This Fermi surface nesting behavior together with the strong electron-phonon coupling effects give rise to the phonon mode $\omega(\mathbf{q})$ softening, and therefore to a lattice distortion.[23] In addition, a nesting vector $\mathbf{q}$ along $\langle 001\rangle$ is expected to give rise to a change in structure from cubic to tetragonal. The transmission electron microscopy measurements at low temperatures[14] are in agreement with these arguments.

The electrons coming from Nb substitution presumably fill unoccupied d-d hybrid states[12] and change the Fermi energy E_f. The change in E_f could alter the Fermi surface nesting and hence make it difficult to soften the phonon mode $\omega(\mathbf{q})$. Our specific heat data for the Nb-doped HfV_2 agree with this argument, i.e., T_{st} shifts to lower temperatures and the size of the anomaly (corresponding to the degree of lattice distortion) becomes much smaller for very low Nb doping in HfV_2. For higher Nb substitution, the Fermi surface nesting no longer occurs, and therefore no structural transformation takes place.

As noted earlier Nb doping produces larger depressions of T_{st} than does Zr or Ta doping. The rate at which Zr, Ta, and Nb depress T_{st} are 1.0, 5.4, and 12 K/at. %, respectively. Zr is directly above Hf in the periodic table and has the same number of $4d$ electrons as Hf has $5d$ electrons. Moreover, it has a metallic radius of 1.585 Å which is very close to Hf's value of 1.575 Å. Hence it is not surprising that Zr depresses T_{st} the least of the three dopants since one expects it to have the least effect on the band structure in particular on the Fermi surface nesting responsible for the mode softening. Both Ta and Nb are one column to the right of Hf. But Ta is a $5d$ metal while Nb is $4d$. Moreover, Ta has a metallic radius of 1.462 Å which is closer to Hf's value of 1.575 Å than is Nb's 1.429 Å. Hence it is not surprising that Ta has a less severe effect on T_{st} than does Nb. Thus a qualitative explanation of the differing effects of Zr, Ta, and Nb on T_{st} can be given.

Also mentioned earlier was the fact that both Ta and Nb have surprising small effects on T_{sc}. Here we report that the 5.0 at. % Nb sample shows a 50% increase in γ, while $\Delta C/\gamma T_{sc}$ remains essentially constant but T_{sc} increases by only 6% or 7%. This result is not consistent with the BCS expression for T_{sc} and suggests that further studies may be of interest.

Crystallographic analysis shows that UCuSn does not form in the hexagonal $CaIn_2$ structure as reported previously, but is an ordered ternary compound and forms in an orthorhombic structure (space group: $P2_1cn$). Bulk and neutron-diffraction measurements reveal that UCuSn orders antiferromagnetically below 62 K. At 4.2 K, high-field magnetization reveals a complex magnetization process with two metamagnetic transitions. Furthermore, bulk investigations show an additional anomaly at 25 K, but a smooth temperature dependence of various magnetic peaks down to the lowest temperature gives no evidence for a second magnetic transition. Possible scenarios responsible for the drastic changes in the electronic properties around 25 K are discussed. © *1996 American Institute of Physics.* [S0021-8979(96)26208-5]

I. INTRODUCTION

The role of $5f$-ligand hybridization in suppressing local-moment magnetism has been studied extensively in the two largest isostructural groups of UTX compounds (T =transition metal, X=p-electron metal), namely, in compounds crystallizing in the hexagonal ZrNiAl and the orthorhombic TiNiSi structures.[1] The aim to search even higher degrees of $5f$-electron localization brings us to compounds reported to crystallize in the hexagonal $CaIn_2$ structure, which is formed for the very late d-metals Cu, Au, and Pd.[2]

In this contribution, we concentrate on UCuSn, which was thought to crystallize in this structure.[2–5] For this compound, antiferromagnetic ordering at low temperatures has been reported on the basis of electrical-resistivity,[4,5] magnetic-susceptibility,[4] and ^{119}Sn Mössbauer studies.[6] In addition, magnetization measurements revealed two metamagnetic transitions at about 12 and 17 T in the ascending field sweep, while in the descending magnetization curve only one transition around 12 T was found.[4] There is also a very unusual temperature dependence of the electrical resistivity: below 60 K, $\rho(T)$ increases suddenly forming a maximum around 25 K, where it drops precipitously.[4,5]

In order to get more insight in the electronic properties of UCuSn, we have checked and extended the study of some basic bulk properties. Here, we briefly describe also the results of additional neutron-diffraction experiments, the details of which will be published elsewhere.

II. SAMPLE PREPARATION AND CHARACTERIZATION

A polycrystalline sample of UCuSn was prepared by arc-melting stoichiometric amounts of the constituents, with no further heat treatment. The sample was powdered for the neutron diffraction experiments, which were performed on the High-Intensity Powder Diffractometer at LANSCE and on the C2 powder diffractometer at Chalk River. We observed a number of nuclear reflections which could not be indexed in the hexagonal system (e.g., $CaIn_2$ structure type), but we were able to index and refine the whole pattern in the related orthorhombic space group $P2_1cn$. The resultant structure and parameters are given in Fig. 1 and Table I.

III. BULK PROPERTIES

We also measured the temperature dependences of the electrical resistivity, of the specific heat, and of the magnetization (at 2 and 4 T) and the results are displayed in Fig. 2.

The absolute resistivity values are intermediate between the values published in Refs. 4 and 5 and the overall shape of

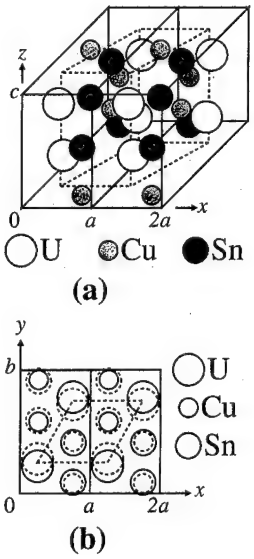

FIG. 1. Crystallographic structure of UCuSn (a) schematically drawn in a doubled cell showing the relation to the "parent hexagonal" cell. For sake of clarity, the z position was shifted by 0.25 with respect to the values given in Table I. In (b), a projection onto the a-b plane is shown, where the dashed lines represent the lower z position with respect to the solid lines. The hexagonal cell is indicated by dashed lines.

c (Å)=7.2203(2)
R factors
R_{wp}=4.29%
R_p=3.09%
reduced χ^2=3.88

all three results is in good agreement. In our sample, antiferromagnetism sets in around 62 K, which is reflected by a sudden increase of the electrical resistivity. Upon further decrease of the temperature, the electrical resistivity passes a pronounced maximum around 25 K. At both temperatures (62 and 25 K), we observe anomalies in the specific heat and the magnetization. While clear maxima evolve in C and M/H around 62 K, the low-temperature anomaly is far less pronounced. Around 25–30 K, only slight changes in the derivatives are observed. In addition, we find that a small, but significant ferromagnetic component ($\sim 0.02\mu_B$/U atom) evolves below 30 K. At present, we are not sure whether this is intrinsic or due to a small amount of a ferromagnetic impurity phase.

High-field-magnetization studies were performed at the High-Field Facility in Amsterdam on powder, both free to be

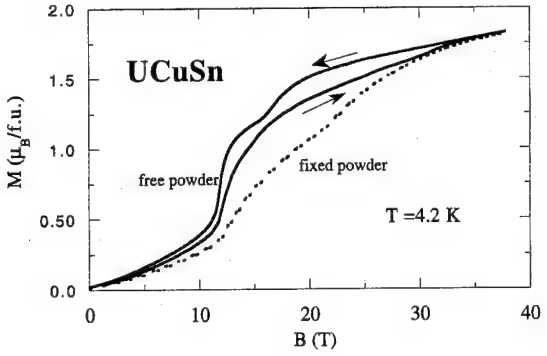

FIG. 3. Field dependence of the magnetization of UCuSn at 4.2 K measured on 'free powder' and 'fixed powder' represented as solid and dotted lines, respectively.

oriented by the applied field (giving the response of the easy magnetization direction), and in random orientation fixed by frozen alcohol (thereby representing an "ideal" polycrystal). The former ("free powder") result reveals a magnetic moment of $1.82\mu_B$ in 35 T, which is in excellent agreement with the results of Fujii *et al.*[4] The antiferromagnetic ground state is corroborated by metamagnetic transitions. In contrast to the results in Ref. 4, we find metamagnetic transitions around 12 and 30 T in the ascending curve and around 11 and 15 T in the descending curve. We believe that this difference could originate in small differences in the compositions of the samples, which could also account for the slight difference in T_N. Two transitions (around 13 and 25 T) are found also in the second (fixed powder) measurement, but no hysteresis was observed. The fact, that both magnetizations are almost equal in the highest field applied, may indicate an anisotropy field only slightly higher than 30 T, which is exceptionally low among U intermetallics.[7]

IV. NEUTRON-DIFFRACTION RESULTS

The bulk results above indicate two magnetic transitions in UCuSn at about 62 and 25 K. At low temperatures, the antiferromagnetic ground state was confirmed by the occurrence of additional purely magnetic reflections below 62 K in the neutron data taken at Los Alamos. However, magnetic intensities were found also on some nuclear reflections, and our results indicate that all magnetic contributions can be indexed in the same orthorhombic unit cell.

In order to clarify the (sometimes pronounced) anomalies in the bulk properties around 25 K, we performed additional neutron-diffraction experiments on the C2 powder diffractometer at Chalk River Laboratories. Data were collected at various temperatures, and the temperature dependences of the peak intensities of some "magnetic" peaks are shown in Fig. 4. In all cases, we observe a smooth temperature dependence with no evidence for a second magnetic phase transition around 25 K and no extra magnetic peaks were observed below this temperature.

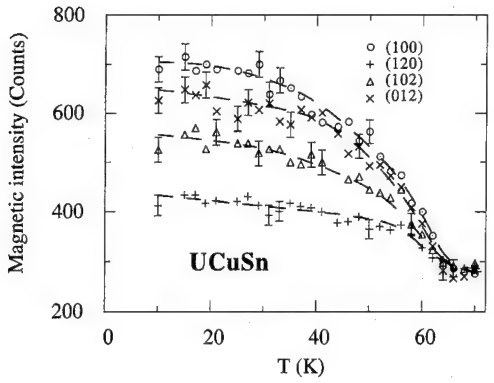

FIG. 4. Temperature dependence of the magnetic intensities of various Bragg reflections. In some cases, the intensities have been corrected for nuclear contributions. The lines are guides to the eye.

V. DISCUSSION

While the investigations of bulk properties seem to indicate a second magnetic transition around 25 K, any moment reorientation seems to be excluded by the neutron-diffraction results. Clearly, this confusing situation cannot be resolved on the basis of the present data, but we may speculate on scenarios which may account for all observations. A possible explanation may involve temperature-induced changes of the antiferromagnetic gap which ultimately could lead to significant changes in the Fermi surface and therefore strongly affects the bulk properties (without a magnetic phase transition). Such a picture has been suggested by Fujii *et al.*[4]

On the other hand, an alternative explanation arises from the comparison with UPdSn, which forms in an ordered version of the $CaIn_2$ structure. UPdSn exhibits two magnetic transitions which are due to ordering of the y and z components of the magnetic moment at the upper transition temperature, while the x component fluctuates until it also stabilizes at the lower transition temperature.[8] For this compound, single-crystal studies show clear anomalies in the temperature dependence of the intensity for most magnetic peaks, while this transition is "smeared out" in powder diffraction. As a consequence only a broad and featureless temperature dependence was found.[9] It may be that UCuSn behaves in a similar fashion, and one moment component stays fluctuating below T_N=62 K, but that its fluctuations gradually slow down until 25 K. In such picture, one may anticipate an enhancement in the resistivity due to fluctuations until they die out, with little or no change in the magnetic moment.

Further high-field magnetization studies at elevated temperature are envisaged to give more insight to the 25 K transition.

ACKNOWLEDGMENTS

H.N. and A.P. would like to thank the Chalk-River staff for the pleasant stay during the neutron experiments. This work was supported by the U.S.-Czechoslovak Science and Technology Joint Fund under project No. 93039. We report on the crystallographic and magnetic structures of the antiferromagnet $UCu_{1.5}Sn_2$, as determined by x-ray and neutron powder diffraction. It crystallizes in the tetragonal $CaBe_2Ge_2$ structure type, with space group P/4nmm, and we find no site disorder between two different Sn $2c$ sites, in contrast with a previous report. $UCu_{1.5}Sn_2$ orders antiferromagnetically with a Néel temperature of about 110 K. This is unusually high among uranium intermetallics. The uranium moments align along the c axis in a collinear arrangement but alternating along the c axis. The low-temperature uranium moment is $2.01\mu_B$. © *1996 American Institute of Physics.* [S0021-8979(96)26308-1]

I. INTRODUCTION

In the last decade many studies have been performed on the large family of tetragonal Ce- and U-based ternary intermetallic compounds with stoichiometry CeT_2X_2 or UT_2X_2 (T =transition metal, X=group IV element), with a view to understanding their magnetic and/or heavy-fermion properties.[1] Those compounds with X=Si or Ge have been studied most extensively, and they include the celebrated heavy-fermion superconductors $CeCu_2Si_2$ and URu_2Si_2. Most such compounds form in the body-centered tetragonal $ThCr_2Si_2$ structure (space group I4/mmm), though a significant minority form in the closely related primitive tetragonal $CaBe_2Ge_2$ structure (space group P4/nmm). In some cases, like UCo_2Ge_2, both forms can be produced depending on the heat treatment and stoichiometry of the sample.[2] The difference between the two structures is in the stacking sequence of the T and X layers between the layers of Ce or U atoms, as one progresses along the tetragonal axis.

We have recently started to work on UT_2Sn_2 compounds, and in this article we report on the crystallographic and magnetic properties of the antiferromagnet UCu_2Sn_2, as studied by x-ray and neutron diffraction. UCu_2Sn_2 is remarkable among uranium intermetallics for having a Néel temperature of 110 K,[3] while it is more typical for uranium compounds (without Co or Fe) to order magnetically at 50 K or below, if at all. UCu_2Sn_2 with a slight copper deficiency had previously been studied by means of x-ray diffraction by Pöttgen *et al.*,[4] and these authors found the $CaBe_2Ge_2$ structure type, but with two interesting features. First, in the stoichiometry $UCu_{1.3}Sn_2$, they found the copper deficiency to be entirely located on the $2c$-type sites, as shown in Fig. 1(a). Second, regarding the tin atoms on the $2c$-type sites in the other half of the unit cell, they found it necessary to use two such sites with significantly different z parameters. Again, this is shown schematically in Fig. 1(a). We have repeated their study on a sample with slightly less copper deficiency using both x-ray and neutron diffraction. While we find the same sort of copper deficiency on the copper $2c$ sites, we find no evidence for a bimodal distribution of Sn atoms over two different sites with different z parameters. In addition, we have used our neutron diffraction data to determine the magnetic structure, the magnitude of the uranium moment and to estimate the Néel temperature.

II. EXPERIMENTAL METHOD

The polycrystalline sample was prepared by arc-melting stoichiometric (1:2:2) amounts of the constituent elements of at least 99.99% purity. The phase purity was checked by powder x-ray diffraction using Cu $K\alpha$ radiation (λ=1.54 Å), and the x-ray data were analyzed using the Rietveld refinement program GSAS.[5] A very small amount of impurity scattering was observed. For the neutron experiment, the UCu_2Sn_2 powder was sealed in a vanadium tube under a helium atmosphere, and this was in turn mounted in a helium

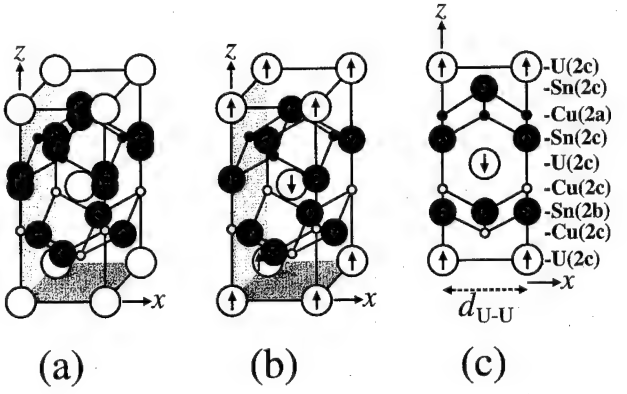

FIG. 1. Schematic diagrams of the structure of $UCu_{1.5}Sn_2$, as reported (a) by Pöttgen *et al.* (see Ref. 4), and (b), (c) in this work. In all cases the tetragonal c axis is shown as vertical. The atomic occupancies are shown in the projection onto the a-c plane in (c), with the partially filled Cu $2c$ sites shown by the open circles, while the fully occupied Cu $2a$ sites are represented by filled circles. The closest U-U distance $d_{U\text{-}U}$ is also shown in (c), while the collinear c-axis antiferromagnetic structure reported in the text is shown in both (b) and (c). The bimodal distribution of Sn atoms over two different z-parameter $2c$ sites reported by Pöttgen *et al.*, but not seen in our work, is shown by the dumbells in (a). The origin in this figure corresponds to (0.25,0.25,0.25) in the coordinates given in Table I.

cryostat. The cryostat was mounted on the C2 powder diffractometer, at the Chalk River Laboratory, in such a way that it could be rotated continuously to give a better powder average over the grains in the sample. A rotating collimator was also used, between sample and the large area detector, to eliminate background peaks from the cryostat tails. We used a Si(531) monochromator with a wavelength of 1.51 Å, and data were recorded between 5° and 85° (for the magnetic scattering) and between 41° and 121° (for the structural analysis). Data were taken at a variety of temperatures between 6 and 120 K, and they were analyzed both by Rietveld refinement using GSAS,[5] as well as by peak-by-peak extraction of integrated intensities for the magnetic structure.

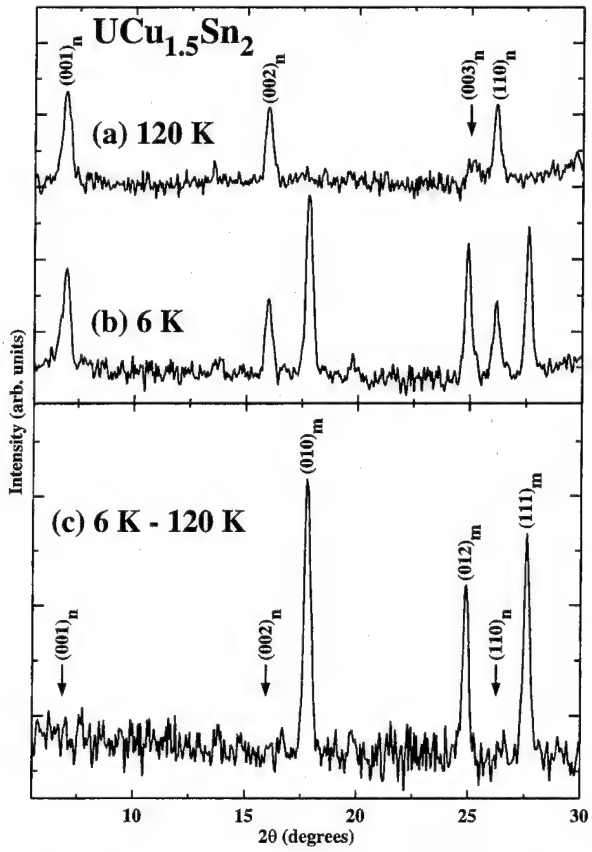

FIG. 2. Low-angle neutron diffraction patterns taken at (a) 120 K, (b) 6 K, and (c) the difference between 6 and 120 K. Note that three magnetic peaks (010), (012), and (111) are observed, but that there is no magnetic contribution to the (001), (002), or (110) nuclear reflections.

III. RESULTS

The results of the Rietveld refinements using our x-ray and neutron data are listed in Table I. We obtain a good refinement using the $CaBe_2Ge_2$ structure. Second, we find a copper deficiency on the Cu $2c$ site, as found before by Pöttgen *et al.*,[4] and we deduce a stoichiometry close to $UCu_{1.5}Sn_2$, i.e., slightly less copper deficient than Pöttgen's

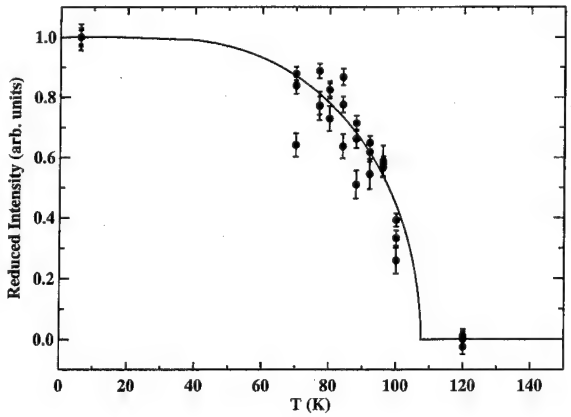

FIG. 3. Variation of the reduced intensity of the (010), (012), and (111) magnetic reflections. The solid line shows a fitted Brillouin function, with $T_N=107$ K.

TABLE II. Observed and calculated intensities for magnetic reflections in $UCu_{1.5}Sn_2$.

Reflection	Observed intensity at 6 K[a]	Calculated intensity
010	10.87±0.26	10.94
012	10.51±0.58	10.55
111	16.96±0.56	16.69
Reduced χ^2=0.4		

[a]$I_{hkl} \sin \theta_{hkl} \sin(2\theta_{hkl})$.

sample. However, in contrast with their results, we find no need to invoke two different Sn $2c$ sites. Not only does Pöttgen's model give a worse χ^2 than the model with a single z value for the Sn $2c$ site, but if the occupancies on the two sites are allowed to vary in the refinement, it converges to 100% on the one site and 0% on the other. We therefore believe that our sample has the structure listed in Table I and shown in Fig. 1(b).

Regarding the magnetic structure, some of our low-angle neutron diffraction data are shown in Fig. 2. Three extra peaks, indexed as (010), (012), and (111), are seen at low temperature. We presume that these are magnetic and also note that no extra intensity is seen at the (001), (002), or (110) positions, which would also fall in this angular range. The fact that the observed reflections have no fractional indices implies that the magnetic cell is probably the same as the crystallographic cell, and that there are only two uranium atoms per magnetic cell. If we ignore the Cu and Sn ions, the two uranium atoms lie on a body-centered tetragonal lattice, and the fact that the magnetic reflections obey the $h+k+l=2n+1$ selection rule implies that the two uranium moments are antiparallel to each other. In addition, the fact that no (001) reflection is seen implies that the moments must be parallel to the c axis, giving the simple collinear antiferromagnetic structure shown in Fig. 1(b) and (c). As it happens, a Shubnikov-group analysis of the $2c$ sites (point group 4 mm) shows that this is one of two allowed magnetic extensions to P4/nmm: the other would be a simple c-axis ferromagnet, which would only contribute extra magnetic intensity to the existing nuclear reflections. Fitting this model to our data yields a low-temperature uranium moment of $2.01\pm0.05\mu_B$. A comparison of the observed and calculated magnetic intensities is given in Table II.

Finally, the intensities of all three magnetic reflections are shown in reduced units, as a function of temperature, in Fig. 3 along with a fitted Brillouin function. This yields a transition temperature of T_N=107 K, which is in good agreement with the value of 110 K extracted from susceptibility data.[3]

IV. DISCUSSION

A large number of uranium-based intermetallic antiferromagnets have now been studied in a variety of cubic, hexagonal, and orthorhombic structures.[6] Almost invariably, these materials show strong magnetic anisotropies, with the moments aligned perpendicular to planes or chains defined by nearest-neighbor uranium–uranium links. The physical rationale for this is that the f electrons are hybridized more strongly, with ligand p and d electrons, in these directions or planes. They can better support "localized" moments in the directions of weaker hybridization, which are necessarily perpendicular. A second observation is that the coupling within the strongly hybridized planes or chains is usually ferromagnetic. This picture has also recently been shown to apply in several tetragonal U_2T_2X (X=In, Sn) compounds.[7] It is instructive to apply this idea in the present case: in $UCu_{1.5}Sn_2$, the nearest-neighbor U–U distance, d_{U-U} in Fig. 1(c), lies in the tetragonal basal plane along the **a** and **b** directions, with a length a=4.39 Å. This is significantly greater than the Hill limit of 3.5 Å, beyond which localized uranium moments might be expected. It also implies that these ordered moments should align perpendicular to the tetragonal basal plane, i.e., along the c axis. This is exactly what we observe. In addition, the moments are also ferromagnetically coupled within the tetragonal sheets, in agreement with the phenomenology in other uranium intermetallics.

In summary, we have shown definitively that $UCu_{1.5}Sn_2$ orders into a simple collinear c-axis antiferromagnetic structure below 110 K, with a low-temperature uranium moment of $2.01\mu_B$. This is quite large, indicating fairly localized moments, though still well short of the full Hund's rule moment which would be in excess of $3\mu_B$. We also find the copper deficiency on the $2c$-type sites in agreement with Pöttgen *et al.*, but find no evidence for a bimodal distribution of Sn atoms on different $2c$-type sites with different z parameters.

ACKNOWLEDGMENTS

Metal-insulator transition in dirty Kondo insulators

P. Schlottmann and C. S. Hellberg
Department of Physics, Florida State University, Tallahassee, Florida 32306

We consider arbitrary clusters of Kondo holes in a Kondo insulator described by the nondegenerate symmetric Anderson lattice with a nearest-neighbor tight-binding conduction band on a simple cubic lattice. The f-electron self energy is considered within the local approximation. Each Kondo hole introduces a boundstate in the gap. The quantum interference in the scattering off the impurities gives rise to interactions among the Kondo holes. The spectral weight of the bound states is predominantly localized on the sites neighboring the Kondo holes. Clusters of impurities separated by more than one lattice site are disconnected for boundstates at the Fermi level. On a simple cubic lattice the metal-insulator transition in the impurity band then reduces to the site percolation of Kondo holes with first, second and fourth nearest neighbors. We use the low density mean cluster size expansion and a small cell renormalization to estimate the critical concentration. Hopping in the conduction band beyond nearest neighbors reduces the percolation threshold. Hence, 9.9% of Kondo holes is an upper bound for the insulator to become a metal. © *1996 American Institute of Physics.* [S0021-8979(96)26408-8]

Kondo insulators like $Ce_3Bi_4Pt_3$, CeNiSn, SmS, SmB_6, TmSe, YbB_{12}, and UNiSn are small-gap semiconductors with properties that strongly depend on strains in the crystal and impurities. The addition of small amounts of impurities gradually destroys the coherence of the ground state of the Kondo insulator. A Kondo hole is the charge neutral substitution of a rare-earth (actinide) ion by a nonmagnetic analog, e.g., La replacing Ce or Th substituting U. Each Kondo hole introduces a δ-function-like bound state in the hybridization gap. The energies of the poles and their spectral weight determine the low-temperature thermodynamic and transport properties of the impure insulator.

We previously reported on the local density of f-states (f-DOS) in the vicinity of an isolated Kondo hole,[1,2] the formation of impurity bands for a finite concentration of Kondo holes,[3,4] the effects of doping and ligand defects,[5] interaction effects between two Kondo holes,[6] and recently we extended our microscopic theory to study interference effects in arbitrary clusters of impurities.[7] Here, we limit ourselves to the symmetric nondegenerate Anderson lattice with nearest-neighbor (n.n.) tight-binding dispersion for the conduction band on a simple cubic (sc) lattice. The bound state for an isolated impurity pins the Fermi level, and its spectral weight is all located on the n.n. sites to the Kondo hole.[1] This is also the case for a pair of Kondo holes separated by more than one lattice spacing.[6] For two Kondo holes on n.n. sites the spectral weight decreases rapidly with increasing distance from the impurities, the main spectral weight still being located on the n.n. sites to the holes. These results remain valid for an arbitrary cluster,[7] in particular, bound states with Fermi energy have only spectral weight on n.n. sites to a Kondo hole. Hence, the bound states of Kondo holes separated by more than one lattice site are disconnected. Since states at the Fermi level are responsible for the electric transport, the insulator-metal transition is reduced to the site percolation of Kondo holes with first, second, and fourth neighbor bonds.

In this paper, we briefly summarize the properties of the Kondo hole bound states at the Fermi level. Then we estimate the concentration of Kondo holes necessary for the percolation using two methods, the low density mean cluster size expansion and a small cell renormalization. Finally, we argue that hopping in the conduction band beyond n.n. reduces the percolation threshold and briefly address the effects of electron-hole asymmetry, finite temperatures and external frequencies (ac conductivities).

We consider the Anderson lattice H_0, and the scattering potential H_i, due to the nonmagnetic impurities at sites $\mathbf{R}_j$, $j=1,\ldots,N_i$,

$$H_0=\sum_{\mathbf{k}\sigma}\epsilon_{\mathbf{k}}c^{\dagger}_{\mathbf{k}\sigma}c_{\mathbf{k}\sigma}+\epsilon_f\sum_{i\sigma}f^{\dagger}_{i\sigma}f_{i\sigma}+U\sum_i n_{i\uparrow}n_{i\downarrow}$$
$$+V\sum_{\mathbf{k}\sigma}(c^{\dagger}_{\mathbf{k}\sigma}f_{\mathbf{k}\sigma}+f^{\dagger}_{\mathbf{k}\sigma}c_{\mathbf{k}\sigma}),$$
$$H_i=(\Delta\epsilon_f/N)\sum_{j\mathbf{k}\mathbf{k}'\sigma}e^{i(\mathbf{k}'-\mathbf{k})\mathbf{R}_j}f^{\dagger}_{\mathbf{k}\sigma}f_{\mathbf{k}'\sigma}. \tag{1}$$

Here, $\Delta\epsilon_f$ is large and positive for the impurity to be nonmagnetic,[1–3,6] N is the number of sites and $\epsilon_{\mathbf{k}}=-2t\cos(k_x)-2t\cos(k_y)-2t\cos(k_z)$ with $|k_i|\leq\pi$ is the n.n. tight-binding dispersion on a sc lattice.

Since the impurity potential is a sum of factorizable potentials, the $U=0$ scattering problem can be solved exactly following similar steps as in Refs. 1, 2, and 6. The one-particle Green's function explicitly depends on the space configuration of the Kondo holes. The interaction between Kondo holes arises from the interference in the scattering off the impurities. We introduce a transform of the f-electron Green's function of the pure insulator

$$\mathcal{G}^0_\sigma(z,\mathbf{R})=\delta_{\mathbf{R},\mathbf{0}}(z-\epsilon_f)^{-1}+[V/(z-\epsilon_f)]^2$$
$$\times F[z-V^2/(z-\epsilon_f),\mathbf{R}], \tag{2}$$

where $\mathbf{R}=\mathbf{0}$ is the zero vector and $F[z',\mathbf{R}]=(1/N)\Sigma_{\mathbf{k}}e^{i\mathbf{k}\cdot\mathbf{R}}/(z'-\epsilon_{\mathbf{k}})$ is the transform of the spectral function of the conduction band. Denoting $\mathbf{R}_{lj}=\mathbf{R}_l-\mathbf{R}_j$ we define the $N_i\times N_i$ matrix $\tilde{\mathcal{G}}^0_\sigma(z,\mathbf{R}_{jl})$ with entries l and j that correlates the impurity sites. In the limit $\Delta\epsilon_f\to\infty$, the local f-DOS at a site $\mathbf{R}_0$ is

 0021-8979/96/79(8)/6414/3/$10.00

$$\rho_{f\sigma}(\omega,\mathbf{R}_0) = -(1/\pi)\mathrm{Im}\ \mathcal{G}^0_\sigma(z,\mathbf{0}) + (1/\pi)\sum_{jl}\ \mathrm{Im}\{\mathcal{G}^0_\sigma(z,\mathbf{R}_{0j}) \times[\tilde{\mathcal{G}}^0_\sigma(z,\mathbf{R}_{jl})]^{-1}\mathcal{G}^0_\sigma(z,\mathbf{R}_{l0})\}, \quad (3)$$

where $z=\omega+i0$ and Im denotes *imaginary part*. The situations of an isolated[1,2] and of a pair of Kondo holes[6] are contained as special limits.

In the absence of impurities the edges of the hybridization gap are approximately at $\epsilon_f \pm V^2/6t$, and the chemical potential μ lies within the gap. Correlations within the f band are introduced via the f self-energy $\Sigma_U(z)$ within the local approximation,[8] which neglects the $\mathbf{k}$ dependence. The $\mathbf{k}$ dependence of $\Sigma_U(z)$ is believed to be less relevant in heavy-fermion systems than the energy dependence. The imaginary parts of $\mathcal{G}^0_\sigma(\omega+i0,\mathbf{R})$ and $\Sigma_U(z)$ vanish inside the gap, so the quantities are real.[1,2,6,8] Within the range of interest, $\Sigma_U(z)$ is approximately given by $\Sigma_U(\omega) = Un_f/2-(\gamma-1)(\omega-\mu)$ and just enters the Green's function as a renormalization of ϵ_f. We incorporate the Hartree–Fock shift $Un_f/2$ into ϵ_f. Electron-hole symmetry then requires $\epsilon_f=0$. The Kondo effect is contained in the parameter γ, which reduces the hybridization gap to $2V^2/\gamma 6t$, i.e., to the size of T_K. Within the local approximation Σ_U is not calculated selfconsistently, so that the $\mathbf{k}$ dependence induced into $\Sigma_U(\omega)$ via the impurities is neglected.

The local f DOS vanishes identically at any Kondo hole site, since the limit $\Delta\epsilon_f\to\infty$ prevents the occupation of the site by an f-electron. With N_i Kondo holes there are N_i boundstates in the gap with energies given by $\det[\tilde{\mathcal{G}}^0_\sigma(\omega+i0,\mathbf{R}_{jl})]=0$, i.e., the poles in Eq. (3). Due to the electron-hole symmetry the bound state energies are symmetrically distributed with respect to the Fermi level at $\mu=0$. Hence, if N_i is odd there is always a bound state at the Fermi level. In general, if N_i is large we expect an accumulation of bound states with energy close to zero, eventually giving rise to the impurity band. These low-energy bound states are the relevant ones for the low-T thermodynamics[3,4] and their mobility (connectivity) determines whether the impure Kondo insulator is a metal or an insulator.

The spectral weights of the bound states follow from the properties of $\mathcal{G}^0_\sigma(z,\mathbf{R})$. For $\mathbf{R}_1$ and $\mathbf{R}_2$ differing by a primitive basis vector of the lattice with $|\mathbf{R}_1|>|\mathbf{R}_2|$, we have that $\mathcal{G}^0_\sigma(z,\mathbf{R}_1)/\mathcal{G}^0_\sigma(z,\mathbf{R}_2)\approx -tz\gamma/V^2$.[7] From Eq. (3) it follows that for low-energy bound states ($|z|$ is small for states close to the Fermi level), the spectral weight at a site dramatically decreases with the distance to the closest Kondo hole. In particular, for states at the Fermi level all the spectral weight is located on n.n. sites to Kondo holes. For $z=0$ all other sites have zero spectral weight. Hence, for clusters separated by more than one lattice site the bound states at the Fermi level are disconnected. A percolating cluster necessarily has a bound state arbitrarily close or at the Fermi level. Hence, the metal-insulator transition on a sc lattice is reduced to the site percolation of Kondo holes with first, second and fourth neighbor bonds.

The critical concentration for the metal-insulator transition is straightforwardly calculated for a Bethe lattice of coordination $\mathcal{Z}$, $c_{\mathrm{cr}}=[\mathcal{Z}(\mathcal{Z}-1)]^{-1}$. For $\mathcal{Z}=6$ this yields $c_{\mathrm{cr}}=0.0333$, which is an underestimate since the lattice connectivity is neglected. For the sc lattice this task is considerably more complicated. We use the low density mean cluster size expansion and a small cell renormalization to estimate the percolation probability.

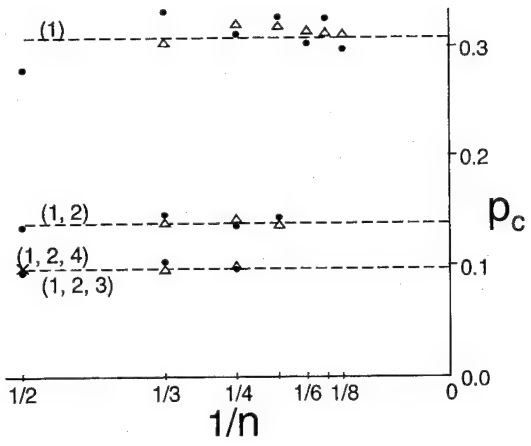

FIG. 1. Estimates of p_c for the low density mean cluster size expansion for the site percolation of (1) first neighbor bonds, (1,2) first and second neighbor bonds, and (1,2,3) first, second, and third neighbor bonds on a sc lattice. The dashed lines are the extrapolated critical concentrations (see Ref. 9). The dots represent estimates using consecutive coefficients a_n and the triangles estimates using a_{n-2}/a_n. The cross is the estimate from a_1/a_2 for the (1,2,4) problem involving first, second, and fourth neighbor bonds.

The mean size of finite clusters $S(p)$, where p is the probability that a site is occupied, can be expanded in a power series in p, $S(p)=1+\Sigma_{n=1}^{\infty}a_n p^n$, by summing over the probabilities of occurrence of all possible clusters up to a desired order. The probability for a class j of clusters of order s is of the form $sb(s,j)p^s(1-p)^r$, where $b(s,j)$ is the number of possible configurations and r is the "perimeter," i.e., the number of unoccupied neighboring sites required for the cluster to be isolated (disconnected from other clusters). The convergence of the series expansion in p is then analyzed with Padé approximants or with the ratio method. In two dimensions the metal-insulator transition corresponds to the site percolation of Kondo holes on a square lattice with first, second, and third neighbor bonds. For this problem all clusters of up to five occupied sites have been computed.[9] Using the ratio method the extrapolated critical percolation probability is $p_c=0.292$.[9]

For the sc lattice the site problem with first neighbor bonds (1) (clusters up to nine occupied sites), first and second neighbor bonds (1,2) (up to six occupied sites), and first, second, and third neighbor bonds (1,2,3) (clusters of fifth order)[9] have been analyzed using the ratio method. The assumption that $S(p)$ diverges as $A(1-p/p_c)^{-(1+g)}$ when $p\to p_c^-$, leads to the large n asymptotic form $a_n\approx An^g/\Gamma(1+g)p_c^n$.[10] We can then determine p_c from the ratio of consecutive coefficients, $p_c=(1+g/n)(a_{n-1}/a_n)$. Critical properties do not depend on the range of the bonds (as long as they are short ranged), so we may use $g=\gamma-1$ ≈ 0.8 (Ref. 11) for all cases. The dots in Fig. 1 are the

estimates from consecutive coefficients a_n. The oscillations present in the estimates for n.n. bonds are suppressed for (1,2) and (1,2,3) due to the higher connectivity of the lattice. The triangles correspond to estimates using $p_c=[(1+g/n)(1+g/(n-1))(a_{n-2}/a_n)]^{1/2}$. This suppresses the oscillations and leads to a monotonic convergence to the extrapolated critical concentrations (dashed lines).

For first, second, and fourth neighbor bonds (1,2,4) we limited ourselves to calculate the first two coefficients of the series are $a_1=24$ and $a_2=342$. This leads to an estimate for p_c of 0.0982 (cross in Fig. 1), a value that is slightly above the corresponding (1,2,3) estimate. Since the estimates for problems with high connectivity do not appear to vary substantially with n, we may use this value as an indication that $p_c\approx 0.10$.

Another method to obtain the percolation threshold is the small cell renormalization which, like the block spin renormalization frequently used for thermal critical phenomena, is based on self-similarity under scaling. Scaling assumes that the linear dimension b of the cell is much smaller than the correlation length ξ. The $M=b^3$ sites of the cell are replaced by a single supersite. The criterium for such replacement in thermal critical phenomena is the majority rule. For a percolation problem the connectivity is the essential ingredient.[12] We consider a supersite occupied if the bottom and top faces of the cell are connected, and empty otherwise. The renormalization transform yielding the probability of occupation of the supersite p' is then

$$p'=\sum_{r=0}^{M} f_r^M \binom{M}{r} p^r(1-p)^{M-r}, \tag{4}$$

where f_r^M is the fraction of clusters of r sites that are connected from top to bottom. The f_r^M are obtained numerically by considering a representative set of clusters. At the percolation point, $p'=p=p_c$ gives a self-consistent equation with three fixed points, the two stable ones $p=0$ and $p=1$ of attraction basins separated by the desired p_c. Figure 2 shows the $p_c(b)$ obtained for the site percolation in the (1,2,4) problem plotted as a function of $b^{-1/\nu}$, where $\nu=0.9$ is the critical exponent of the correlation length. The straight line in Fig. 2 shows the scaling of the data for $b\geq 18$ and extrapolates to $p_c=0.099$ for the infinite system. This value is consistent with the estimate from small cluster expansions.

In summary, the insulator-metal transition for the nondegenerate symmetric Anderson lattice with n.n. hopping for the conduction band on a sc lattice can be reduced to the site percolation of Kondo holes with first, second, and fourth neighbor bonds. We estimated the critical concentration of Kondo holes at about 9.9%. Assuming a constant mean-free path in the vicinity of p_c, the electrical conductivity tends to zero proportionally to $(p-p_c)^2$ as $p\to p_c^+$.[11] In the critical region the correlation length diverges as $\xi\propto(p-p_c)^{-\nu}$ with $\nu\approx 0.9$ and the mean size of finite clusters as $S\propto(p-p_c)^{-\gamma}$ with $\gamma\approx 1.8$, while the strength of the infinite network (for $p>p_c$) increases as $P\propto(p-p_c)^{\beta}$ with $\beta\approx 0.4$.[11]

If the tight-binding dispersion extends beyond n.n., also the physical extension of the bound states increases accordingly, e.g., for states at the Fermi level the spectral weight is nonzero on all sites that can be reached by simple hopping from a Kondo hole.

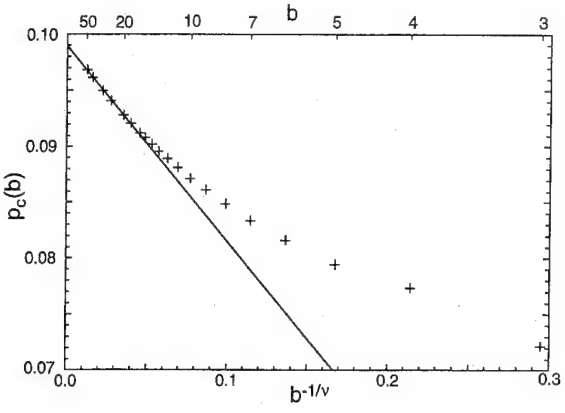

FIG. 2. Small cell renormalization for the (1,2,4) site problem for several cell sizes from $b=3$ up to $b=50$. $p_c(b)$ is obtained as the nontrivial fixed point of the renormalization transformation (4). The extrapolated critical concentration is 0.099. The straight line shows the scaling of the data for $18\leq b\leq 50$ with $b^{-1/\nu}$, where $\nu=0.9$ is the exponent of the correlation length.

For states that are close to the Fermi level or for a small electron-hole asymmetry, also sites beyond n.n. to a Kondo hole have a small spectral weight. The spectral weight decreases very fast with the distance. Hence, electron-hole asymmetry, an ac electric field, a constant magnetic field or a finite temperature increase the connectivity. Two types of connections have to be distinguished: the strong ones we considered in this paper and weak ones induced by the above parameters. Below, the p_c for the strong connections the impure Kondo lattice is expected to behave like a very poor metal or a dirty semiconductor. Although there may be a percolating cluster, the tunneling probability will be very small.

Tb impurities in Th: A Kondo system with undercompensated magnetic moment?

J. G. Sereni
Centro Atómico Bariloche, 8400 Bariloche, Argentina

P. Schlottmann
Department of Physics, Florida State University, Tallahassee, Florida 32306

Dilute Tb_xTh_{1-x} alloys have been thoroughly studied in the light of a possible valence instability and Kondo effect in Tb^{3+} and Tb^{4+} ions. We review the experimental data for the specific heat, magnetic susceptibility, magnetization, magnetoresistivity, and the change of the superconducting properties of Th. In analogy to Tm (Tm^{2+} and Tm^{3+}) and Pr (Pr^{3+} and Pr^{4+}) impurities in metals, Tb involves two electronic configurations each with a magnetic Hund's rule ground multiplet. Two classes of models for valence admixtures of two magnetic configurations have been investigated in the past. Depending on the form of the hybridization and the jj coupling within the $4f$ shell, the models either have a singlet or a magnetic ground state. As for Tm impurities the latter class of models, related to the undercompensated Kondo effect, appears to describe the system Tb*Th* more appropriately. A qualitative explanation of the data is attempted within a scheme that combines Kondo screening with crystalline field splitting. © *1996 American Institute of Physics.* [S0021-8979(96)26508-4]

The exact solution of the Coqblin–Schrieffer and the degenerate $U\to\infty$ Anderson models in terms of Bethe's ansatz opened the possibility of quantitative comparisons with experimental data for dilute Ce and Yb alloys,[1] i.e., systems with *one* localized electron or hole in the f shell. A remarkably good agreement was obtained for the temperature and magnetic field dependence of the susceptibility, the specific heat, the magnetization, and the valence for impurity systems (see Ref. 1 for a review), alloys[1] and compounds.[1–3]

This analysis has been extended to the transition-metal impurities Fe and Cr in simple metals like Cu and Ag.[4] Realistic models for these impurities, as well as for Mn^{2+} and Eu^{2+} impurities, involve more than one localized electron (hole) and are necessarily more complex. The n-channel Kondo model[5] provides a suitable description if one assumes that the orbital degrees of freedom are quenched to an orbital singlet by one or more mechanisms. The low-T properties of such impurity systems are those of a totally compensated impurity spin (spin-singlet ground state), which is realized within the n-channel Kondo model if the number of channels n is equal to $2S$.[6]

Two further qualitatively different situations may occur: (a) If $n<2S$, the impurity spin is *undercompensated*, since there are not enough conduction electron channels to yield a singlet ground state, leaving an effective spin degeneracy of $(2S+1-n)$. (b) If $n>2S$, the number of channels is larger than required to compensate the impurity spin. The impurity is said to be *overcompensated* and critical behavior is obtained as both the temperature and the field tend to zero. The overcompensated case for $S=1/2$ and $n=2$ represents the physical situations of the quadrupolar Kondo effect[7] and electron-assisted tunneling of an atom in a double-well potential.[8] An alloy possibly displaying the quadrupolar Kondo effect is $U_xY_{1-x}Pd_3$ (Ref. 9) and an experimental realization for tunneling with multichannel characteristics is the differential resistance of metal point contacts containing structural disorder.[10]

A possible application of the *undercompensated Kondo effect* are dilute alloys of impurities with two magnetic configurations in simple metals. The experimentally most studied case is Tm as dilute impurities,[11] and TmSe and its alloys.[12] For mixed-valent Tm ions the Hund's rule ground multiplets of the two configurations $4f^{12}$ and $4f^{13}$ are $J=6$ and $J=7/2$, i.e., both are magnetic. The experiments seem to point towards a magnetic ground state. Other candidates are Pr ions and Tb impurities. In this paper we explore the possibility of interpreting experiments on dilute TbTh alloys as undercompensated Kondo impurities.

The main experimental results for dilute Tb_xTh_{1-x} alloys can be summarized as follows. (i) The high-T susceptibility for $T>100$ K essentially has the full magnetic moment of Tb^{3+}.[13] The magnetic moment is considerably reduced at intermediate T,[14] probably as a consequence of Kondo screening and/or crystalline fields. (ii) At low T the susceptibility χ has a spin-glass-like peak at a T_{max} that monotonically increases with the Tb concentration, x.[14] The value of χ at T_{max} decreases with x. (iii) The specific heat in zero field is proportional to T at low T with a γ coefficient of about 450 mJ/(K^2 mol Tb).[13] As a function of T the electronic specific heat shows a maximum at about 4 K. At higher T the specific heat of Tb impurities follows a $(\gamma T+\beta T^3)$ law with positive β (after subtracting the electron and phonon contributions of the host). The sign of β is then opposite to that of spin-1/2 Kondo impurities. (iv) The increase of entropy from very low T to about 6 K is approximately R ln(2) but still showing clear tendency to grow.[13] (v) A relatively large magnetic field enhances the specific heat of the alloy at higher T, reduces it at intermediate T and an interesting up-turn is observed in-field at low temperatures. This remarkable behavior is displayed in Fig. 1. (vi) The resistivity due to the Tb impurities is only weakly T dependent (if not constant) and independent of the magnetic field (no magnetoresistance). (vii) The magnetization as a function of field has the characteristics of a free spin or Kondoesque impurity.

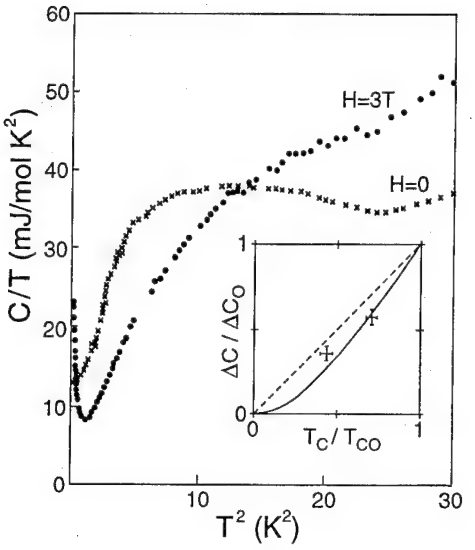

FIG. 1. Specific heat over T as a function of T^2 for the alloy Tb_xTh_{1-x} with $x=0.015$ in zero field and a magnetic field of 3 T. For $H=0$ a Schottky-like structure arising from the impurities is seen, which is quenched by the moderate field of 3 T. At low T an up-turn of C/T develops in magnetic field as a consequence of the Tb ions. The inset shows the discontinuity of the specific heat at T_c normalized to the value for the pure superconductor as a function of T_c/T_{c0}. The two samples correspond to $x=0.0045$ and 0.0084. The solid curve refers to pure pair breaking (Abrikosov–Gor'kov) and the dashed line to pair weakening (BCS law of corresponding states).

(viii) The Th matrix is a superconductor with $T_{c0}=1.36$ K. Tb impurities reduce T_c approximately linearly with the concentration.[15] The extrapolated critical concentration is roughly 1.5 at. %. The pressure dependence of T_c apparently scales that of the host. The suppression of superconductivity is neither pure pair breaking (Abrikosov–Gor'kov) nor pure pair weakening, but consistent with a Kondoesque mechanism with $T_K \approx 3T_{c0}$.[16] (ix) The discontinuity of the specific heat for the alloy normalized to the value of the pure superconductor is shown in the inset of Fig. 1 for two samples. On one hand, the data lies below the BCS law of corresponding states (pair weakening), but on the other hand, the sample of larger concentration of impurities lies above the Abrikosov–Gor'kov curve (pair breaking). These results could be consistent with a Kondoesque mechanism not displaying reentrance ($T_K > T_{c0}$).[16]

Many of the above properties are not consistent with a singlet ground state for the Tb impurities. Tb ions in a metallic environment are close to a valence instability so that two electronic configurations, namely, Tb^{3+} ($4f^8$) with a Hund's rule ground multiplet of $J=6$ and Tb^{4+} ($4f^7$) (S-state isoelectronic to Gd^{3+}) with $J=7/2$ are expected to coexist via valence admixture through conduction electrons. The high-T magnetic moment of the susceptibility[13] indicates that the energetically favorable and dominating configuration is $4f^8$. The Hund's rule groundstate for both configurations is magnetic. Two classes of models for valence admixtures of two magnetic configurations were extensively investigated in the past. One class of models involves the hybridization with two (or more) conduction electrons, while the other class only considers the jj coupling with one band state. Neither class decomposes the f-shell states using fractional parentage coefficients. We briefly review the main results below.

A representative Hamiltonian of the first class of models (several related variants have been studied) is the following generalization of the Anderson model[17,18]

$$H=\sum_{km}\epsilon_k c^\dagger_{km}c_{km} + E_1\sum_m |1m\rangle\langle 1m| + E_2\sum_{mm'}|2mm'\rangle\langle 2mm'| + V\sum_{kmm'}(|2mm'\rangle\langle 1m|c_{km'}+c^\dagger_{km'}|1m\rangle\langle 2mm'|), \tag{1}$$

where ϵ_k is the dispersion of the conduction states, m labels the z component of $j(|m|\leq j)$, and $|1m\rangle$ and $|2mm'\rangle$ denote f states with *one* and *two* localized electrons (of z components m and m'), respectively. Model (1) is formulated for Pr ions ($j=5/2$) or Tm impurities (holes with $j=7/2$ instead of electrons). The reported calculations of the ground state are perturbative in V, variational ansatze and selfconsistent diagram summations in the spirit of the $1/N$ expansion,[17–22] and consistently yield a singlet as the state of lowest energy, even if Eq. (1) is modified to include Clebsch–Gordan coefficients to provide a more realistic coupling.

Representative for the second class of models is[23,24]

$$H=\sum_{km}\epsilon_k c^\dagger_{km}c_{km}+\sum_{M_1}E_{J_1M_1}|J_1M_1\rangle\langle J_1M_1| + \sum_{M_2}E_{J_2M_2}|J_2M_2\rangle\langle J_2M_2| + V(2J_2+1)^{1/2}\sum_{kmM_1M_2}(J_2M_{2j}m|J_{2j}J_1M_1) \times[|J_1M_1\rangle\langle J_2M_2|c_{km}+c^\dagger_{km}|J_2M_2\rangle\langle J_1M_1|], \tag{2}$$

where $|J_1M_1\rangle$ and $|J_2M_2\rangle$ denote the states of the Hund's rule ground multiplets of the $4f^{n+1}$ and $4f^n$ configurations, respectively. The relevant conduction states have total angular momentum j and z component m. The model corresponds to the $U\to\infty$ limit of an Anderson impurity excluding states other than the J_1 and J_2 manifolds and a hybridization within a simplified jj scheme. The Clebsch–Gordan coefficient selects $m=M_1-M_2$. This model contains all the relevant mixed valent situations as limiting cases: (1) For $J_2=0$ and $j=J_1=5/2$ it reduces to the Anderson model for Ce. (ii) For $j=J_2=7/2$ and $J_1=0$ we recover the standard picture for Yb. (iii) The case of Pr is obtained for $J_2=j=5/2$ and $J_1=4$, while (iv) Tm ions are parametrized by $J_2=6$ and $J_1=j=7/2$. (v) Mixed-valent Sm impurities are described by $J_2=0$ and $J_1=j=5/2$. (vi) Finally, Eu corresponds to $J_2=0$ and $j=J_1=7/2$.

Several treatments of model (2) (and its generalization to a lattice) have been reported for the situation of two degenerate ground multiplets (i.e., $J_1\neq 0$ and $J_2\neq 0$), e.g., mean-field approaches,[23,25] perturbative summations using Mori's projector formalism,[24,26] the coherent potential

approximation,[27] Wilson's numerical renormalization group,[28] exact solutions via Bethe's ansatz (only $J_2=j=1/2$ and $J_1=1$ is integrable)[29,30] and numerical diagonalizations using Lanczos method.[31] The main result common to all these approaches is a magnetic groundstate.

The magnetic groundstate can be made plausible with the following *Gedanken experiment* based on the fact that an impurity does not undergo a phase transition. Consider model (2) as a function of $\Delta = E_{J_1} - E_{J_2} - \mu$, where μ is the chemical potential. If Δ is very large (either positive or negative) compared to V, one of the configurations can be projected out by means of a Schrieffer–Wolff transformation. Assume $J_2+j \geqslant J_1$ and $J_1>J_2$ (otherwise interchange electrons with holes). As an example consider first the well-known case of a Ce impurity: If $\Delta \gg 0$ the ground state is the $4f^0$ singlet, while for $\Delta \ll 0$ the impurity spin J_1 is Kondo compensated into a singlet via the Coqblin–Schrieffer mechanism. The ground state is a singlet for all values of Δ and character of the ground-state wave function gradually interpolates between these two limits. The general case can be understood in a similar way. If $\Delta \gg 0$ the ground multiplet is J_2, which is coupled to the conduction electrons via a ferromagnetic spin exchange (which includes Clebsch–Gordan coefficients). Under renormalization the model then evolves into a weak coupling fixed point, i.e., asymptotically the impurity is free and decoupled from the host. The impurity has a J_2 ground multiplet. Δ is now continuously decreased from $\Delta \gg 0$ to $\Delta \ll 0$; although the character of the ground state of the impurity changes as a function Δ, it will remain a multiplet of total angular momentum J_2. In the limit $\Delta \ll 0$ the exchange coupling of the J_1 multiplet with the conduction electrons is antiferromagnetic leading to a strong coupling fixed point under renormalization. Here the conduction electrons of total angular momentum j compensate the J_1 multiplet via the Kondo effect into a J_2 multiplet. This *undercompensated* Kondo effect picture emerges from all approaches[23–31] for model (2).

We now explore the possibility to qualitatively explain the experimental facts for Tb*Th* with model (2). Via the Kondo effect the $J_1=6$ multiplet of Tb^{3+} is screened to a $J_2=7/2$ multiplet by conduction electrons in the channel $j=7/2$. Assuming that T_K for this undercompensated Kondo effect is large (e.g., about 50 K which is consistent with the drop of the magnetic moment as a function of T) compared to the cubic crystalline field, the octet is split into two doublets, Γ_6 and Γ_7, and a Γ_8 quartet. The peak in the specific heat at about 4 K is the Schottky anomaly for the crystalline field splitting between the two lowest levels. The low-T entropy excludes the Γ_8 from being the ground multiplet; the most likely scenario is that the two lowest levels are the doublets [$\Delta S=R \ln(2)$], but the quartet as the first excited level cannot be excluded [$\Delta S=R \ln(3)$]. The ground doublet opens the possibility of magnetic "order" of the spin-glass type. The specific heat is a superposition (and possible interference of) crystalline field Schottky anomalies and the Kondo effect. The Kondo effect gives rise to the $\gamma T+\beta T^3$ contribution. The numerical value of γ associated with $T_K=50$ K is about a factor of two smaller than the experimental one, while the β arising from the impurities (phonons have been subtracted) has the correct (positive) sign. The sign of β would be the same as for the $J=7/2$ Anderson model in the $U\rightarrow\infty$ limit.[1] The magnetic ground doublet is also consistent with the depression of the superconducting T_c and $\Delta C/\Delta C_0$ deviating from the BCS law of corresponding states. A strong magnetic field would lift the degeneracy of the ground doublet and induce another Schottky anomaly at very low T. This Schottky anomaly could be the origin of the up-turn in the specific heat shown in Fig. 1.

In summary, the above speculations are consistent with most of the properties of Tb*Th*. We would like to point out that the above scheme cannot be reconciled with the absence of magnetoresistivity.

There is a great change in the nature of the magnetic ordering on going from $CeIn_3$, a local moment antiferromagnetic system, to $CePb_3$, a heavy fermion itinerant antiferromagnetic system, both of which have Cu_3Au crystal structure. We have applied *ab initio* electronic structure calculations, based on the linear-muffin-tin-orbital method, and a phenomenological theory of orbitally driven magnetic ordering, to study the effects of the band-f hybridization-induced interactions and the band-f exchange-induced interactions, pertinent to the magnetic behavior of these systems. The position of the Ce $4f$ energy level relative to the Fermi energy and the intra-atomic Coulomb interaction are obtained from a sequence of three total-energy supercell calculations with two, one and zero f electrons in the Ce $4f$ core. The calculations elucidate the origins in the electronic structure of the variation of the f-state resonance width characterizing the strength of the hybridization and the density of states at the Fermi energy characterizing the number and character of band states available for hybridization. We present results for the hybridization potential and the hybridization-induced exchange interactions on going from $CeIn_3$ to $CePb_3$, where the only obvious change is the addition of an anion p electron. © *1996 American Institute of Physics.* [S0021-8979(96)26608-0]

I. INTRODUCTION

The CeX_3 compounds with X=In, Sn, and Pb provide the opportunity to study the competition between different ground states in cerium systems.[1] These compounds are all cubic with the Cu_3Au structure. $CeIn_3$ is a local moment antiferromagnetic system[2] (LMAF) with a Néel temperature of about 10 K and a weak low-temperature moment of $0.4\mu_B$ that shows strong Kondo resistivity.[3] The cerium moments are aligned antiferromagnetically in adjacent (111) ferromagnetic planes. When a small amount of tin is substituted for indium, the magnetic ground state is no longer stable, and the system no longer orders.[1] This indicates that the underlying energy parameters in $CeIn_3$ lie near the values at which a magnetic-nonmagnetic instability of the $4f$ electron occurs. $CeSn_3$ is a mixed valent (MV) system[1] which does not order magnetically. Finally, $CePb_3$ has been shown[4] to be an itinerant antiferromagnet with an extremely small moment and a Néel temperature of 1.2 K. Moreover, several $CePb_3$ properties show heavy fermion-like behavior.[4]

The purpose of the work reported here was to investigate the origins in the electronic structure, of the variation of the f-state resonance width characterizing the strength of the hybridization, the density of states at the Fermi energy, characterizing the number and character of band states available for hybridization, the hybridization potential, and the hybridization-induced and exchange-induced interactions on going from $CeIn_3$ to $CePb_3$, where the only obvious change is the addition of an anion p electron. We have employed a unified theory that we have recently developed,[5–11] which involves a synthesis of (i) a phenomenological theory of moderately delocalized f-electron systems which includes explicit correlation effects and treats both the band-f hybridization and the band-f Coulomb exchange on an equal footing, and (ii) *ab initio* electronic structure calculations, based on the linear-muffin-tin-orbital (LMTO) method,[12] allowing a first-principles evaluation of the parameters entering the phenomenological theory. The interconfigurational correlation effects, which are important for this class of systems and which are treated explicitly in our theory, are not preserved in band theory and cannot be captured by the exchange correlation potential used in band theory.

The self-consistent one-electron potential is obtained from a warped-muffin-tin LMTO calculation without recourse to the atomic sphere approximation,[12] i.e., using a nonzero tail parameter in the interstitial, which is treated as a variational parameter. Two energy windows are employed to allow coverage of various subbands: the semicore cerium $5p$ states are calculated with a tail parameter about -0.9 Ry, and the cerium valence $6s$, $6p$, and $5d$ states and anion In(Pb) $5s(6s)$ and $5p(6p)$ states with a tail parameter, which is the average energy over occupied states in the interstitial. The full potential in the interstitial is used and the only shape approximation to the potential is a spherical averaging in nonoverlapping muffin-tin spheres. The cerium $4f$ electrons are treated as localized rather than itinerant states and thus they are included self-consistently as core states at each iteration, not being allowed to hybridize with band states. The relative magnitude of the muffin-tin radii are chosen so that nearest-neighbor muffin-tin spheres touch at the minimum in the charge density between nearest neighbors. While the basis functions for the band states are scalar relativistic,[13] spin-orbit coupling is included self-consistently. The electronic structure provides the band states and energies, and a self-consistent hybridization potential, thereby allowing determination of the band-f hybridization potential matrix elements, $V_{\mathbf{k}m}$ and the band-f coulomb exchange matrix elements $J_{nn'}(\mathbf{k},\mathbf{k}')$. The $4f$-state energy relative to the Fermi energy $E_f - E_F$, and the intra-atomic correlation energy U, are determined from differences of total energy calculations for different f configurations as impurities in a supercell

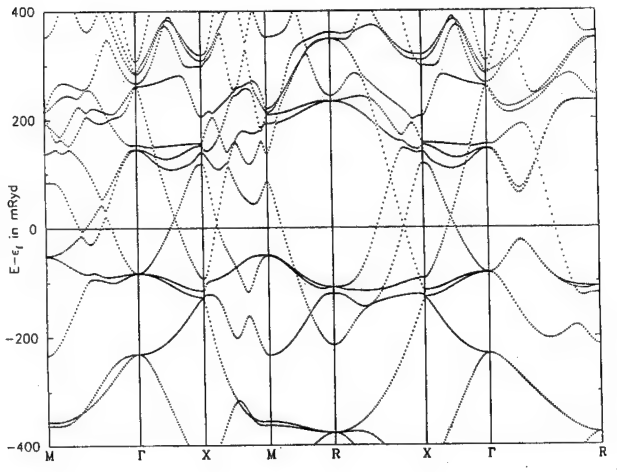

FIG. 1. The band structure of $CeIn_3$, calculated with the cerium $4f$ states treated as core states, along symmetry lines in the Brillouin zone. The band energies are with respect to the Fermi energy.

TABLE I. Summary of LMTO results for the Fermi energy E_F, the Ce $4f_{5/2}$ resonance energy, the total density of states $N(E_F)$ at E_F, the Ce d-derived and anion (In or Pb) p-derived partial density of states at E_F, the Ce $4f_{5/2}$ resonance width Γ, and the hybridization potential $v(\kappa_F)$, for $CeIn_3$ and $CePb_3$, respectively. Also listed are the results of the supercell LMTO calculations for the position of the f state relative to the E_F, and the intra-atomic Coulomb interaction U.

	$CeIn_3$	$CePb_3$
Lattice constant (a.u.)	8.859	9.210
Ce muffin-tin radius (a.u.)	2.975	3.100
Anion muffin-tin radius (a.u.)	3.132	3.256
E_F (Ry)	0.487	0.453
Ce $4f$ resonance energy (Ry)	0.503	0.442
$N(E_F)$ (Ry^{-1})	27.3	41.5
$N_d^{Ce}(E_F)$ (Ry^{-1})	5.5	7.5
$N_p^{anion}(E_F)$ (Ry^{-1})	12.3	23.3
Γ (mRy)	6.30	5.13
$v(\kappa_F)$ (mRy)	−2.55	−2.21
$E_f - E_F$ (eV)	−3.2	−3.0
U (eV)	6.2	6.3

(f^0, f^1, f^2) where all cerium sites but one have the nominal configuration f^1. Having determined the phenomenological model Hamiltonian parameters on an absolute basis, one can evaluate[6–11] the hybridization-induced and RKKY (but with the orbital part included) two-ion exchange interactions pertinent to the unusual magnetic ordering in this class of systems.

II. RESULTS AND DISCUSSION

The band structure of $CeIn_3$ (typical of this class of systems), calculated with the Ce $4f$ states treated as core states, is plotted along symmetry lines in Fig. 1, with the band energies measured with respect to the Fermi energy. We treat the effects of band-f hybridization within the context of the Anderson model Hamiltonian, where the hybridization matrix element V_{km} in the model Hamiltonian is taken to be the matrix element of the muffin-tin Hamiltonian between band states of non-f character and the wave function representing the Ce $4f_{5/2}$ state, ψ_f, which is obtained (self-consistently) from the resonance in the potential within the Ce muffin tin.[6,7] The bands dominating the hybridization-induced properties are those lying near the Fermi energy, which are largely derived from anion p-derived and cerium d-derived bands. Within the context of the model Hamiltonian, anion derived p-states hybridize more strongly with the Ce $4f$-resonance states, because the Ce-anion separation is smaller than the Ce–Ce separation. The bands at Γ which are 85 mRy below the Fermi energy are indium p bands, whereas those which are 144 mRy above the Fermi energy are Ce d bands. The addition of an anion p electron on going from $CeIn_3$ to $CePb_3$ causes the anion p-derived bands at Γ to shift at 189 mRy below the Fermi energy, thus suppressing the p-f hybridization. This is consistent with the decrease of the f-state resonance width listed in Table I, characterizing the strength of hybridization. The partial density of states (DOS) corresponding to the band structure in Fig. 1 is shown in Fig. 2. Plotted are the partial DOS for the Ce d-derived (solid curve), the In s-derived (dashed curve), and p-derived (dotted curve) bands, respectively. The Fermi energy E_F, and the DOS at the Fermi energy $N(E_F)$, in $CeIn_3$ are 0.487 Ry and 27.3 states/Ry, respectively, compared to the corresponding values of 0.453 Ry and 41.5 states/Ry in $CePb_3$. On going to $CePb_3$ there is an opening of a gap in the DOS between −0.025 and 0.18 Ry, and there is an increase (by a factor of 2) in the anion p-projected density of states at the Fermi energy.

For the purpose of analyzing hybridization effects within the context of our procedure for calculating Anderson model Hamiltonian parameters, band-f hybridization in these compounds may be approximately characterized by two quantities arising from our band structure calculations: f-state resonance widths, characterizing the strength of hybridization, and the density of states at the Fermi energy, characterizing the number and character of bands available for

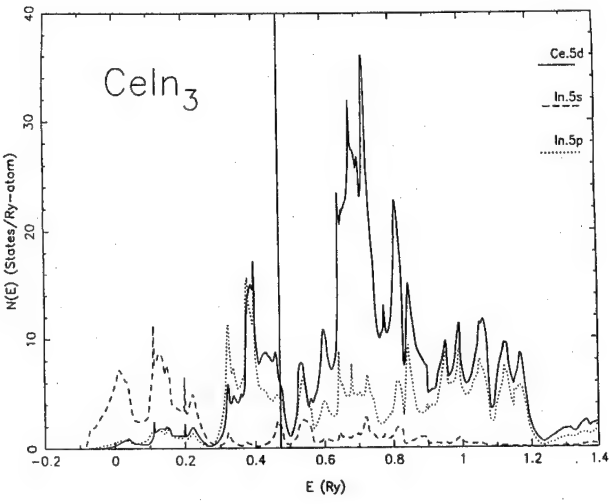

FIG. 2. Calculated partial density of states of $CeIn_3$ corresponding to the band structure of Fig. 1. Plotted are the density of states for the Ce d-derived (solid curve), the In s-derived (dashed curve), and p-derived (dotted curve) bands, respectively.

hybridization.[6,7] Calculated results of the cerium and anion muffin-tin radius, the Fermi energy, the cerium $4f$ resonant energy, the total and partial cerium d- and anion p-derived density of states at E_F, the f-state resonance width Γ, and the hybridization potential $v(\kappa_F)$, are listed in Table I, for $CeIn_3$ and $CePb_3$, respectively. The density of states at E_F, $N(E_F)$, are largely derived from anion p states and cerium $5d$ states. It is important to note that the values of Γ for both $CeIn_3$ and $CePb_3$ are comparable to that calculated[7] for CeTe (Γ=5.7 mRy), which was found to be at the *borderline* between magnetic and nonmagnetic behavior in contrast to the almost fully magnetically ordered CeSb. While the total density of states available for hybridization increases on going from $CeIn_3$ to $CePb_3$, the resonance width decreases because of the larger Ce-anion separation in $CePb_3$.

The energy necessary to place the Ce f-electron in a band state at the Fermi energy, E_F-E_f, and the energy required to change from an f^1 configuration to an f^2 configuration, E_f+U-E_F, have been evaluated for both systems. The values of E_F-E_f and U are then obtained from the f^0, f^1, and f^2 f-state eigenvalues by the use[7] of linear transition theory. We find that E_F-E_f and U are 3.2 and 6.2 eV in $CeIn_3$, and 3.0 and 6.3 eV in $CePb_3$, respectively. We have also calculated the 6×6 hybridization-induced exchange interaction matrix, $E_n=E(m,m',\mathbf{R}_n)$,[7] pertinent to the magnetic behavior of this class of systems. We find that the dominant matrix elements involve the $m=m'=\pm 1/2$ states, which correspond to the piling up of charge along the interionic axis. E_1, which in the phenomenological treatment,[5] is chosen to match the Néel temperature, is about the same in $CeIn_3$ (2.9 K) and in $CePb_3$ (3.0 K). More importantly, we find that $E_2(E_3)$ are ferromagnetic and large in both compounds, 3.1 K (2.9 K) in $CeIn_3$ and 2.7 K (2.8 K) in $CePb_3$. As for the case of other cerium systems (CeSb,CeTe), Coulomb exchange rather than hybridization was found[10] to be the larger contributor to the highly anisotropic effective two-ion interaction which determines the magnetic ordering behavior. Work currently in progress is aimed at the evaluation of the Coulomb exchange-induced interactions (proportional to J^2).[10,11] Having determined the two-ion exchange interactions, the equilibrium magnetic behavior (i.e., the ordered moment and the ordered temperature) of a given magnetic structure will be determined by treating the exchange Hamiltonian [Eq. (3) in Ref. 7] within mean-field theory.

We focus on $YbCu_4Ag$ and $YbCu_4Au$ and interpret the optical conductivity, measured from 2 meV to 6 eV at 10 and 300 K, in terms of self-consistent electronic structure calculations. Most of the relevant spectral structures are interpreted as interband transitions from hybridized $f-d$ states below and at the Fermi level at high symmetry points. In particular, the large shoulder at about 2.4 and 2 eV in the spectrum of $YbCu_4Au$ and $YbCu_4Ag$, respectively, can be interpreted in terms of a transition $\Gamma_4 \rightarrow \Gamma_3$ involving mostly d states. We also compare the electronic structure of $YbCu_4Ag$ with that of $LuCu_4Ag$, to ascertain the influence of the f states on the conduction bands and carrier density at E_F. This allows us to draw some qualitative considerations on the f-band hybridization in these compounds. © *1996 American Institute of Physics.* [S0021-8979(96)26708-7]

Ytterbium, the *hole* counterpart of cerium, is expected to form in several intermetallic compounds with Kondo lattice- and valence fluctuations properties. This has in fact been found in some experiments. In particular, an interesting group of ternary compounds, isostructural to cubic $MgCu_4Sn$, is $YbCu_4M$, where M=Ag, Au, Pd, In. They have been investigated by optical, neutron, Mössbauer, photoemission, and x-ray spectroscopy[1–6] as well as by electrical and magnetic fields[7,8] also performed at high-pressure and high magnetic fields.[9–11]

A new interest towards this series of compounds is raised by the observation of very different ground states reached by decreasing temperature. In fact, $YbCu_4Ag$ displays a Kondo-like behavior below $\simeq 100$ K[2,3,8] that is absent in isovalent $YbCu_4Au$. The latter one, like $YbCu_4Pd$, undergoes a magnetic transition below 1 K. Finally, $YbCu_4In$ exhibits a first-order valence phase transition at $T=40$ K from Yb^{2+} to Yb^{3+} with a sharp volume change.[7] Interestingly, no structural distortions have been detected in any of the above compounds at the transitions. Therefore, since the only ground-state parameters varying through the series are the lattice constant and the electronic charge, a clue to the understanding of all the phenomena could be the interplay between volume and electronic structure.

Optical measurements and electronic band calculations are suitable to test this point. The goal of the present paper is twofold: one is the direct interpretation of the low-temperature conductivity spectra of isovalent $YbCu_4Ag$ and $YbCu_4Au$.[2] The other is to relate, at least qualitatively, the observed Kondo behavior of the Ag compound with the electronic $f-d$ hybridization.

With these aims in mind we have performed self-consistent electronic FLAPW calculations[12] within the LDA approximation for the two isovalent compounds as well as for $LuCu_4Ag$, as the f-full analog of $YbCu_4Ag$. Calculations have been performed at the experimental volumes with $a_0=7.0834$ Å for YCu_4Ag and $a_0=7.0519$ Å for YCu_4Au. The band structure is displayed in Fig. 1. For the sake of comparison we have labeled the conduction bands at the Γ point in Fig. 1 with the irreducible representation of the T_d symmetry in Bethe's notation. The results are consistent with the main features observed in photoemission and x-ray absorption in $YbCu_4Ag$. A peak of Yb $5d$ density is observed at about 4 eV above E_F,[6] a Cu $3d$ band appears at 3 eV below E_F and Yb $4f$ states seem located within 2 eV below E_F.[5] A slight shift seems to exist for Ag $3d$ states which should be around 6 eV below E_F.[5] Anyway, no matrix element analysis has been yet performed on the data.

The bands of the two compounds are quite similar. Differences appear along the lines connecting Γ with the points L and K for states at and above E_F with consequences on the optical spectra, as discussed below. In particular, there is in Fig. 1(a) an inversion of the triplet Γ_4 with the singlet Γ_1 above E_F with respect to the same bands in Fig. 1(b). In particular we find that the Γ_1(Au) is 1.5 eV lower in energy

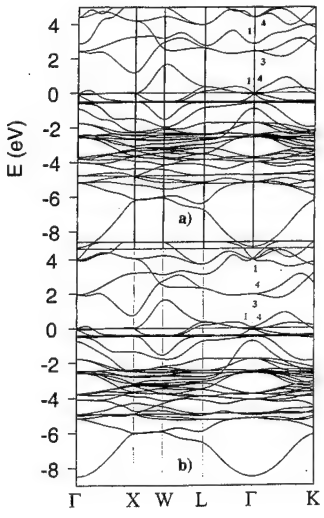

FIG. 1. Calculated band structure of (a) $YbCu_4Au$ and (b) $YbCu_4Ag$. The zero of the energy scale is the Fermi level E_F and some irreducible representation at Γ are indicated with the corresponding numerical labels in order of decreasing energy from the top of each panel. Notice the different order of the highest states Γ_4 and Γ_1 in the two compounds.

 0021-8979/96/79(8)/6423/3/$10.00

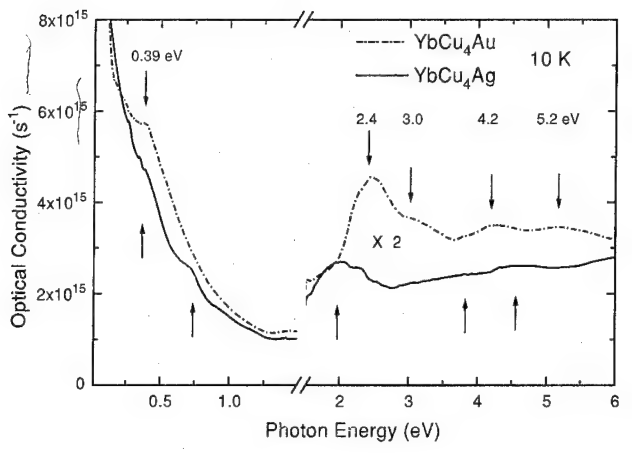

FIG. 2. Optical conductivity of $YbCu_4Au$ and $YbCu_4Ag$ measured at 10 K. The excitations indicated by the arrows are discussed.

than Γ_1(Ag). Moreover, another singlet Γ_1 is almost degenerate with the triplet Γ_4 at E_F in $YbCu_4Au$ and is slightly above it in $YbCu_4Ag$.

In order to test the role of volume as the possible origin of these differences we have calculated the bands of $YbCu_4Au$ with the lattice constant of $YbCu_4Ag$. Practically no changes are introduced by volume expansion, actually quite small, with respect to Fig. 1(a). We are thus led to think that the differences in the band structures of $YbCu_4Ag$ and $YbCu_4Au$ are due to purely electronic effects.

From the analysis of the wave-function composition it results that the higher Γ_1 singlet is made mainly of s states coming from Ag (34%) and Au (36%), in the corresponding compounds. The doublet Γ_3 and the triplet Γ_4 originate from d (Yb, Au/Ag) and p,d states (Yb, Au/Ag, Cu), respectively. The triplet and singlet at E_F (Γ_4, Γ_1) show essentially Yb d, f and Yb f character, respectively.

From this analysis it seems that the singlet Γ_1 does not interact with neighboring states but with other s states of much lower energy (e.g., bands bottom). Due to the much larger atomic weight of Au with respect to Ag the energy difference of the atomic valence s states is $E_{6s}(\mathrm{Au})-E_{5s}(\mathrm{Ag})\simeq -1.4$ eV. This is of the same order of magnitude as the energy difference between the highest Γ_1 singlets in the two compounds. This interpretation is supported by the fact that the order of the excited states in $LuCu_4Ag$ is the same as in the $YbCu_4Ag$.

We have also carried out a symmetry analysis of the allowed optical transitions in the dipole approximation, considering as initial states (i) the narrow f bands at $\simeq -0.5$ eV (Γ_1, Γ_4, Γ_5, not shown) in both compounds and (ii) the states at E_F in Fig. 1. In both cases there are not any symmetry allowed transitions between states Γ_1 and Γ_3. In $YbCu_4Ag$ there are allowed transitions from f states at 0.50, 2.3–2.5, 4.2, and 4.5 eV (2) and from the triplet Γ_4, at E_F as initial state, at 0.16, 2, and 4.1 eV. In $YbCu_4Au$ transitions from f states are at 2.7–2.9 eV (2), 3.7, 4.8–5 eV (2), and from E_F at 2.5, 3 and 4.4 eV.

The optical conductivity, measured at 10 K is shown in Fig. 2. The results at 300 K, not shown, change appreciably only below 0.5 eV. Many structures corresponding to interband transitions may be recognized in the energy range 0.1–6 eV. The arrows in the figure indicate approximately the possible transitions: two shoulders at about 0.35 and 0.7 eV and three broad structures at 2.2, 3.9, and 4.6 eV in $YbCu_4Ag$ and five main transitions at 0.39, 2.4, 3.0, 4.2, and 5.2 eV in $YbCu_4Au$. A very small bump at 1.4 eV in the spectra of both compounds could be related to the spin-orbit splitting of hybridized Yb $4f$ states.[5] Some small anomalies around 1 eV can be noticed in the spectrum of $YbCu_4Ag$. All these structures seem to be relatively independent on the temperature and on the heavy fermion features occurring at the lowest energies and at low T.

The most striking differences among the two spectra at low T, except for the first one of $YbCu_4Ag$ at 0.35 eV, are the structures at 2 and 2.4 eV in $YbCu_4Ag$ and $YbCu_4Au$, respectively.

Comparing with the excitation energies deduced from the bands in Fig. 1 we can ascribe the broad shoulder at 2 eV (2.4) eV in the Ag(Au) compound to the transition $\Gamma_4 \rightarrow \Gamma_3$, which involves basically d states, as deduced from the analysis of the eigenvectors at this symmetry points. From the same analysis we could ascribe the broadening of the shoulders to transitions from the f states. We notice that, according to our band calculations, the $\Gamma_4 \rightarrow \Gamma_3$ excitation may be predicted in $LuCu_4Ag$ and it would be interesting to check with experimental results. Transitions at other symmetry points may add to those at Γ. The agreement we find is surprisingly good considering the uncertainties implicit in LDA for the energy of the excited states. We may argue that for transition involving relatively close states of the same symmetry, there could be a common energy shift with respect to E_F not affecting the energy of the transition altogether.

The second goal of this article, i.e., the understanding of the Kondo behavior of $YbCu_4Ag$ can be carried out also on the basis of our electronic calculations. It is known that the Kondo temperature is directly related to the $f-d$ hybridization at E_F, a quantity that can be evaluated in an approximated way from electronic calculations.[13] However, it is also possible to have a crude, qualitative estimate of the hybridization from the relative weight of the density of f,d states at E_F. In fact, if we roughly assume that, for a given value of the total number of f electrons/Yb, n_f, the larger is their DOS(E_F) the weaker the hybridization,[14] we can draw some qualitative conclusions in the present compounds.

We have calculated the density of states of $YbCu_4Ag$, $YbCu_4Au$,[15] and also $LuCu_4Ag$, to have a reference material where, due to the complete filling of the f states, the $f-d$ hybridization is certainly negligible. The total density of states of $YbCu_4Ag$ and $LuCu_4Ag$, reported in Fig. 3, shows the different f filling: the f peak centered at about -1 eV in the Yb compound, shifts to $\simeq -5$ eV in the Lu compound. Its intensity increases with respect to the Yb compound. We have estimated that the f bandwidth in the Lu compound is an order of magnitude smaller than in the Yb compounds. The DOS of $YbCu_4Au$ (not shown) is quite similar to that of the Ag compound. We attribute these facts to the lack of hybridization of the f states with extended states (typically

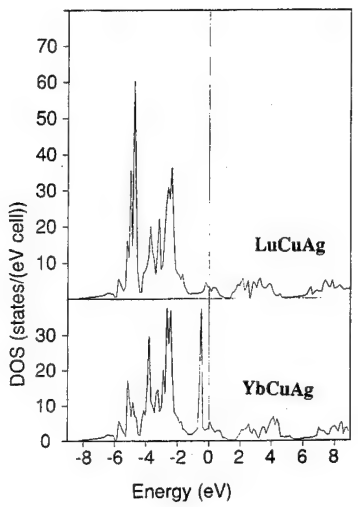

FIG. 3. Calculated total density of states of $YbCu_4Ag$ and $LuCu_4Ag$.

d), that keeps the f states very well localized in energy and separated from band states. Nevertheless, the detailed analysis of the partial DOS and E_F gives some quantitative indications on the different degree of hybridization in $YbCu_4Ag$ and $YbCu_4Au$.

In fact, even if n_f is constant in the two compounds, the f DOS at E_F drops from 11.5 states/eV atom in $YbCu_4Au$ to 9.8 states/eV atom in $YbCu_4Ag$, indicating a higher hybridization (i.e., a higher Kondo temperature), in the latter compound. Accordingly, the d component at E_F on Ag drops by about 40% with respect to Au.

In conclusion, the present theoretical calculations agree quite well with the experimental results and explain the main features of the optical conductivity. A clearcut answer about the nature of the observed peaks at 2 and 2.4 eV in $YbCu_4Ag$ and $YbCu_4Au$, respectively, should come from measurements in the corresponding Lu compounds. We have also given qualitative indications of the reason of the observed *heavy fermion* behavior of $YbCu_4Ag$ in terms of a large $f-d$ hybridization. The smaller hybridization found in $YbCu_4Au$ gives rise to a Kondo minimum in the resistivity but this effect is overwhelmed by the onset of intersite magnetic order.[8]

An experimental and theoretical study of magnetic circular dichroism in valence band photoemission from 15 monolayer thick fcc Ni films on Cu(001) is presented. A highly symmetric configuration (light incidence, electron emission, magnetization direction, photon helicity, and surface normal all parallel) allows the illustrative interpretation of the dichroism in terms of the relativistic band structure. Photoemission experiments in the photon energy range of 11–27 eV are compared to fully relativistic one-step photoemission calculations. From this comparison, the dichroic features can be directly related to the double group symmetry of the initial states, which is demonstrated by two examples. © *1996 American Institute of Physics.* [S0021-8979(96)26808-3]

The interplay of spin-orbit and exchange interaction in ferromagnets is of great interest for a variety of effects. Magnetic dichroism in photoemission, which is the change of intensity distribution curves by reversal of the magnetization direction, is exclusively due to this interplay of spin-orbit and exchange interaction.[1] Magnetic circular dichroism in valence-band photoemission (MCDAD), therefore, is an especially well-suited method to study this interaction in the valence states. We want to demonstrate in this contribution that information on the relativistic electronic structure is available by MCDAD which otherwise would have been accessible by spin-resolved photoemission only.

Thin Ni films (10–56 ML), grown epitaxially on Cu(001), have their easy axis of magnetization perpendicular to the film surface.[2] They offer thus the advantage to study the MCDAD in a totally symmetric configuration. Such a configuration, in which the light incidence, electron emission, magnetization direction, and photon helicity are all aligned parallel to the surface normal, allows the illustrative interpretation of the observed dichroism in terms of double-group symmetry of the initial bands along the Δ axis of the relativistic band structure.

We present an experimental and theoretical MCDAD study of the spin-orbit and exchange split electronic structure of fcc-Ni(001) films. Fully relativistic one-step photoemission calculations were performed. We show that from the comparison between experiment and theory it is possible to determine details of the relativistic band structure such as band dispersion and hybridization between bands of the same double group symmetry.

Ni films of 15 ML thickness were deposited at room temperature by electron bombardment of a high-purity nickel rod. The films were annealed immediately after deposition for 10 min at 450 K in order to minimize the film roughness.[3] Photoemission spectra were taken at the Berlin synchrotron radiation facility (BESSY), with $\approx$ 90% circularly polarized light. The overall energetic resolution was approximately 200 meV, the angular acceptance better than $\pm 2°$. The films were remanently magnetized perpendicular to the surface prior to the acquisition of the spectra. All spectra were collected at room temperature.

Fully relativistic one-step photoemission calculations of the layer Korringa–Kohn–Rostoker (KKR) type were performed using a recently developed Green's function formalism.[4] Details of the calculation procedure will be given elsewhere.[5] The spectra were calculated for a semi-infinite Ni(001) crystal with the lateral lattice constant of bulk Cu, namely, 2.55 Å (compared to 2.49 Å for bulk Ni). The vertical layer spacing was taken as 1.69 Å, which means a 6% tetragonally compressed fcc structure. Such a structure is deduced from our LEED $I(V)$ measurements of the specular beam. Furthermore, we assume $T=0$ K and complete polarization of the incident light.

In a highly symmetric arrangement without the presence of a magnetic field, electronic transitions induced by circularly polarized light are governed by relativistic dipole selection rules.[6] In the presence of a perpendicular magnetization, the electronic states can be classified due to four one-dimensional irreducible representations of the double group, which read Δ_6+, Δ_6-, Δ_7+, and Δ_7-. Their Δ^5 spatial parts can be labeled Δ_6^5+, Δ_6^5-, Δ_7^5+, and Δ_7^5-.[5] The $+/-$ sign should not be attributed to majority or minority spin because the latter is not a "good quantum number" in the presence of spin-orbit coupling.

Figure 1 illustrates the situation. In the bottom panel, the energetic positions of the four bands are depicted schematically. Transitions from this states induced by circularly polarized light depend on the relative orientation of photon spin σ and magnetization $\mathbf{M}$. If $\boldsymbol{\sigma}$ is parallel (antiparallel) to $\mathbf{M}$, only states with Δ_7^5+ and Δ_6^5- (Δ_7^5- and Δ_6^5+) symmetry contribute to the spectrum.[6] In the center panel of Fig. 1, schematic intensity distribution curves for the two cases are shown. The solid (dotted) lines correspond to parallel (antiparallel) alignment of $\boldsymbol{\sigma}$ and $\mathbf{M}$ [($I(\uparrow\uparrow)$ and $I(\uparrow\downarrow)$, respectively)]. The resulting normalized intensity asymmetry, defined as $A=[I(\uparrow\uparrow)-I(\uparrow\downarrow)]/[I(\uparrow\uparrow)+I(\uparrow\downarrow)]$, is depicted in the top panel. It exhibits a characteristic plus/minus/plus feature, where the minus indentation is evoked by emission from the Δ_6^5+ and Δ_7^5- bands.

Figure 2 shows a series of intensity spectra for different photon energies. Following the convention of Fig. 1, spectra

 0021-8979/96/79(8)/6426/3/$10.00

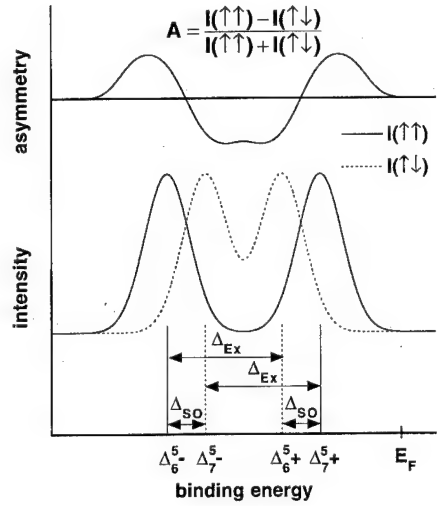

FIG. 1. Bottom: schematic representation of the four bands of Δ_7^5+, Δ_6^5+, Δ_7^5-, and Δ_6^5- symmetry contributing to the spectra in the totally symmetric geometry. The arrows indicate the splitting due to spin-orbit (Δ_{SO}) and exchange interaction (Δ_{Ex}). Center: schematic intensity distribution curves for parallel (solid lines) and antiparallel alignment (dotted lines) of photon spin and magnetization direction. Top: normalized asymmetry A of the spectra of the center panel.

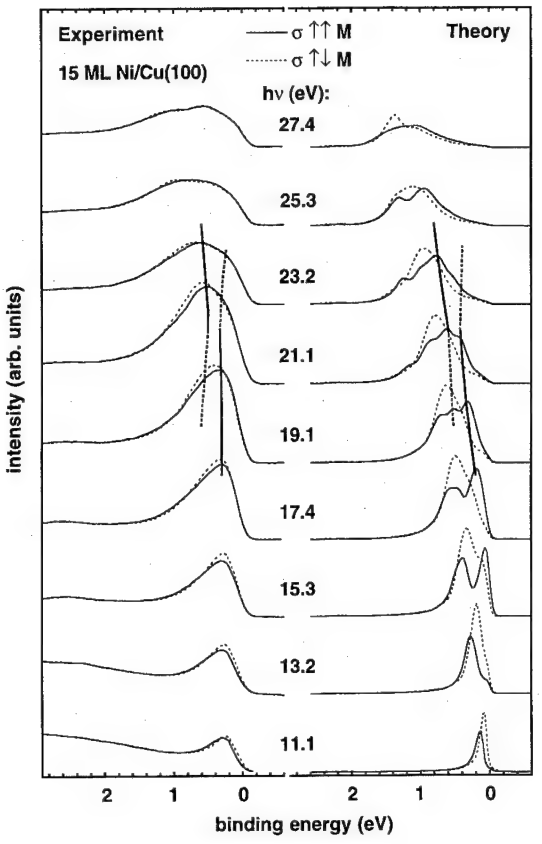

FIG. 2. Series of partial intensity spectra for different photon energies $h\nu$. Shown are spectra for parallel (solid lines) and antiparallel alignment (dotted lines) of photon spin and magnetization direction. Left: experimental spectra, right: theoretical spectra. The vertical lines indicate the occurrence of a hybridization region as explained in the text.

for parallel (antiparallel) alignment of $\boldsymbol{\sigma}$ and $\mathbf{M}$ are reproduced by solid (dotted) lines. Experimental spectra, normalized to the photon flux, are depicted on the left-hand side, the results of the calculation on the right-hand side. The spectra for 11.1 eV photon energy display relatively sharp peaks just below the Fermi energy; with increasing photon energy a dispersion towards higher binding energies and a broadening of the peaks are observed both in the experimental and in the theoretical spectra.

Figure 3 displays asymmetry spectra, corresponding to the intensity spectra of Fig. 2. Again, experimental asymmetries are shown on the left, theoretical curves on the right-hand side. At small photon energies, experimental asymmetries as large as 20% are observed. In order to facilitate comparison with the experimental data, the theoretical asymmetry curves are scaled by a factor of 0.2. The experimental spectra exhibit significantly broader intensity curves and lower asymmetries compared to the calculated ones, which must be attributed to the limited energetic and angular resolution, to possible imperfections in film morphology, and to the background of inelastically scattered electrons not considered in the calculations. Furthermore, the theoretical spectra were calculated for $T=0$ K and 100% circular polarization. A larger broadening of the calculated spectra would lead to a better agreement but impedes the identification of the underlying electronic transitions. Apart from the different size of the dichroic asymmetry, very good qualitative agreement between experiment and theory is seen both in the intensity and in the asymmetry spectra. This enables us to correlate the experimentally observed features to the calculated relativistic band structure.

We will now demonstrate by two examples how this comparison of experiment to theory serves to identify specific details of the electronic states, assuming direct interband transitions. Figure 4 shows the relativistic band structure of Ni along the Δ axis, calculated with the same parameters as the photoemission spectra. The bands are reproduced with differently dashed and dotted lines according to their double group symmetry, as labeled in the figure.

Let us now as the first example consider the dispersion of the four bands with Δ^5 spatial symmetry which were used for the schematic illustration of Fig. 1. In Fig. 4 these bands are marked by four arrows at both sides of the panel. Starting at the Γ point at binding energies between 1.5 and 1.9 eV, these bands jointly disperse upwards, interrupted by hybridization with other bands, to reach the X point at energies between 0.15 eV below and 0.3 eV above the Fermi energy. In the experiment a photon energy of 11 eV corresponds to transitions near the X point, whereas 27 eV corresponds to transitions near the Γ point. Comparing experimental spectra to the calculated band structure, off-axis contributions due to the experimental angular resolution have principally to be considered and may contribute to the linewidth of the spectra. At $\pm 2°$, however, these effects are small and affect mainly the relative peak heights.[7] Because of the broadening of the spectra at higher photon energies, it is difficult to obtain the dispersion of the Δ^5 bands from intensity spectra alone. As we see from Fig. 1, the pronounced minus feature in the asymmetry curves is correlated to the energetic posi-

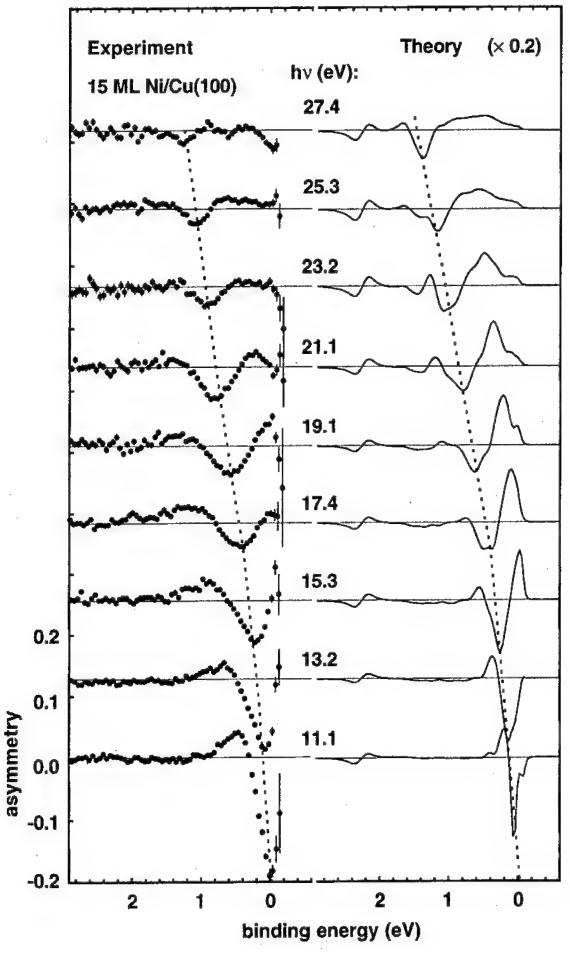

FIG. 3. Series of asymmetry spectra for different photon energies $h\nu$, calculated from the corresponding spectra of Fig. 2. Left: experimental asymmetries, right: theoretical asymmetries. The vertical dotted lines mark the dispersion of the prominent minus peak.

tions of the Δ_6^5+ and Δ_7^5- bands. The dispersion of this minus peak, marked by vertical dotted lines in Fig. 3, indicates the dispersion of the Δ^5 bands.

As a second example we will consider the hybridization of Δ_7+ bands around 0.5 eV binding energy at about the middle of the Δ axis. This hybridization is caused by an avoided crossing between a band of Δ_7^2+ symmetry, which is recognized in Fig. 4 by a weak dispersion, and a band of Δ_7^5+ symmetry with a steeper dispersion. As a consequence of the avoided crossing, the bands interchange their symmetry character in the hybridization region and contain both a mixture of Δ_7^2+ and Δ_7^5+ symmetry. This can be seen in the intensity spectra for $\boldsymbol{\sigma}\uparrow\uparrow\mathbf{M}$ (solid lines in Fig. 2). As already mentioned, only bands which contain Δ^5 single group symmetry character contribute to the spectra. This means that the hybridization is observed as an energetic displacement of the corresponding peak towards higher binding energy with increasing photon energy. The vertical lines in Fig. 2 indicate the region of hybridization in the photoemission spectra.

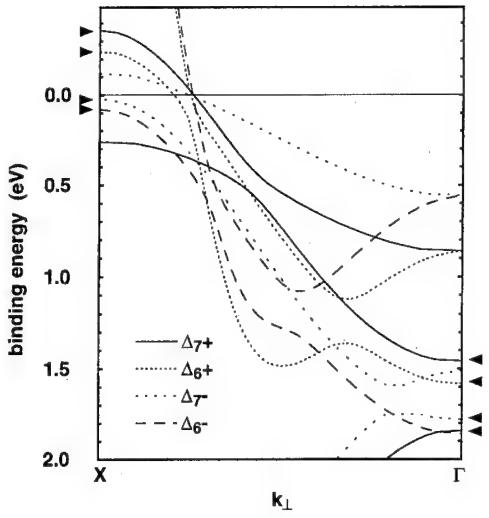

FIG. 4. Relativistic band structure of Ni along the Δ axis, calculated with the same parameters as the photoemission spectra. Bands with Δ_7+, Δ_6+, Δ_7-, and Δ_6- double group symmetry are distinguished as labeled in the figure. The arrows indicate bands of Δ^5 orbital symmetry.

They mark the positions of bands containing Δ_7^5+ symmetry, and fade out into dotted lines where the Δ_7^2+ symmetry character in these bands predominates. In the calculated spectra (right-hand side of Fig. 2), both of the hybridizing bands can be distinguished as separate peaks in the solid line spectra. In the experimental spectra (left-hand side of Fig. 2), the hybridization shows up as energetic shift of the intensity weight of the peak for $\boldsymbol{\sigma}\uparrow\uparrow\mathbf{M}$ between 19.1 and 21.1 eV. Whereas at 19.1 eV the peak is asymmetrically shaped with higher weight at the low binding energy side, at 21.1 eV the weight is shifted to the side with higher binding energy.

Both examples demonstrate how the relativistic band structure can be correlated to MCDAD spectra. It has been shown how from the comparison to fully relativistic calculations even fine details of the band structure can be resolved. This demonstrates the capability of magnetic circular dichroism in valence-band photoemission for the investigation of the exchange and spin-orbit split relativistic band structure of ferromagnets.

Density functional study of fcc iron and iron particles in copper

Diana Guenzburger
Centro Brasileiro de Pesquisas Fisicas, Rua Xavier Sigaud 150, 22290-180 Rio de Janeiro, RJ, Brazil

D. E. Ellis
Department of Physics and Astronomy and Materials Research Center, Northwestern University, Evanston, Illinois 60208

The first-principles spin-polarized discrete variational method in the framework of density functional theory was employed to investigate the electronic and magnetic structure of fcc (γ) Fe and of γ-Fe particles in copper, represented by 62-atom embedded clusters of cubic geometry. The influence of Al substitutional impurities in γ-Fe and in the Fe particle in Cu was also investigated. Magnetic moments and hyperfine fields were obtained. © *1996 American Institute of Physics.* [S0021-8979(96)26908-X]

I. INTRODUCTION

Pure fcc (or γ) iron cannot be found at room temperature, only between 1183 and 1667 K; however, it may be stabilized at low temperatures as small coherent precipitates in copper or copper alloy matrices, or as thin epitaxial films on Cu or Cu-based alloy substrates.[1,2] Thus the magnetic and hyperfine properties of fcc Fe may be investigated experimentally. Band structure calculations[3,4] have demonstrated the existence of multiple magnetic states, the stability of which depends on the lattice constant. This may be varied experimentally by using pressure or bulkier atoms in the Cu alloys of the matrix or substrate, such as Al or Au.[2]

We report first-principles embedded-cluster electronic structure calculations for pure fcc Fe and for a coherent Fe particle in fcc copper. Magnetic moments, spin density distributions, and magnetic hyperfine fields were obtained. The influence of an Al substitutional impurity in γ-Fe and in the Fe particle in Cu was also assessed.

II. THEORETICAL METHOD

γ-Fe was represented by a 62-atom cubic cluster embedded in the charge densities of several shells of neighboring atoms in the crystal. Several lattice constants were considered, varying from $a=3.38$ to 3.77 Å. For smaller values, an antiferromagnetic (AFM) phase consisting of alternating layers of up and down spins normal to the (001) direction was considered. An AFM spin state is found to be more stable at smaller lattice constants.[2] For larger interatomic distances we studied a ferromagnetic (FM) phase.

A coherent γ-Fe particle in Cu was represented by a 62-atom cubic cluster, with the 14 innermost atoms representing the Fe particle and the 48 outer atoms being copper ($Fe_{14}Cu_{48}$, see Fig. 1). In the case of Al substitution, two Fe atoms of the particle were substituted for Al, forming the cluster $Fe_{12}Al_2Cu_{48}$. The influence of Al in pure γ-Fe was also explored, with calculations for the clusters $Fe_{60}Al_2$. The spin-polarized self-consistent numerical discrete variational method,[5,6] in the framework of density functional theory, was employed. The local exchange-correlation potential, which is a functional of the electron density ρ_σ for each spin σ, was that of von Barth and Hedin.[7] A mixed numerical three-dimensional grid of sampling points was employed, consisting of a random Diophantine mesh in the interatomic region and a precise polynomial grid within a sphere of ~2 a.u. around the atoms where the local properties are calculated. A total of ~24 000 points was employed for each cluster. The magnetic moments are defined as the integral of the spin density $\rho\uparrow(\mathbf{r})-\rho\downarrow(\mathbf{r})$ within the Wigner–Seitz sphere of the atom. A multipolar expansion of the charge and spin density, centered at the nuclei of the cluster atoms, is considered to construct the model potential employed, in which only spherical terms were retained. The model density is fitted to the true (eigenvector) density by a least-squares minimization procedure. In determining local properties, such as local densities of states (DOS), magnetic moments, and hyperfine fields, the innermost atoms of the clusters are considered, since they best represent the situation in the bulk.

III. RESULTS AND CONCLUSIONS

For AFM and FM γ-Fe, the magnetic moments μ increase as the lattice constant is increased. The values obtained are not far from those computed by full-potential band structure calculations.[4]

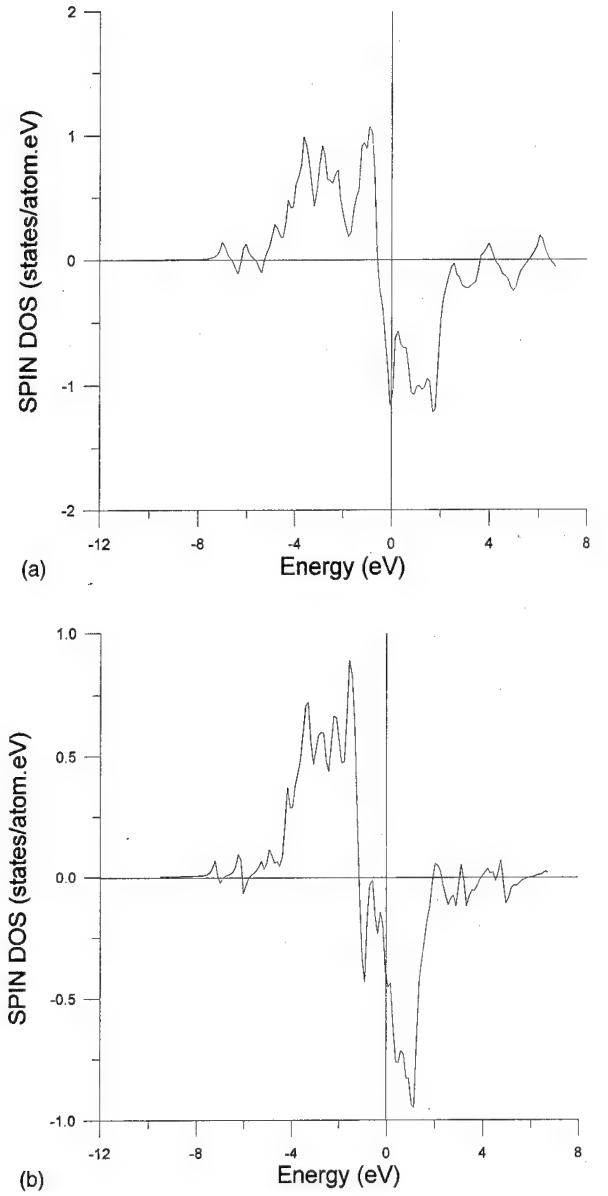

FIG. 2. (a) Valence $(3d+4s+4p)$ spin density of states (DOS $\uparrow$ minus DOS $\downarrow$) for ferromagnetic configuration of fcc Fe. (b) Valence $(3d+4s+4p)$ spin density of states for antiferromagnetic configuration of fcc Fe.

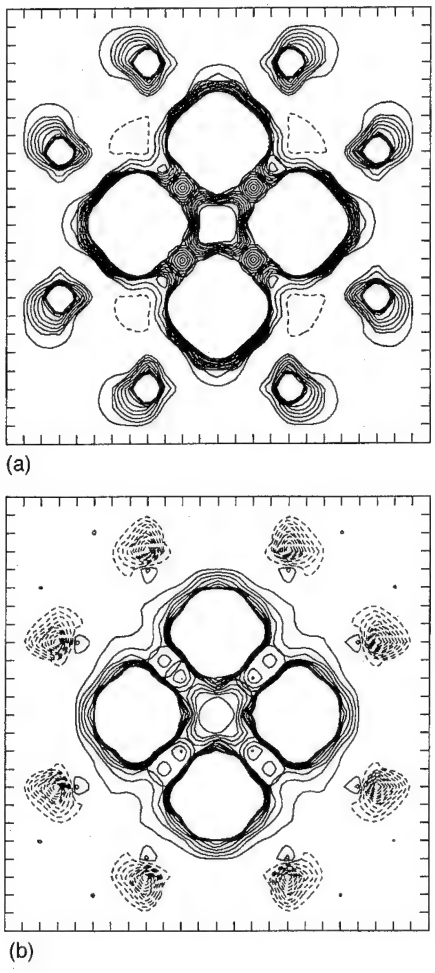

FIG. 3. (a) Spin density contour map, plotted on the (x,y) plane for the ferromagnetic γ-Fe particle in Cu. Contours range from -0.01 to $+0.01$ e/a.u.^{3} with intervals of 0.001. Full lines are positive values. (b) Spin density contour map, plotted on the (x,y) plane for the antiferromagnetic γ-Fe particle in Cu. Contours range from -0.01 to $+0.01$ e/a.u.^{3} with intervals of 0.001. Full lines are positive values.

Experimental measurements by Mössbauer spectroscopy show a large gap between the values of the hyperfine fields H_F for AFM γ-Fe, at smaller lattice constants, and FM γ-Fe, at larger lattice constants. For the latter, the magnitude of H_F is much larger. However, the calculated values of μ for both phases do not seem to justify this large discrepancy. In fact, it was found that the large difference observed experimentally in the magnitude of the hyperfine fields of AFM and FM γ-Fe originates mainly from the different sign of the conduction electrons contribution in both phases. For FM γ-Fe, the conduction electrons contribution is negative, and adds to the negative core contribution, resulting in hyperfine fields of large magnitude. For AFM, the conduction electrons contribution is positive, thus cancelling part of the negative core contribution and resulting in hyperfine fields of small magnitude.[8] In Figs. 2(a) and 2(b) are shown the valence $(3d+4s+4p)$ spin DOS (spin $\uparrow$ DOS minus spin $\downarrow$ DOS) for FM and AFM fcc Fe, respectively. A larger number of occupied spin down states near the Fermi level for AFM results in smaller values of μ than for FM. Oscillations at the bottom of the band for both cases are mainly due to polarization of the $4s$ states.

Both FM ($Fe_{14\uparrow}Cu_{48}$) and AFM ($Fe_{4\uparrow}Fe_{10\downarrow}Cu_{48}$) γ-Fe particles in copper were considered, at interatomic distances typical of the two magnetic phases. In the case of the AFM particle, four spin $\uparrow$ Fe atoms are on the (x,y) plane, with five spin $\downarrow$ atoms on the layers above and below (see Fig. 1). The self-consistent calculations revealed that the $3d$ orbitals of copper tend to polarize parallel to the Fe $3d$ in both cases. As an example, we show in Figs. 3(a) and 3(b) the spin density plotted on the (x,y) plane (see Fig. 1) for the FM and AFM γ-Fe particles in Cu, respectively. For FM, we see the compact $3d$ spin density on the Cu atoms aligned parallel to the moments on Fe. Dotted lines in Fig. 3(a) represent the spin density of the $(4s,4p)$ conduction electrons which is negative in both Fe and Cu. For the AFM particle [Fig. 3(b)], the $3d$ moments on the Cu atoms are parallel to the negative

TABLE I. Magnetic moments (in μ_B) and hyperfine fields H_F (in kG) of γ-Fe, γ-Fe in Cu, γ-Fe with two Al atoms as first neighbors and the γ-Fe particle in Cu with two Al neighbors (FM only). Conduction-electron contribution H^{cond} and core contribution H^{core} to H_F are given separately. Values given are for AFM and FM states, at typical interatomic distances.

		Cluster	μ	H^{cond}	H^{core}	$H^{tot}=H_F$
AFM	γ-Fe	$Fe_{36\uparrow}Fe_{26\downarrow}$	1.50	+44	−157	−113
	γ-Fe+2Al	$Fe_{36\uparrow}Fe_{24\downarrow}Al_2$	1.61	+35	−171	−136
r=2.63 a.u.	γ-Fe in Cu	$(Fe_{4\uparrow}Fe_{10\downarrow})Cu_{48}$	1.34	+86	−130	−44
FM	γ-Fe	$Fe_{62\uparrow}$	2.44	−59	−288	−347
	γ-Fe+2Al	$Fe_{60\uparrow}Al_2$	2.29	−60	−268	−328
r=2.72 a.u.	γ-Fe in Cu	$(Fe_{14\uparrow})Cu_{48}$	2.54	−23	−296	−319
	γ-Fe in Cu+2Al	$(Fe_{12\uparrow}Al_2)Cu_{48}$	2.39	−23	−275	−298

moments on the Fe atoms of the particle in the layers above and below, since these are the majority. This result is entirely in agreement with recent measurements with magnetic circular x-ray dicroism at the K edge of copper for Co/Cu and Fe/Cu multilayers, which show that the $3d$ electrons of Cu are polarized parallel to the $3d$ moments of Fe, whereas the $4p$ of Cu are antiparallel.[9]

Finally, the influence of substitutional Al in γ-Fe and in the Fe particle in Cu was also explored. The results of the self-consistent calculations revealed that the presence of Al substituting for Fe disrupts the AFM spin arrangement: for the AFM γ-Fe particle in copper, the presence of two Al atoms resulted in nonconvergence for the self-consistent potential (after iteration, the FM state resulted), indicative of the instability of that state. In pure AFM γ-Fe the two Al impurities caused a tendency to local ferromagnetic arrangement. Details of these calculations will be given in a forthcoming publication.[10]

In Table I are given values of the Fe magnetic moment μ and hyperfine field H_F for γ-Fe, γ-Fe in Cu, pure γ-Fe with Al neighbors and the γ-Fe particle in Cu with Al neighbors (FM only). It may be seen in this table that the sign of the conduction-electrons contribution is positive for the AFM state and negative for FM in all cases. The significant influence of the Cu matrix and of Al neighbors in μ and H_F may be also seen.

We report on recent inelastic neutron scattering measurements of the magnetic response close to the metal–insulator transition in $La_{1-x}Sr_xTiO_3$. Specific heat and susceptibility data from Tokura *et al.*[1] give evidence for a divergent effective mass at the critical concentration $x_c = 0.05$ in agreement with recent mean-field theories of the transition. The mass enhancement is believed to arise from the formation of a *d*-electron resonance at the Fermi energy close to the transition. The aim of this investigation is to look for evidence of this resonance in the dynamic magnetic susceptibility. We studied samples with $x = 0$, 0.05, and 0.2 using incident energies between 25 and 200 meV. After correction for the phonon scattering, we observe a broad response above a threshold of 20–30 meV extending to over 100 meV. In addition, the Mott insulating antiferromagnet ($x = 0$) has a peak at 40 meV, consistent with the estimated activation energy derived from resistivity measurements. This feature becomes washed out with temperature and doping. Possible origins for this peak are discussed. [S0021-8979(96)44908-6]

On perturbation theory for the three-band model of cuprates

T. A. Kaplan, S. D. Mahanti, and Yen-Sheng Su
Department of Physics and Astronomy and Center for Fundamental Materials Research, Michigan State University, East Lansing, Michigan 48823

K. Kubo

We raise and discuss the following question. Why does the spectrum for the three-band model of Hybertson, Stechel, Schluter, and Jennison, claimed not to be approachable by perturbation theory because of rather large hopping integrals compared to site energy differences, follow precisely what would be expected by low-order perturbation theory? The latter is, for the insulating case, that the low-lying levels are describable by a Heisenberg Hamiltonian with nearest-neighbor interactions plus much smaller next-nearest-neighbor interactions and n-spin terms, $n \geqslant 4$. We first check whether perturbation theory actually does not converge, treating the hopping and p-d exchange terms as perturbations. For the crystal, we find that the first three terms contributing to the nearest-neighbor exchange coupling J (which are of third, fourth, and fifth order) *increase* in magnitude, and are not of the same sign, i.e., there is no sign of convergence to this order. We also consider the small cluster, Cu_2O_7, for which we have carried out the perturbation series to 14th order; there is still no sign of convergence. Thus the nonconvergence of this straightforward perturbation theory is convincingly established. Yet the apparent perturbative nature of the spectrum suggests the existence of *some* perturbation theory that does converge. The possibility of a particular transformation of the Hamiltonian leading to a convergent perturbation series, thereby answering the above question, is discussed. [S0021-8979(96)27008-4]

I. INTRODUCTION

Hybertson, Stechel, Schluter, and Jennison[1] (HSSJ) diagonalized the three-band Hubbard model for finite clusters (on a CuO_2 plane) using parameter values determined previously[2] for La_2CuO_4 by a constrained local density approximation. These values are in essential agreement with those found by others,[3,4] one of which used a different approach; this is a reason these values are considered to be realistic. Because the hopping parameters are not very small compared to on-site energy differences, particularly ϵ_{pd}, it was claimed[2] that usual low-order perturbation theory is not appropriate for the model. We were therefore puzzled by the resulting spectrum, which follows precisely what is expected on the basis of low-order perturbation theory.

In particular for the cluster Cu_5O_{16} with five holes, the low-lying energies were shown[1] to agree with the Heisenberg model (for the five Cu spins) with antiferromagnetic nn (nnn) exchange parameters $J=128$ ($J'=3$) meV. And these levels were separated from the higher ones by an appreciable gap. The puzzling aspects of these results are the smallness of J'/J, the apparent negligibility of four-spin terms in the spin Hamiltonian, and the separation of the low-lying levels from the higher ones, since these are just the properties expected from the usual perturbation theory if it is rapidly converging at low orders.

The first step we have taken in trying to sort out this matter is to check the statement that usual perturbation theory is not expected to be appropriate. In fact we go further and consider the possibility that convergence does not appear until fairly high order, so that four-spin terms, which come in rather high order, might be small. Our results indicate strongly that the usual perturbation theory (the hopping and exchange terms are the perturbation) is not convergent at all, and the consideration of a few orders is useless. Discussion of these results constitutes the main body of this paper. We also indicate that a particular change of one-electron basis, to what Anderson[5] termed the exact localized functions, which were actually defined appropriately by others,[6] might lead to a rapidly converging perturbation theory.

II. HAMILTONIAN AND PERTURBATION THEORY

Because of ambiguities in previous presentations, we write the Hamiltonian explicitly:

$$H = H_1 + H_U + H_K, \tag{1}$$

where

$$H_1 = \epsilon \sum_i n_i^p + t_{pd} \sum_{\langle i,l\rangle,\sigma} (c_{i\sigma}^{d+} c_{l\sigma}^{p} + \text{h.c.}) + t_{pp} \sum_{\langle l,l'\rangle,\sigma} (c_{l\sigma}^{p+} c_{l'\sigma}^{p} + \text{h.c.}), \tag{1a}$$

$$H_U = U_d \sum_i n_{i\uparrow}^d n_{i\downarrow}^d + U_p \sum_l n_{l\uparrow}^p n_{l\downarrow}^p + U_{pd} \sum_{\langle il\rangle} n_i^d n_l^p, \tag{1b}$$

and

$$H_K = K_{pd} \sum_{\langle i,l\rangle} \left(\frac{1}{2} n_i^d n_l^p + 2 \vec{s}_i^{\,d} \cdot \vec{s}_l^{\,p} \right) + K_{pp} \sum_{\langle l,l'\rangle} \left(\frac{1}{2} n_l^p n_{l'}^p + 2 \vec{s}_l^{\,p} \cdot \vec{s}_{l'}^{\,p} \right). \tag{1c}$$

$c_{i\sigma}^{\nu+}$ creates a hole in a Wannier function at site i of type ν, $n_i^\nu = \Sigma_\sigma n_{i\sigma}^\nu$, $n_{i\sigma}^\nu = c_{i\sigma}^{\nu+} c_{i\sigma}^{\nu}$, $s_i^z = (1/2)(n_{i\uparrow} - n_{i\downarrow})$, $s_i^+ = c_{i\uparrow}^+ c_{i\downarrow}$, whose adjoint is the spin lowering operator s_i^-. The orbital at a copper site is $d_{x^2-y^2}$; at each oxygen site there is one p

 0021-8979/96/79(8)/6433/3/$10.00

orbital, of sigma-bonding character. The parameter values are[7] $\epsilon=3.6$, $t_{pd}=-1.3$, $t_{pp}=-0.65$, $U_d=10.5$, $U_p=4$, $U_{pd}=1.2$, $K_{pd}=-0.18$, $K_{pp}=-0.04$, all in eV. [The signs correspond to orbital phases chosen as follows: if $d_{x^2-y^2}$ exists at a particular Cu, then at the O's immediately to its right and left (along the x axis) the orbitals are p_x and $-p_x$, respectively; similarly, the orbitals at the nearest O's below and above are p_y and $-p_y$, respectively. The remaining phases are determined by having the nearest neighbor d-p overlap always negative.]

We choose as the perturbation V the sum of the hopping (t) terms and the exchange (K) terms, the unperturbed Hamiltonian H_0 being H-V. The unperturbed ground state is then characterized by $n_l^p=0$, $n_i^d=1$, its energy is 0 and its degeneracy is 2^N, where N is the number of d sites. We define P as the projection operator on to this unperturbed ground state manifold, with $Q=1-P$. Let Ψ be an eigenstate of H with eigenvalue E. Then the effective Hamiltonian[8] operating on $P\Psi$ can be shown to equal $EP\Psi$, an equation called the projected Schrödinger equation. Considering that the unperturbed ground state energy E_0 is zero, so that E is the change in energy, this projected Schrödinger equation can be expanded in the form[9]

$$P\{VG_0V+VG_0VG_0V+VG_0VG_0VG_0V-(VG_0^2V)\times(VG_0V)+\cdots\}P\Psi=EP\Psi, \tag{2}$$

where $G_0=[Q(E_0-H_0)Q]^{-1}$, Löwdin's inverse of the corner,[8] assumed to exist, and $(A)(B)$ means APB.

Using Eq. (2), we calculated the exchange couplings for two cases. One is the infinite crystal; here we found the three leading contributions for the nn coupling to be

$$J_3=\frac{4t_{pd}^2K_{pd}}{\Delta_1^2},$$

$$J_4=\frac{4t_{pd}^4}{\Delta_1^2}\left(\frac{1}{\Delta_4}+\frac{2}{\Delta_5}\right)-\frac{16t_{pd}^2t_{pp}K_{pd}}{\Delta_1^3},$$

$$J_5=4\left[-\left(\frac{4}{\Delta_1^3\Delta_4}+\frac{8}{\Delta_1^3\Delta_5}+\frac{4}{\Delta_1^2\Delta_2\Delta_4}+\frac{16}{\Delta_1^2\Delta_3\Delta_5}+\frac{8}{\Delta_1^2\Delta_2\Delta_3}\right)t_{pd}^4t_{pp}+\left(\frac{2}{\Delta_1^3\Delta_4}+\frac{4}{\Delta_1^3\Delta_5}+\frac{20}{\Delta_1^3\Delta_3}+\frac{12}{\Delta_1^3\Delta_6}+\frac{4}{\Delta_1^3\Delta_7}+\frac{12}{\Delta_1^2\Delta_3^2}\right.\right.$$
$$\left.\left.+\frac{12}{\Delta_1^2\Delta_6^2}-\frac{42}{\Delta_1^4}\right)t_{pd}^4K_{pd}+\frac{8}{\Delta_1^2\Delta_3^2}t_{pd}^4K_{pp}+\frac{1}{\Delta_1^4}t_{pd}^2K_{pd}^3+\left(\frac{12}{\Delta_1^4}+\frac{4}{\Delta_1^3\Delta_2}+\frac{2}{\Delta_1^2\Delta_2^2}\right)t_{pd}^2t_{pp}^2K_{pd}\right]+\frac{8t_{pd}^2t_{pp}K_{pd}^2}{\Delta_1^4}. \tag{3}$$

(The exchange coupling constant $J=J_3+J_4+J_5+\cdots$.) Here,

$$\Delta_1=\epsilon+U_{pd},\quad \Delta_2=\epsilon+2U_{pd},\quad \Delta_3=2\epsilon+U_{pd}+U_{pp},$$

$$\Delta_4=U_d,\quad \Delta_5=2\epsilon+U_p,$$

$$\Delta_6=2\epsilon+2U_{pd}+U_{pp},\quad \Delta_7=2\epsilon+U_{pd}.$$

(We have added nn p-p repulsion, U_{pp}.) The numerical values of J_3, J_4, J_5 are -0.053, 0.107, 0.231 eV, respectively. The negative value indicates a ferromagnetic contribution. Clearly these do not show an indication of convergence.

The other case is the small cluster Cu_2O_7 with two holes, considered also in HSSJ. In this case there are just singlets and triplets, the lowest singlet-triplet splitting being given by J. Equation (2) in the space defined by zero total z component of spin is a 2×2 matrix equation. Here we calculated up to 14th order, the contributions J_n to J obtained being, for $n=3,4,\ldots,14$,

$$-.053,\ .107,\ .238,\ .065\ ,\ -.267,$$
$$-.272,\ .153,\ .430,\ .077,\ -.474,\ -.375,\ .349. \tag{4}$$

Obviously there is absolutely no sign of convergence. As a check in this small cluster case, we replaced V by λV and took λ small enough to obtain convergence, comparing the result with the exact value (found by directly diagonalizing H).

III. DISCUSSION

The above considerations having given rather convincing evidence that the (standard) perturbation approach used is simply not convergent, we are left with our original question, why then do the *results* of exact calculation show the properties expected from perturbation theory? The following possibility seems promising. The Hamiltonian (1) is written in terms of field operators c_i for some set of Wannier functions, w_i. These have been assumed real and to have certain symmetry under point group and translation operations. But such functions are not unique; i.e., there are real linear orthogonal transformations of these functions which preserve this symmetry property. In trying to provide a realization of Anderson's concept[5] of "exact localized or Wannier functions," a simple model of a small cluster and of a linear chain (which can be considered as Cu-O-Cu with two holes and an infinite Cu-O-Cu-O chain with one hole per Cu) were studied.[6] There the general two-band model was treated. In perturbation theory based on arbitrary Wannier functions, there are contributions to J of fourth order in the d-p overlap from first through fourth order in formal perturbation theory. It was shown that in a perturbation expansion based on the nonmagnetic localized solutions of the thermal single determinant approximation (TSDA),[10] the convergence through fourth-order perturbation theory is dramatically improved. Higher-order studies were not carried out since the materials of interest at that time, e.g., NiO and $KNiF_3$, are highly ionic and the perturbation expansions were expected to converge

rapidly. Clearly that approach might be very useful in the present case of the cuprates where the degree of covalence is so high that the perturbation theory is nonconvergent. We have made some preliminary calculations along these lines for very small clusters. In particular we were able to convert the nonconvergent series (4) to a convergent series (converging to the exact value of J). These ideas will be submitted for publication elsewhere.[11]

We note that if there is a rapidly convergent perturbation approach for the present problem with its presumably realistic parameter values, there is an implication that precise *ab initio* quantum chemical calculations for the solid as a whole might be possible.[12]

We add that after the present work was completed, we became aware of some literature that is quite relevant, namely, Refs. 13 and 14. The approaches of these two groups (Refs. 13 and 14) are very similar to each other, and are in the spirit of our attempts to find a convergent series. But their approach is different from ours. The relationship between the approaches is presently under study, and will be discussed elsewhere.[11]

Magnetic measurements on $Cd_{1-x}Cr_xTe$ and $Zn_{1-x}Cr_xTe$

T. M. Pekarek, I. Miotkowski, and B. C. Crooker
Department of Physics, Purdue University, West Lafayette, Indiana 47907

We have investigated the magnetic properties of single-crystal $Cd_{1-x}Cr_xTe$ and $Zn_{1-x}Cr_xTe$ samples. The magnetization is anisotropic (~7% for $Zn_{1-x}Cr_xTe$ and ~0.4% for $Cd_{1-x}Cr_xTe$) with the (111) direction having the greatest value. We have found that the magnetic behavior in fields up to 6 T and temperatures between 1.5 and 324 K for both systems is well described by a theoretical model with crystal field, Jahn–Teller, spin-orbit, and spin-spin terms including ligand field corrections to the spin-orbit and spin-spin parameters. Good agreement was found between the experimental results and the theoretical calculations for a Jahn–Teller splitting of 370 and 320 cm^{-1} and effective spin-orbit parameters of −49.9 and −59.4 cm^{-1} for $Cd_{1-x}Cr_xTe$ and $Zn_{1-x}Cr_xTe$, respectively. The key feature is an orbital singlet, $S=2$ ground state with a small splitting (1.5 K for $Cd_{1-x}Cr_xTe$ and 12.4 K for $Zn_{1-x}Cr_xTe$) of the m_s states. © *1996 American Institute of Physics.* [S0021-8979(96)27108-0]

I. INTRODUCTION

The class of II–VI diluted magnetic semiconductors (DMS)[1] include the systems of the form $A^{II}_{1-x}M_xB^{VI}$, where M is a transition metal ion (e.g., Mn, Fe, Co, or Cr) and $A^{II}B^{VI}$ is a II–VI semiconductor host. Over the past two decades, much work has been done on the magnetic behavior of Mn,[1] Fe,[2,3] and Co[4–6] based systems. Early work on low concentration Cr-based II–VI semiconductor crystals include optical absorption,[7–10] luminescence,[11] and electron paramagnetic resonance[12] (EPR) experiments. Recently, interest in the chromium based systems has reemerged resulting in the publication of several theoretical[13–17] and experimental[18–21] papers including magnetization measurements for $Zn_{1-x}Cr_xTe$[18] and $Zn_{1-x}Cr_xSe$.[17,19,20] What makes these systems interesting is the presence of a static Jahn–Teller distortion as well as the observation of a ferromagnetic p-d coupling in $Zn_{1-x}Cr_xSe$.[17,21]

$Cd_{1-x}Cr_xTe$ is unique among the chromium-based DMS because of its small splitting of the ground multiplet. Early work reported a value of $D=+0.260\pm0.004$ cm^{-1} (=0.374 K) for $Cd_{1-x}Cr_xTe$ which was obtained from EPR measurements.[12] This value of D is approximately an order of magnitude below the other chromium-based DMS which all have a magnitude for D within a factor of 1.4 of each other ranging from 2.6 K in $Cd_{1-x}Cr_xS$ to 3.6 K in $Zn_{1-x}Cr_xSe$.[12] It has been proposed previously that the trend in D in $Zn_{1-x}Cr_xS$, $Zn_{1-x}Cr_xSe$, and $Zn_{1-x}Cr_xTe$ could be accounted for with a model including ligand field corrections to the spin-orbit and spin-spin parameters.

In this article we present magnetization measurements taken on bulk $Cd_{1-x}Cr_xTe$ and $Zn_{1-x}Cr_xTe$ crystals. Using the model Hamiltonian discussed previously,[10,18] we numerically diagonalized the 25×25 matrix to compare the predicted magnetization with our experimental results. We discuss the slight magnetic anisotropy (0.8%±0.9% at 5.2 K in 6 T) in $Cd_{1-x}Cr_xTe$ with the larger anisotropy in the magnetization observed for $Zn_{1-x}Cr_xTe$[18] and $Zn_{1-x}Cr_xSe$[19,20] in the context of the splitting of the ground multiplet. And, the anomalously low value of D in $Cd_{1-x}Cr_xTe$ is compared with the $Zn_{1-x}Cr_xB^{VI}$ series.

II. EXPERIMENTAL DETAILS

Single-crystal samples of $Cd_{1-x}Cr_xTe$ and $Zn_{1-x}Cr_xTe$ were taken from boules with nominal concentration of $x=0.05$ and 0.005, respectively. Typically, samples grown by the vertical Bridgman method yield actual concentrations less then the nominal value. We report on samples with actual concentrations, which is the only adjustable variable for the magnetization calculated from the 25×25 Hamiltonian, of $x=0.0036$ and $x=0.0031$ for $Cd_{1-x}Cr_xTe$ and $Zn_{1-x}Cr_xTe$, respectively. Both samples were oriented along the (111) and (100) directions using the standard Laue technique.

Magnetic measurements were made between 1.5 and 324 K in fields up to 6 T using a Cryogenic Consultants Limited SQUID magnetometer. A ferromagnetic minority phase was observed in each of our samples which accounts for ~10% of the chromium and is 90% saturated by 0.25 T at 10 K. Above 0.4 T at low temperatures, the ferromagnetic component is nearly saturated. A detailed analysis of the temperature dependence of the ferromagnetic phase will be presented elsewhere.[22] Both the diamagnetic signal from the host II-VI semiconductor and the saturated magnetization from the minority ferromagnetic phase were subtracted to yield the magnetization as a function of field.

III. EXPERIMENTAL RESULTS AND DISCUSSION

Shown in Fig. 1 is the magnetization versus field data at 5.2 K for $Cd_{1-x}Cr_xTe$ oriented along the (111) and (100) directions. A slight anisotropy of 0.8%±0.9% is observed at 6 T. The solid line in Fig. 1 is a Brillouin fit assuming a pure spin two system with a concentration of $x=0.0037$. If there were a significant splitting of the ground multiplet, we would expect the magnetization to deviate noticeably from the Brillouin response and exhibit a significant anisotropy.[6,18–20] However, as can be seen, the data up to 6 T are well described by this simple model indicating, along with the very slight anisotropy, that the zero-field splitting of the ground multiplet is small. We have also made calorimetric measurements which further confirm the anonymously small value of D in $Cd_{1-x}Cr_xTe$.

 0021-8979/96/79(8)/6436/3/$10.00

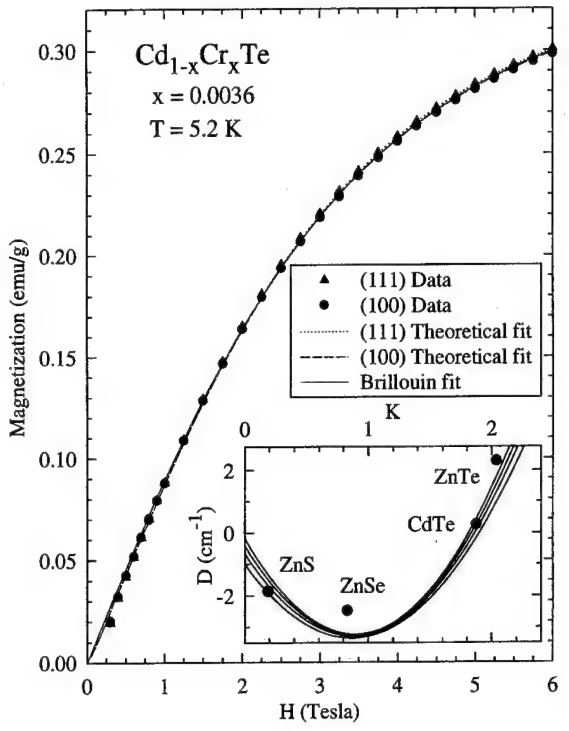

FIG. 1. Magnetization data for $Cd_{1-x}Cr_xTe$ taken at 5.2 K for the (111) and (100) orientations. The theoretical fit obtained from the 25×25 Hamiltonian for each orientation is shown by the dotted and dashed lines. Note that the theoretically predicted anisotropy is negligible on this scale. The solid line is a fit using a Brillouin function. Good agreement is found between the data and a Brillouin function because of the very small splitting of the ground multiplet. The ferromagnetic and diamagnetic contributions have been subtracted. Shown in the inset is a plot of D vs K for several chromium based DMS. The solid lines in the inset show the theoretical prediction for a model including ligand field corrections to the spin-orbit and spin-spin parameters.

However, it is not transparent why the ground multiplet is nearly degenerate. In order to explain our magnetic measurements on $Cd_{1-x}Cr_xTe$, the complete 25×25 complex Hamiltonian for the ^5D state was constructed including the crystal field, Jahn–Teller, spin-orbit, and spin-spin effects including ligand field corrections to the effective spin-orbit and spin-spin parameters.[12,18] It has been shown previously[12] that the general trend in D in $Zn_{1-x}Cr_xS$, $Zn_{1-x}Cr_xSe$, and $Zn_{1-x}Cr_xTe$ could be accounted for with a model including ligand field corrections to the spin-orbit and spin-spin parameters using the perturbative result

$$D=\frac{\lambda_1^2}{E_1}-\frac{4\lambda_2^2}{E_2}-3\rho_3, \tag{1}$$

where $E_1=3E_{JT}$, $E_2=E_{JT}+\Delta-2E_{JTE}$, Δ is the crystal field splitting parameter, and E_{JT} and E_{JTE} are the Jahn–Teller energies for the orbital triplet ($^5T_2$) and doublet (^5E), respectively. The corrections due to the ligand field can be reduced to one adjustable parameter K which sets the magnitude of the coupling. The effective spin-orbit and spin-spin parameters are then given by

$$\lambda_1\cong\lambda(1-K),$$

$$\lambda_2\cong\lambda\left(1-\frac{K}{8}\right), \text{ and} \tag{2}$$

$$\rho_3\cong\frac{5}{9E}(-\lambda_1^2+4\lambda_2^2)+\rho,$$

where $E\cong 20\,000$ cm^{-1} is the energy of the next highest LS state of the same symmetry ($3d^4$) and λ and ρ are the free-ion spin-orbit and spin-spin parameters, respectively.

Shown in the inset of Fig. 1 is a plot of D vs K for several chromium based DMS which are shown by solid circles. We note that our value for $K=2.0$ for $Zn_{1-x}Cr_xTe$ was determined from numerically diagonalizing the 25×25 Hamiltonian and is lower then the previously reported value of 2.33 determined from a perturbative treatment. The values of K for $Zn_{1-x}Cr_xS$ and $Zn_{1-x}Cr_xSe$ were calculated by scaling our value of K for $Zn_{1-x}Cr_xTe$ by the ratio of the ligand spin-orbit constants $\zeta_S/\zeta_{Te}=1689$ cm^{-1}/382.4 cm^{-1} or $\zeta_{Se}/\zeta_{Te}=1689$ cm^{-1}/4136 cm^{-1}.[12] The four solid lines were calculated using Eq. (2) for the set of parameters for each of the four systems shown.[10,18,22] As can be seen, the general trend is satisfactorily predicted for $Cd_{1-x}Cr_xTe$ ($K=1.9$) as well as the $Zn_{1-x}Cr_xB^{VI}$ series.

The dotted and dashed lines shown in Fig. 1, which are nearly indistinguishable on this scale, are theoretical fits for the (111) and (100) directions which were calculated using the 25×25 Hamiltonian with a Jahn–Teller energy of 370 cm^{-1} and effective spin-orbit and spin-spin parameters within the lower 15×15 ($^5T_2$) state of −49.9 and 0.29 cm^{-1}, respectively. These parameters result in a small 1.5 K total splitting ($4D$) of the ground orbital singlet multiplet in agreement with the EPR measurements.[12] The Hamiltonian predicts a 0.44% anisotropy in 6 T which is in good agreement with the data. In our analysis we have assumed that the Jahn–Teller distortions are randomly distributed along the three equivalent crystalline axes as was observed in the $Zn_{1-x}Cr_xTe$ system.[18] As can be seen from Fig. 1 the agreement between the theory and experiment is good with the concentration $x=0.0035\pm0.0005$ being the only adjustable parameter.

Shown in Fig. 2 is the magnetization versus field data at 3.67 K for a $Zn_{1-x}Cr_xTe$ crystal oriented along the (111) and (100) directions which has been presented previously.[18] The solid line is a Brillouin fit assuming a pure spin two system with a concentration of $x=0.0035$. In contrast with the $Cd_{1-x}Cr_xTe$ data, the disagreement between the data and Brillouin fit is obvious indicating a splitting of the ground multiplet. Further magnetic evidence of the splitting of the ground multiplet is the presence of an anisotropy (~7% at 3.67 K in 6 T) in the data. The theoretical response obtained from the Hamiltonian is shown by the dotted and dashed lines for a Jahn–Teller energy of 320 cm^{-1} and effective spin-orbit and spin-spin parameters within the ground $^5T_2$ state of −59.4 and 0.32 cm^{-1}, respectively.

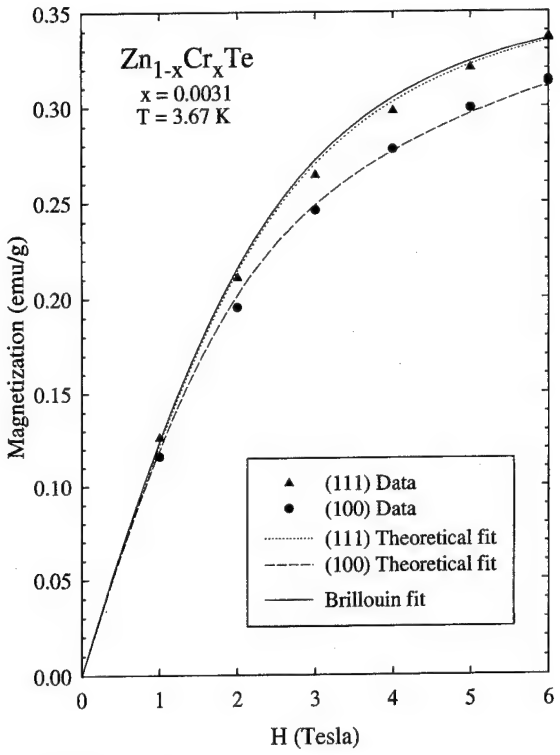

FIG. 2. Magnetization data for $Zn_{1-x}Cr_xTe$ taken at 3.67 K for the (111) and (100) orientations. A theoretical fit obtained from the 25×25 Hamiltonian for each orientation is shown by the dotted and dashed lines. The solid line is a fit using a Brillouin function. An ~7% anisotropy and deviation from the Brillouin fit is evident due to the splitting of the ground multiplet. The ferromagnetic and diamagnetic contributions have been subtracted.

IV. CONCLUSIONS

We have presented magnetization data on $Cd_{1-x}Cr_xTe$ and $Zn_{1-x}Cr_xTe$. The key feature of these systems is an orbital singlet, $S=2$ ground state with a small splitting (1.5 K for $Cd_{1-x}Cr_xTe$ and 12.4 K for $Zn_{1-x}Cr_xTe$) of the m_s states. The theoretical model we have used provides a good description for the magnetization for both the $Cd_{1-x}Cr_xTe$ and $Zn_{1-x}Cr_xTe$ systems which are the only chromium based II–VI DMS which are reported to have a positive value for D. Agreement was found between the experimental results and the theoretical calculations for a Jahn–Teller splitting of 370 and 320 cm^{-1} and effective spin-orbit parameters of -49.9 and -59.4 cm^{-1} for $Cd_{1-x}Cr_xTe$ and $Zn_{1-x}Cr_xTe$, respectively. The theory correctly predicts the anisotropy and field dependence of the magnetization for both systems and accounts for the anonymously low value of D in $Cd_{1-x}Cr_xTe$.

Specific heat of R_3Co (R: La,Pr, and Nd) (abstract)

I. Umehara, K. Nakano, Q. F. Lu, and K. Sato
Department of Physics, Faculty of Engineering, Yokohama National University, Yokohama, Japan

It was reported that La_3Co is an interesting superconductor which has a critical temperature T_c of 4.5 K.[1] Pr_3Co and Nd_3Co are ferromagnetic materials, which have Curie temperatures of 10 and 25 K, respectively. It was claimed that their magnetic structures are associated with the canting moment reflected to the symmetry of their crystal structure.[2] In this paper we present the results of the specific heat measurement in these compounds in the temperature range from 2 to 30 K by a standard adiabatic heat pulse method. Two phase transitions are observed at 8 and 25 K in Nd_3Co. One of them at 25 K corresponds to the Curie temperature mentioned above. Another is the transition corresponds to the moment reorientation, which was observed in the thermomagnetic curves and electrical resistivity measurement. This results claim that the moments are canted in this compounds. Magnetic entropy reaches 90% of R ln 2 at 25 K. However, it increases above the Curie temperature because the crystalline electric field effects plays an important role in this compounds. There are two peaks of 10 and 12 K in Pr_3Co. The above temperature corresponds the Curie temperature but another was unknown. Thus we performed the specific heat measurement for Pr_7Co_3, which is very close to the Pr_3Co in the phase diagram. We could observe the phase transition at 12 K for Pr_7Co_3 in the specific heat measurement and electric resistivity measurement. It is clear that the phase transition at 12 K comes from impurity of Pr_7Co_3 in our Pr_3Co compound. We prepare the good quality sample of Pr_3Co and try to examine the specific heat measurement. Magnetic force microscopy is finding widespread use in the analysis of magnetic structure at length scales relevant to modern storage densities. We present a new technique which uses the extremely localized stray fields of MFM tips to probe submicron media characteristics. The tip is brought into contact with the magnetized media, and a uniform external field H_{ext} is momentarily added to the tip's stray field. If the net field exceeds the local media coercivity, the magnetization is reversed locally, and a "bit" is written. High-resolution MFM imaging of the results is done immediately using the same probe. Bit arrays of several Gbit/in^2 can be produced with the lithography software of a commercial MFM. Using the external field H_{ext} as a parameter, the threshold for bit writing can be determined, giving a measure of the local, or "point", coercivity of the media on a 100 nm scale. Results for perpendicular Co–Cr and magneto-optical media can deviate significantly from conventional bulk hysteresis measurements, in some cases reversing the bulk coercivity ranking. Intermediate values of H_{ext} reveal spatial variations in the point coercivity due to fluctuations in composition or microstructure. In square media, sufficiently strong fields H_{ext} cause existing bits to grow, leading to bulk reversal via front propagation, and allowing a direct measurement of wall motion coercivity. Possible extensions to longitudinal media will be discussed. In general, combining the imaging and writing capabilities of MFM probes gives a direct assessment of media response to very localized fields, and leads to a powerful method for relating microstructure to bulk hysteresis properties. Magnetic force microscopy (MFM) in the presence of an external magnetic field has been developed. This has led to further understanding of image formation in MFM as well as new insights concerning the interaction of magnetic recording media with an external field. Our results confirm that, at low applied fields, image formation results from the interaction of the component by the local surface field along the direction of the probe's magnetization. By reorienting the probe's magnetization by an appropriate application of an external field, it is possible to selectively image specific components of the local field. At higher applied fields, the probe becomes saturated and the changes in the images may be attributed to magnetization reversal of the sample. We have observed the transformations that occur at various stages of the dc erasure of thin-film recording media. This technique has also been applied to conventional magneto-optical media to study domain collapse caused by increasing temperature with an external bias field. The methods, results, and their analysis are presented. © *1996 American Institute of Physics.* [S0021-8979(96)57008-5]

I. INTRODUCTION

Since the first reports of its development in 1987,[1] magnetic force microscopy (MFM) has emerged as a powerful tool in understanding the micromagnetics of surfaces.[2] Its capability to resolve $\lesssim$100 nm features, combined with lenient requirements on sample preparation and operating environments, has made it a workhorse in technology development as well as fundamental investigations of surface[3] and biological[4] magnetism. Despite its widespread use, however, most MFM images were obtained under ambient magnetic field conditions. As a result, studies have been limited to samples being either in a locally nonmagnetized or remanent states.

Recently, the capability of imaging samples in the presence of an external magnetic field has been developed.[5] This has allowed direct imaging of the microscopic evolution of thin-film recording patterns undergoing dc erasure; and has opened up the possibility of investigating microscopic magnetic properties of surfaces at any point along the magnetization curve. In this paper, we provide the details of our technique and discuss the implications of subjecting both the probe and sample to an external field. We focused our studies on thin-film recording and magneto-optical media, not only because of their importance in the storage industry but because they represent excellent case models for in-plane and out-of-plane magnetization structures.

II. TECHNIQUE

A. Background

Magnetic force microscopy generates a two dimensional mapping of the local force-gradient between a magnetic probe and a sample, separated by about a hundred nanometers. The probe is comprised of a cantilever beam with a sharp, magnetic tip at one end that is forced to oscillate at its resonance frequency. It is then rastered across the surface while the changes in the oscillation phase of the cantilever are recorded in an array as a function of its two dimensional lateral position. The change of the oscillation phase is directly proportional to the force gradient, so that the resulting array, by using computer graphics, forms an image of the distribution of the local force gradient.

The technique can be understood by considering the motion of the cantilever probe as a single-point mass m undergoing one-dimensional forced harmonic oscillation along the vertical z axis.[6] The resonance frequency is determined by the intrinsic elastic constant of the cantilever, in combination with a small perturbation due to the probe-surface interaction force $F(z)$. The latter is incorporated by expanding $F(z)$ in a Taylor series and keeping the first order term $F' = \partial F/\partial z_0$. When the driving frequency is near the resonance, $\omega \sim \omega_0$, the local force gradient F' will shift the resonance frequency by an amount $\Delta\omega_0 \approx \omega_0(F'/2k)$. As a consequence, the phase will vary from its nominal 90° out-of-phase condition relative to the driving term by an amount

$$\Delta\phi \approx -2Q\frac{\Delta\omega}{\omega_0} = -\frac{QF'}{k}, \tag{1}$$

where Q is the quality factor of the cantilever. The phase variation at each point is proportional to the local force gradient.

Our commercial device, the Nanoscope III MFM, operates in the so-called lift and phase sensitive detection method.[7] The topography of the surface is first measured by using atomic force microscopy techniques and the contour is retraced with the probe at a preset height above the surface

 0021-8979/96/79(8)/6441/6/$10.00

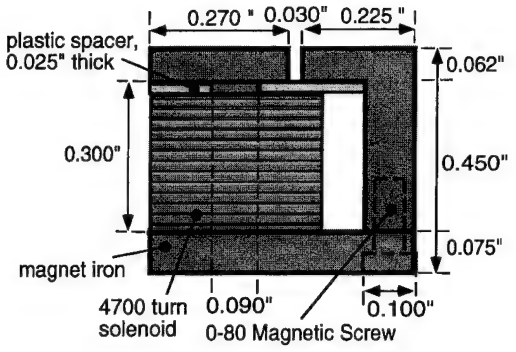

FIG. 1. Electromagnet design for MFM with an external in-plane magnetic field.

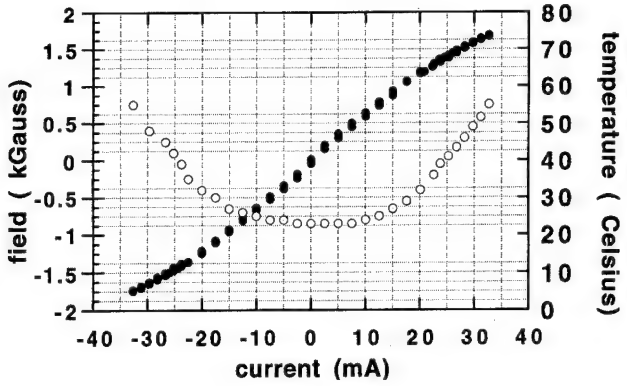

FIG. 2. Magnetic field and temperature calibration vs input current.

as the force-gradient is measured. In this manner, the surface topographical effects are minimized.

Since the probe is coated with a ferromagnetic alloy, the tip-surface force is dominated by the magnetic interaction if short-range adhesion forces[8] are neglected. For simplicity, we describe the tip as a single constant magnetic dipole, $\mathbf{m}_{\text{tip}}$. The force experienced by this dipole in a local magnetic field $\mathbf{H}$ is[2]

$$\mathbf{F}=-(\mathbf{m}_{\text{tip}}\cdot\nabla)\mathbf{H}. \tag{2}$$

Only the z component of the force contributes to the oscillation. By differentiating with respect to z and using $\nabla\times\mathbf{H}=0$, Eqs. (1) and (2) yield an explicit expression for contrast formation in phase-detection MFM:

$$\Delta\phi\approx\frac{Q}{k}\sum_i m_i\frac{\partial^2 H_i}{\partial z^2}. \tag{3}$$

This equation states that as long as the magnetic properties of the sample and the probe are unaffected by their mutual interaction, the contrast in MFM arises from the variations of the second z derivative of the component of the surface field in the direction of the probe's magnetization.

One consequence of Eq. (3) is that it is possible to selectively image specific components of the second derivative of the local surface magnetic field by appropriately orienting the probe magnetization direction. In other words, by a judicious choice of probe magnetization directions, it is feasible to individually map out the z derivatives of the three Cartesian components of the local surface magnetic field vectors. One way, of course, is to prepare probes in a highly controlled manner in order to have the easy axis aligned along definite directions. In principle, specific probes can be used to image particular surface field components. In our experiments, however, the reorientation of the direction of the probe's magnetization is accomplished by applying an external dc magnetic field during imaging. The intention is to orient the probe magnetization by sufficiently low fields which preclude significant effects on the sample.

B. Magnet design

Adding an external field in MFM involves the incorporation of an electromagnet at the sample stage. Figure 1 shows the critical details of our design which produces magnetic fields primarily oriented along the sample surface plane. The dimensions were constrained by the available space in our device. The materials and coil specifications were chosen to optimize the magnetic field strength generated at the gap location and subject to a heating constraint to prevent temperature-induced problems, such as drifts, depolarization of the piezoelectric scanners, and heat-induced changes in the sample magnetic properties. The magnetic field generated in the gap of length L_g can be estimated as

$$B_g\cong\frac{\mu_0 NI}{L_g}\quad\text{(MKSA units)}, \tag{4}$$

where N is the total number of turns, I is the current, and μ_0 is the permeability of free space. This can be derived from Ampere's law for the case where the permeability of the iron core is large. The relevant parameters are: N=4700 turns and L_g=0.76 mm. At 30 mA, B_g=2330 G and it is expected to reach saturation at B_g=4500 G for a current of 56 mA. A measurement of the horizontal component of the field, shown in Fig. 2, was obtained by using a miniature Hall probe (LakeShore HT 2100) which was calibrated against a known field. The data indicate that the magnetic field varies linearly with current from 0 to 30 mA, demonstrating that within this range, the iron yoke is driven at the reversible regime of its magnetization curve. High-frequency fluctuations in the field were found to be about 0.5%. Similarly, the temperature was measured by using a calibrated thermocouple which was spot welded near the gap region. Heating effects, concurrently plotted in Fig. 2, show that a dc current of up to 32 mA elevates the temperature to less than 55 °C.

III. RESULTS AND DISCUSSION

The samples used in our experiment were obtained from conventional and experimental thin film disks as well as conventional magneto-optic samples. The macroscopic properties of some of these samples were previously measured and reported elsewhere.[5,9]

A. Probe effect: Component-resolved imaging

Confirming the predictions of Eq. (5), the individual components of the local surface magnetic fields of the thin film in-plane recorded medium are shown in Fig. 3. A diagram representing the expected distribution of the magneti-

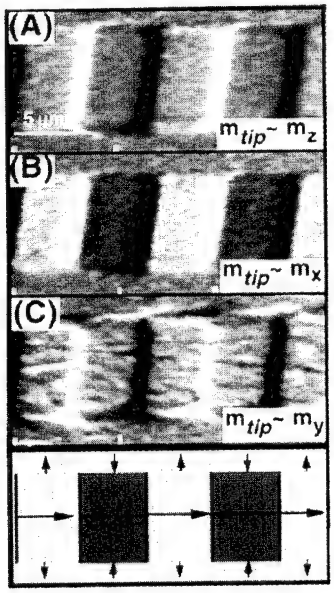

FIG. 3. Component-selective images of a thin-film recording medium. Images obtained with probe nominally oriented along the (A) normal z axis, (B) in-plane x axis, and (C) in-plane y axis, reflecting the contributions of the local surface field at these directions, respectively. Bottom: sketch of the magnetization pattern.

zation distribution is drawn in the bottom of the figure. Figures 3(A) and 3(B) were obtained from the same area of the disk. In Fig. 3(A), the probe was premagnetized by a 3.5 kOe magnet along the vertical direction prior to image acquisition and no external horizontal field was applied to the sample. Neglecting some nonlinear effects due to the probe-sample interaction, the probe magnetization in Fig. 3(A) can be taken as $m \sim m_z; m_x, m_y \sim 0$. The contrast formation in Fig. 3(A) arises predominantly from $\partial^2 H_z/\partial z^2$ and it appears as an alternating series of bright and dark strips that are more or less localized along the transition regions. Note that despite the fact that the pattern is a series of alternating in plane magnetizations, very little contrast can be observed within the interior regions of the patterns. In fact, the image contrast in the interior regions is similar to the background areas outside of the patterns. In Fig. 3(B), which was acquired with a 200 Oe field along the track direction, the interior features have emerged and the two opposite magnetization directions are clearly distinguishable. This arises because the external horizontal dc magnetic field produced a nonvanishing m_x component of the probe magnetization which induces a dominant term proportional to $\partial^2 H_x/\partial z^2$.

We offer the following qualitative interpretation of these images in terms of the physical quantities such as the magnetic charges and the magnetization. For illustrative purposes, consider the simple case of a one-dimensional sinusoidal magnetization pattern $M_x = M_0 \sin(kx)$, in a medium of thickness δ. The local surface magnetic field components above the surface for this configuration can be computed,[10] and the corresponding second derivatives with respect to z are

$$\frac{\partial^2 H_z}{\partial z^2} \propto \nabla \cdot M = \frac{\partial M_x}{\partial x} \tag{5}$$

and

$$\frac{\partial^2 H_x}{\partial z^2} \propto M_x . \tag{6}$$

In other words, MFM imaging with the z-axis probe orientation yields images that are proportional to the divergence of the magnetization or the volume magnetic charge density while the x-axis orientation yields images that are proportional to the distribution of magnetization. In real systems, the images may deviate from this simple interpretation, albeit only slightly. For example, for an in-plane arctangent transition with a transition length of 150 nm, the main difference between the divergence of the magnetization and the second derivative of the field with z is the broadness of the peak. The FWHM widths are 400 nm for $\partial M/\partial x$ and 200 nm for $\partial^2 H_z/\partial z^2$.[11] Once instrumental resolution limits of about 100 nm are taken into account, the distinction becomes less conspicuous. Naturally, in order to obtain quantitative results, one would have to use Eq. (3) to derive the actual image of magnetization from a set of MFM raw images.

By extending this approach, we have selectively imaged the crosstrack or y component[12] as shown in Fig. 3(C). This is obtained by preparing the sample such that the tracks are perpendicular to the direction of the applied field. Note that apart from the contrast at the transition regions, pairs of localized bright and dark areas are visible along both edges of the track. These crosstrack features are distinctive in that a predominantly bright edge structure is paired with a dark edge structure on the opposite edge in any specific "bit." (By a "bit," we mean the entire rectangular area having a constant magnetization direction.) These edge features are clearly distinct from the edges in Fig. 3(A), although both are manifestations of the same magnetic feature. In one case, the transverse component of the edge magnetization (as drawn in the diagram) is detected, and on the other, the z component or the magnetic charges accompanying the edge magnetizations are measured. The intensity of the features are relatively weak in comparison with the main transitions, which explains the higher noise contribution in the image. In general, they depend upon the combined effects of the head geometry and a weakly oriented recording medium.[12]

While the images still show partial mixing between the individual components of the field, they nevertheless clearly support the assertions of Eq. (3). The recurring influence of the z contribution may have resulted from the combination of two effects, namely, the external field having a component along the z direction or the probe having a slight anisotropy favoring vertical alignment.

B. Probe hysteretic effects

Having established the reorientation of the probe due to the external field, we now study the probe hysteretic behavior along the x direction. Specifically, we focus on the transformation of the images as the horizontal field is cycled between moderately large negative and positive values. The

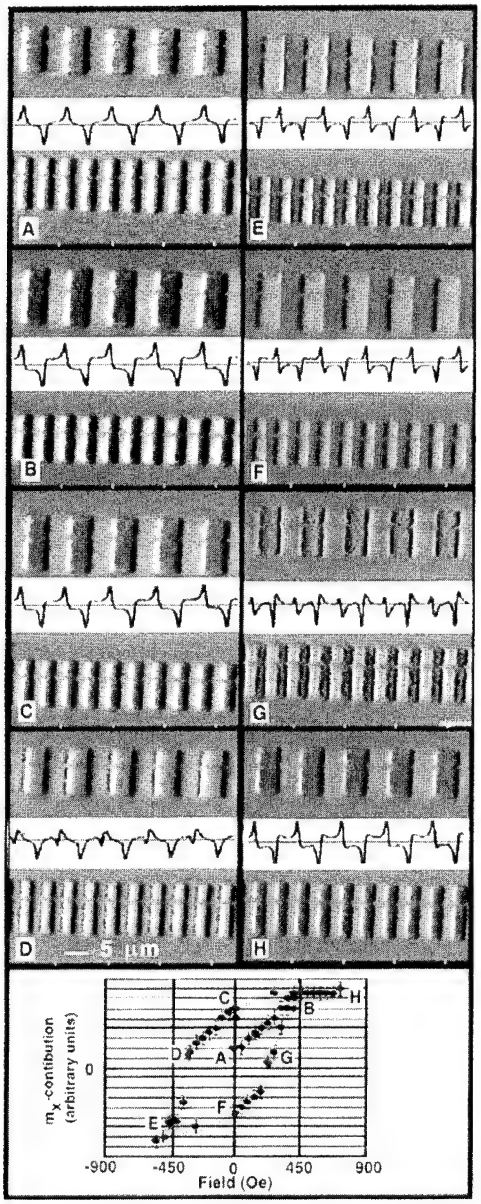

FIG. 4. Hysteretic behavior of MFM probe magnetization along x axis and corresponding images at saturation, remanence, and coercivity.

main goal is to derive, from the images, the changes in the m_x component of the probe under an external bias dc field.

The result is summarized in Fig. 4. The sequence was started by premagnetizing the probe along the vertical direction and acquiring the initial image. The horizontal field was slowly raised up to +500 Oe, ramped back down to −500 Oe, and again reversed direction to +700 Oe. Images were acquired at each field increment all along the cyclic path. The plot at the center of the figure is an actual measurement of the probe's horizontal magnetization component. Each data point along this curve was derived by averaging the line profiles of the upper (long wavelength) track as shown in the images. Since the images were obtained from the same area and the external field was low in comparison with the coercivity of the medium (H_c>1600 Oe), then the magnetization component of the probe along the track direction can be derived from the images and Eq. (3). Ideally, this can be done by fitting each of the experimental lineshapes with the modeled response given by Eq. (3) and extracting the relative coefficients m_x and m_z. However, since the z-component contribution is confined at the transition regions, we simply derived the m_x contribution for each image by measuring the average contrast levels at the midpoints of the "bits" while keeping track of the separate magnetization directions. The resulting plot clearly exhibits the hysteretic property of the probe.

Special points along the probe's magnetization loop are shown in images 4(A)–4(H). They depict how changing the probe magnetization alters the image formation. The contrast mechanism with no applied field is shown in image 4(A), after performing the standard procedure of pre-magnetizing the probe along the z direction. The features are confined exclusively at the transition regions and thus, the horizontal probe magnetization components m_x can be taken to be nearly zero at this initial state. This is a widely used implementation of the MFM and most images of thin-film media in the literature belong in this category.

The contribution of the horizontal component increases linearly with the field until it attains the contrast shown in 4(B). Further increases of the external field do not produce significant variations since the probe's magnetization is saturated along the direction of the field. Once the field has been removed, however, image 4(C) differs only slightly from the saturated state, indicating that horizontally realigned domains maintain their orientation. This large remanent magnetization can be beneficial in being able to premagnetize the probe along the horizontal direction instead of the customary vertical direction, and increase its sensitivity in detecting the local horizontal field contribution. Note, however, that while the horizontal component is large, the contribution from the z component is still quite significant. This implies that the probe contains numerous domains, some of which have strong anisotropy favoring magnetization along the z direction.

The onset of m_x reversal is illustrated in 4(D), which also identifies the coercivity of this specific probe. Note that while $m_x \sim 0$, the image is clearly different from 4(A). Weak dark strips have appeared to the left of the nominally bright areas. This suggests that the process of magnetization reversal in the x direction invariably causes some moments to rotate in the opposite z direction. At negative saturation, image 4(E) shows the complete reversal of the contrast, including the vertical component. Upon removal of the field, the resulting image 4(F), which is at negative remanence, shows a somewhat weaker vertical component. It appears that some of the moments that were oriented along the $-z$ direction have reverted back to $+z$ or to the other orthogonal directions when the field was removed. The amount of m_z retention appearing less in 4(F) than in the positive remanence image 4(C) is due to the fact that the probe was deliberately oriented in the $+z$ direction before application of the field.

At positive coercivity, image 4(G) is analogous to 4(D), with the exception that the dark regions are affected by high-frequency noise. We speculate that since the probe is in a demagnetized state, the influence of local fields at the dark

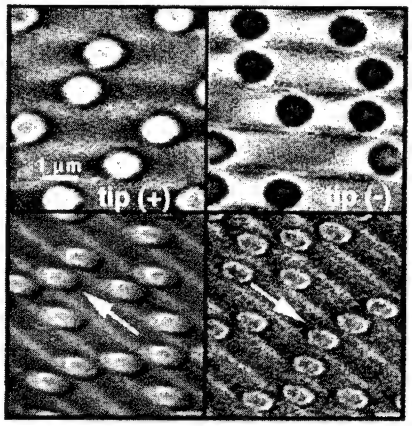

FIG. 5. MFM images of magneto-optic medium at various probe orientations. Tip (+) and tip (−) indicate vertically premagnetized probes, arrows indicate directions of the 600 Oe in-plane external field.

regions may induce transient switching of some magnetic moments of the probe which leads to a noisy image. As the field is brought back to positive saturation, image 4(H) appears identical to 4(B), except that the contrast at the transition areas (z contribution) appears to be less pronounced. In successive experiments, we observed that the z contribution decreases progressively and repeated cycling of the horizontal fields destroys the m_z alignments of the probe.

In the above discussion, the probe orientation was assumed to be perpendicular to the surface. In practice, however, there is a slight angle of about 10° between the main axis of the conical tip and the true vertical direction. This may account for some of the asymmetries between the equivalent points along the ascending and descending branches of the m_x-H loop.

Probe reorientation effects for perpendicularly magnetized surfaces are a conventional magneto-optic media are shown in Fig. 5. The upper images, obtained at no bias field, correspond to a vertically oriented $m_{\text{tip}} \approx m_z, m_x, m_y \approx 0$ while the lower images, obtained at ± 500 Oe horizontal applied fields, correspond to a nonvanishing m_x component. The contrast reversals follow directly from the change in sign of Eq. (3).[13] In analogy with the treatment of in-plane magnetization, we assume a simple model for the surface magnetization $M_z = M_0 \sin(kx)$. The interpretation that the z-component imaging is sensitive to the distribution of magnetic charges still holds. One distinction, however, is that in this case the volume charge density vanishes and the discontinuity of magnetization at the surface-air interface produces the surface magnetic charges. Hence, the z-component images are proportional to M_z. From Laplace's equation, it follows that the x-component images must be proportional to the discontinuity of surface charges. In other words, the x-component images are sensitive to the domain walls.[14] This property is illustrated in the lower images which show the bright and dark features on opposite edges of the marks which follow the direction of the applied field.

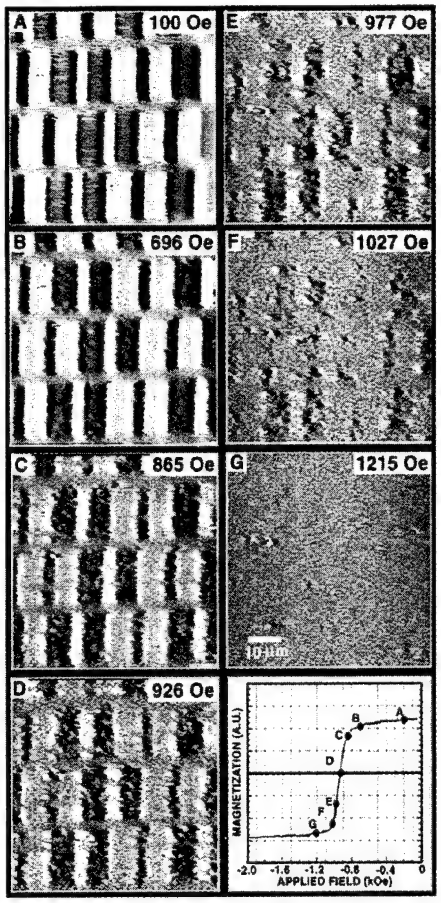

FIG. 6. Erasure of thin-film recording medium with increasing dc field.

C. Erasure process of a thin-film medium

Once the probe's response to the field is understood, the microscopic characteristics of the sample undergoing gradual dc erasure can be studied. A typical result is shown in Fig. 6. The plot at the bottom is the descending branch of the measured magnetization curve, and the images are labeled according to the positions on this curve. The horizontal field reinforces the magnetization component of the pattern parallel to its direction and at the same time reverses the component in the opposite direction. Thus, the curve represents the magnetization component being reversed by the applied field.

The patterns were unperturbed by relatively weak magnetic fields, and image (A) shows the initial magnetization distribution. The system was stable up to about 700 Oe where changes in the patterns become noticeable. The initial stage occurred over some field range which is characterized by subtle expansion of the bright areas and moderate roughening of the transition regions. By taking the power spectrum of the image at 700 Oe, we obtain an average roughness correlation distance of about 0.4 μm, which may be related to the average switching volume for this medium. Roughening continued with increasing field and as the field approached coercivity, favorably magnetized areas conglomerated at various spots along the track. Expanding domains

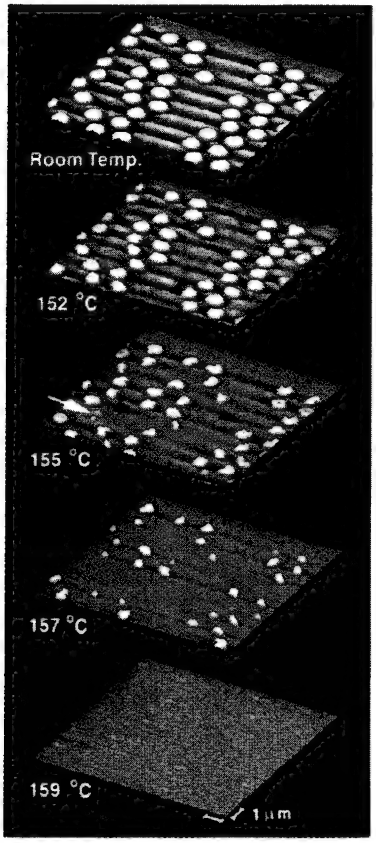

FIG. 7. Erasure of TbFeCo magneto-optic marks with increasing temperature.

adjacent to one another tended to break or percolate through the unfavorable domains. This is best observed at 865 and at 926 Oe where light-intensity streaks can be found in most of the dark contrast bits. At still higher fields, the percolated areas expanded along the crosstrack direction and at 1027 Oe, most parts have reoriented in the direction of the field. The terminal distribution of the remaining clusters appear to be uncorrelated with their previous patterns, and their random distribution may reflect the local fluctuations in the magnetic properties of the medium.

D. Erasure process of a magneto-optic medium

Since the coercivity of conventional magneto-optic media at room temperature is several kOe, direct imaging of their erasure processes is inaccessible with our device. However, we show the results of a related experiment to elucidate the nature of domain collapse in these systems. These images were obtained at room temperature and under ambient magnetic field after exposure to progressively increasing temperatures in the presence of a 1.8 kOe vertical magnetic field.

The evolution of individual magnetic marks can be seen in Fig. 7, as they were subjected to progressively increasing temperatures in a 1.8 kOe dc external field from a permanent magnet. These images correspond to their final room-temperature configurations after recovering from the elevated temperatures. No visible perturbation of the patterns occurred with heating until about 150 °C where subtle shape variations became evident. The onset of domain movement produced irregular wall boundaries as the marks deviated from their originally circular shapes. This clearly suggests nonuniformity on a local scale and our observations are in qualitative agreement with theoretical simulations of "patchy" amorphous media with voids.[15] This inhomogeneity further resulted in the multidomain character of individual marks and caused the domains to collapse at different rates. The blue and red arrows indicate the locations of marks which disappeared at 155 °C even as most other marks were still intact. The white arrow shows direct evidence of patterns breaking up to microdomains which shrink independently. The microdomains had diameters less than 200 nm wide and were located on opposite grooves. The images at 157 °C and higher exhibit the final states of domain disappearance. In general, there was no correlation between erasure characteristics and the position relative to other marks, i.e., stray magnetic fields did not influence the stability of the marks. Just prior to complete erasure, the image at 157 °C shows that all remaining domains were those attached to the mechanical grooves, providing direct evidence that wall pinning occurred at the mechanical defects. The combination of reduced film thickness, tilted easy axis and increased substrate jaggedness at the side walls of the grooves are believed to be responsible for retarding complete domain collapse at those regions.

Single-crystal iron films grown epitaxially on (111) silicon were studied using a magnetic force microscope (MFM). The crystalline anisotropy easy axes (⟨100⟩), directed 35° out of the film plane, result in a significant magnetic charge density at the film surface and a sixfold symmetry in the energy minima of the system. To reduce the magnetostatic energy of this configuration, an alternating, stripe domain pattern formed in samples of thickness ranging from 1240 to 315 nm. Because of the wavelike form of the MFM response across the stripes, two-dimensional Fourier transforms of the MFM images were used to give measures at the domain period, i.e., the wavelength of the stripes, as well as the complexity of the patterns. The stripe domain period was found to be approximately equal to the film thickness which is consistent with previous theoretical predictions. The domain patterns of the films in various remanent states and progressive stages of the magnetization process were investigated using the MFM and an *in situ*, variable magnetic field. A MFM tip that is magnetically soft compared to the iron is most suitable for this. Measurements of the domain period and pattern complexity as a funciton of applied field were correlated with bulk hysteresis measurements. [S0021-8979(96)62208-2]

Force gradient mapping of domain wall structures in magnetite (abstract)

We have used a magnetic force microscope (MFM) in a new imaging mode to study domain walls in magnetite. The oscillation amplitude and phase of a vibrating cantilever were recorded versus cantilever tip-sample separation at each point in an x-y raster scan of a conventional MFM image. Amplitude and phase changes of the MFM cantilever depend on the topographic, interferometric, damping, and magnetic force gradients effects the cantilever experiences. For small scan areas, the magnetic force gradient acting between the tip and sample could be separated from the other interactions. This allowed quantitative extraction of the magnetic force gradients into a three-dimensional dataset called a force gradient map (FGM). FGMs were made over a number of samples; the work reported here focuses on domain wall structures in single crystal magnetite. The results of previous conventional MFM images and FGM images will be compared. One result was that the apparent resolution of the MFM tip was strongly dependent on the oscillation amplitude of the cantilever tip, implying that this must be considered when modelling MFM response. The data also suggest that FGMs may provide more sensitive tests of micromagnetic models than conventional MFM imaging of magnetite. This is for two reasons: (i) as mentioned above, FGMs allow the magnetic signal to be separated from the topographic, damping and interferometric effects and (ii) because FGMs sample the interactions between the tip and sample at a variety of well defined separations, it is possible to identify critical micromagnetic structural length scales. We report on magnetic force microscopy (MFM) images of a thin-film magnetic recording head taken using batch micromachined silicon tips coated with nanocomposite $Fe_{60}(SiO_2)_{40}$ and $Fe_{70}(SiO_2)_{30}$ films. The small Fe grain size (<10 nm) and dilute Fe volume fraction (0.29–0.4) of these granular films produce tip coatings of low remanence and essentially zero coercivity, reduced by the superparamagnetic properties of these films. We have used these tips to obtain MFM images of the write field of the head with high spatial and magnetic-field resolution. In comparison to images taken using commercial $Co_{85}Cr_{15}$-coated tips, these MFM images show reduced tip memory effects and clearly delineate the gap field from the pole pieces. © *1996 American Institute of Physics.* [S0021-8979(96)57108-8]

Batch fabrication of silicon micromachined cantilevers with integral tips[1,2] coated with thin magnetic films has facilitated the emergence of magnetic force microscopy (MFM) as a qualitative high-resolution magnetic imaging tool.[3] Improvements in magnetic tip coatings are necessary, however, to extend MFM capabilities to imaging stronger stray fields and for quantitative field measurements. Typically, tips coated with 10–50 nm of a magnetically hard material (such as $Co_{85}Cr_{15}$) are used for MFM, providing high sensitivity with an assumed tip magnetic moment **m** which is fixed in direction and magnitude.[2] High-resolution imaging of high-coercivity materials and current-biased magnetic recording heads, however, can subject these tips to fields higher than the coercive field H_c of the tip coating,[2] resulting in a time-dependent **m** and generating images which are difficult or impossible to interpret.

One alternative is to use tips coated with a ferromagnetically soft material such as NiFe.[1,4] The tip moment **m** is assumed to align with the local stray field **B** and have a magnitude equal to the saturated value m_s. Unfortunately, the shape and small size of the tip can change the domain structure and greatly enhance the coercivity[1] of these coatings, producing MFM images that also contain artifacts due to hysteresis of the tip moment. To completely eliminate memory effects from MFM images requires tips which have zero hysteresis over the operating field range.

MFM tips coated with granular magnetic films consisting of isolated superparamagnetic particles (<10 nm) would have zero remanence and coercivity, resulting in images with no tip memory effects. Unlike NiFe and other ferromagnetic coatings, the magnetic properties of the individual particles in the superparamagnetic films should not be altered by the shape of the tip, for tip radii larger than the particle size. Sensitivity, determined by **m**, would be orders of magnitude larger than tips coated with paramagnetic films and in strong magnetic fields could approach or exceed that of available ferromagnetic-coated tips. These tips might also be useful for nonperturbative imaging of domain patterns in low coercivity films,[5] due to the lower stray fields emanating from these tips.[1] In contrast to the assumed fixed moment **m** of the ferromagnetic-coated tips, **m** of the superparamagnetic tips can increase with field. This results in a shorter range tip–sample force $\mathbf{F}=\nabla(\mathbf{m}\cdot\mathbf{B})$. In the case of tips of extended geometry where the forces over the tip volume must be summed,[3] the shorter range force means a smaller tip volume contributes to the signal. This leads to improved resolution providing the tip–sample force yields a sufficient signal-to-noise ratio.

We have coated commercial silicon micromachined MFM cantilevers and tips with granular Fe–(SiO_2) films. These nanocomposite films consist of small Fe crystallites (3–7 nm) in an amorphous SiO_2 matrix.[6–8] By growing films with dilute Fe volume fractions p of 0.29–0.4 we have manufactured Fe–(SiO_2)-coated tips that show no noticeable tip memory effects and which have the following additional advantages for batch MFM tip fabrication: (1) excellent adhesion to silicon; (2) high corrosion resistance and wear resistance; (3) the deposition process can be scaled up for coating entire wafers; and (4) the magnetic properties can be engineered by controlling the film microstructure.[6–8]

Cantilevers with spring constants $k=1-5$ N/m, resonant frequencies $f_0=70-89$ kHz, and quality factors $Q\sim200$ in air were rf magnetron sputter-coated at 300 K using a homogeneously mixed composite Fe–(SiO_2) target of the desired composition.[8] As listed in Table I, one batch of six cantilevers with tips was coated with 40 nm (±10%) of $Fe_{70}(SiO_2)_{30}$ and another batch was coated with 40 nm of $Fe_{60}(SiO_2)_{40}$. A third batch of commercial $Co_{85}Cr_{15}$-coated tips[2] was also used in this study. Variations in the Fe atomic percentages are less than 5%. Scanning electron micrographs of the Fe–(SiO_2)-coated cantilevers show tip end radii of 50–100 nm.

The magnetic data in Table I were derived from Figs. 1(a) and 1(b), which show the volume magnetization M versus applied field H (in plane) for the three different films. The Fe–(SiO_2) data were taken at 300 K on films simultaneously deposited with the tips on glass coupons; the data were normalized to the saturation magnetization (1714 kA/m) of pure Fe by multiplying by the volume fraction p. For the CoCr data, the actual coated cantilever substrate was

TABLE I. Properties of MFM tip coatings. Listed for the three films are the thickness t and the Fe volume fraction p. The measured coercivity H_c and remanence M_r are from Fig. 1.

Coating	t (nm)	p	H_c kA/m	H_c (Oe)	M_r (kA/m)
$Fe_{70}(SiO_2)_{30}$	40	0.39	0.08	(1)	4
$Fe_{60}(SiO_2)_{40}$	40	0.29	1	(13)	6
$Co_{85}Cr_{15}$	40	···	34	(430)	300

measured after being saturated in plane with a 160 kA/m field; the data were normalized to 400 kA/m (400 emu/cm^3).[2] The instrumentation error for H_c is 200 A/m (2 Oe). The measured H_c and remanence for the Fe–(SiO_2) films in Fig. 1(a) are very small but nonzero. The nonzero values probably occur because a small fraction of the Fe forms clusters larger than the superparamagnetic limit.[6] In the absence of clustering, these films would be completely superparamagnetic. Major and minor hysteresis loops for CoCr are shown in Fig. 1(b), demonstrating a substantial coercivity and remanence.

Figures 2(a) and 2(b) are 10 μm scans of magnetic force derivative[3] and topography, respectively, of a commercial thin-film inductive magnetic recording head. The images were taken simultaneously as described in Ref. 9 using an $Fe_{70}(SiO_2)_{30}$-coated tip and with the head current biased at 10 mA. The cantilever was vibrated at the resonance frequency f_0 with a 30 nm root-mean-square (rms) amplitude. Figure 2(a) was scanned with the tip 100 nm above the air bearing surface (ABS), about twice the designed flying height of the head above the disk. Plotted in Fig. 2(a) is the resonant frequency shift Δf of the cantilever, arising from the magnetic force **F** between the tip and the write field of the head. For small shifts, Δf can be approximated by the expression $\Delta f = -f_0 F'/(2k)$, where F' is the gradient along the tip axis of the axial component of the magnetic force **F**.[2,3] The strongest feature in Fig. 2(a) occurs at the gap between the two NiFe pole pieces where the field (240–320 kA/m) and its spatial derivatives are the highest, resulting in the strongest attractive tip–sample force and largest decrease in the cantilever resonant frequency. Contrast can also be seen around the edges of the pole pieces where fringing fields are present. There is essentially no frequency shift in the body of the pole pieces. Figure 2(b) is the sample topography and shows polishing scratches across the 0.2-μm-wide gap and the pole pieces P1 and P2. The contrast between the soft NiFe poles and the surrounding harder alumina material arises from effects due to the polishing process and magnetic forces affecting the topographical force image.

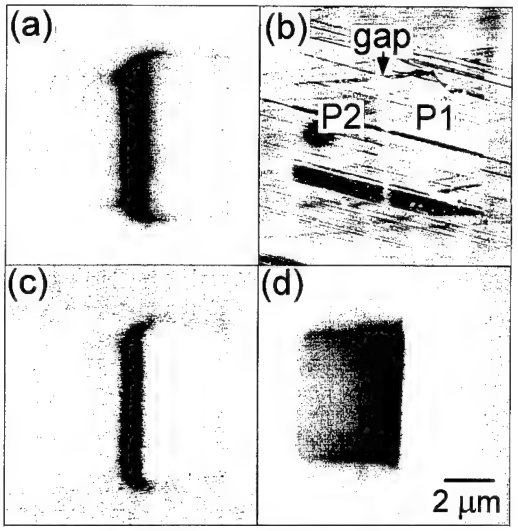

FIG. 2. 10 μm images of a thin-film inductive magnetic recording head. (a) MFM frequency shift image using a tip coated with 40 nm of $Fe_{70}(SiO_2)_{30}$, a 100 nm tip–sample spacing, and 10 mA current bias of the head; (b) simultaneous topographical image showing the leading (P1) and trailing (P2) pole pieces and the 0.2-μm-wide gap; (c) MFM image, 40 nm $Fe_{60}(SiO_2)_{40}$-coated tip, 10 mA bias; and (d) MFM image, 40 nm $Co_{85}Cr_{15}$-coated tip, 2 mA bias. The contrast scales are 50 Hz, 50 nm, 10 Hz, and 70 Hz, respectively.

Figures 2(c) and 2(d) are magnetic images taken with $Fe_{60}(SiO_2)_{40}$ and CoCr-coated tips, respectively, under the same imaging conditions as Fig. 2(a). The head was biased at 10 mA for Fig. 2(c) and 2 mA for Fig. 2(d). Figure 2(c) is similar to Fig. 2(a) with contrast centered at the gap; however, the signal has dramatically decreased by roughly a factor of 10. Figure 2(d) was taken immediately after magnetizing the CoCr tip in an external field of 700 kA/m applied along the tip axis. This image is qualitatively different from Figs. 2(a) and 2(c) because of the substantial coercivity of the CoCr tip. One pole piece is darker than the other, and near the center of the gap the contrast changes from dark to light. Unlike Figs. 2(a) and 2(c), Fig. 2(d) is not reproducible, and depends on the prior magnetic history of the tip.

Figure 2 can be better understood by looking at individual MFM line traces taken horizontally across the center of the head using the same three tips, with the head biased at different current levels. Each trace pictured in Fig. 3 is an average of at least 40 line scans and shows the resonant frequency shift Δf of the cantilever versus position of the tip over the head. The noise in each line scan was approximately 0.2 Hz rms. The gap center is at 5±0.1 μm. The traces in Figs. 3(a) and 3(b) are essentially flat and featureless except near the gap, where the largest negative frequency shift

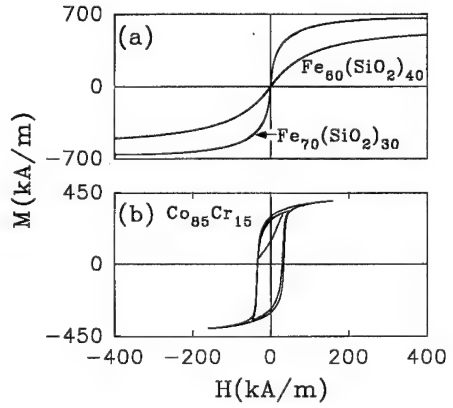

FIG. 1. Magnetization vs applied field H at 300 K with H in the plane of the films: (a) 40-nm-thick $Fe_{70}(SiO_2)_{30}$ and $Fe_{60}(SiO_2)_{40}$ films on glass coupons; (b) commercial cantilever substrate coated with 40 nm of $Co_{85}Cr_{15}$.

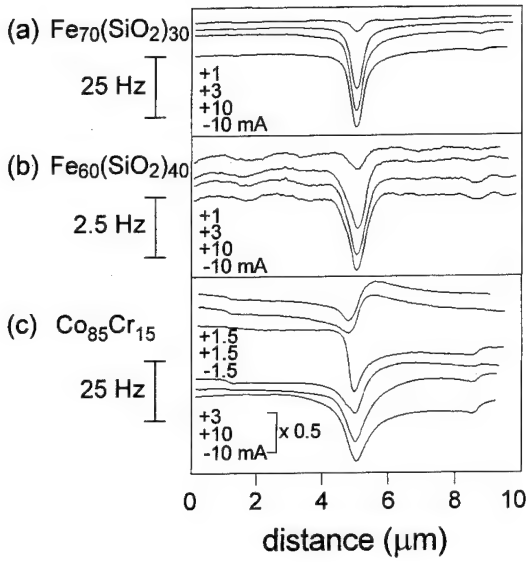

FIG. 3. Line traces taken horizontally across the center of the head, with head biases shown: (a) $Fe_{70}(SiO_2)_{30}$ tip; (b) $Fe_{60}(SiO_2)_{40}$ tip; and (c) $Co_{85}Cr_{15}$ tip previously magnetized to saturation along the tip axis. The gap is located at 5 μm. Arbitrary offsets were used to display the traces. The bottom three traces in (c) have been reduced by 50% ($\times 0.5$).

(Δf_{max}) occurs. The frequency shifts are primarily negative denoting an attractive tip–sample force, as expected for a soft tip. The response of both Fe–(SiO_2) tips near the gap increases with increasing current bias and saturates at roughly 4 mA bias, in agreement with the manufacturer's specifications of the head. There is no detectable spatial shift of Δf_{max} at different current biases. Also expected for magnetically soft tips, the scans are identical for opposite current polarity as illustrated by the ± 10 mA traces. There is a small feature at ~ 9 μm corresponding to the fringing field on the outside of the P1 pole piece. The smaller features in Fig. 3(b) are due to topography and interface effects in the optical detection. All traces in Figs. 3(a) and 3(b) were reproducible, demonstrating the absence of tip memory effects with the Fe–(SiO_2)-coated tips. We also imaged bits on longitudinal hard disk media with the $Fe_{70}(SiO_2)_{30}$ tips and found that opposite polarity transitions gave equal response. The sensitivity of the $Fe_{60}(SiO_2)_{40}$ tips was not high enough to image these bits.

Figure 3(c) is illustrative of a CoCr tip while imaging an energized head whose peak field exceeds H_c of the tip coating. After magnetizing the tip as for Fig. 2(d), the second through sixth traces were taken in the order they appear, top to bottom. Finally, the top trace was taken. The two traces at the same current bias of +1.5 mA are not identical due to hysteresis of the tip moment. Traces of opposite current polarity (± 1.5 and ± 10 mA) are neither identical nor show odd symmetry with respect to the gap. This lack of symmetry along with the predominantly attractive tip–sample response near the gap at higher current biases suggest that the CoCr tip response has both magnetically hard and soft components. This dual nature of the tip makes it difficult to determine important properties of the recording head such as the precise position of the center of the gap, the relative write field strengths at various current biases, and the symmetry of the field near the gap. For example, there is a spatial shift of 0.2 μm for Δf_{max} for the second and third traces (± 1.5 mA) in Fig. 3(c), a shift comparable to the width of the gap. Differences between prior and subsequent MFM images of bits on a hard disk confirmed that the tip moment **m** was changed (written) by the write head.

Figure 3 shows that the tip response to the gap field is spatially the narrowest for the $Fe_{70}(SiO_2)_{30}$ tip. We can quantify this from the line traces by measuring the full width at half-maximum (FWHM). At +2 and +10 mA biases we measure the FWHM for the $Fe_{70}(SiO_2)_{30}$ tip to be roughly 430 and 500 nm, for the $Fe_{60}(SiO_2)_{40}$ tip 580 and 600 nm, and for the CoCr tip 500 and 600 nm, respectively.

As mentioned above, the presence of magnetic forces can cause an error in the topographical force image and requires that a correction be made to obtain the true tip–sample spacing for the magnetic image. By subtracting the topography of the unbiased head from the image taken at +10 mA bias, we found a maximum correction near the gap of approximately +2, +1, and +30 nm for the $Fe_{70}(SiO_2)_{30}$, $Fe_{60}(SiO_2)_{40}$, and CoCr tips used in Figs. 2 and 3. This correction for the CoCr tip is substantially larger than the true topographical features and is approaching the intended 100 nm tip-sample spacing for the MFM image.

In conclusion, MFM images taken with $Fe_{70}(SiO_2)_{30}$ and $Fe_{60}(SiO_2)_{40}$-coated tips show substantially reduced tip moment hysteresis effects compared to images taken with $Co_{85}Cr_{15}$-coated tips. Given the signal-to-noise ratio of existing commercial MFMs, the higher sensitivity of the $Fe_{70}(SiO_2)_{30}$ tips makes them more appropriate than the $Fe_{60}(SiO_2)_{40}$ tips for imaging the write field above heads. These tips should also be useful for imaging permanent magnet materials and very high-coercivity media. Optimization of the Fe particle size, size uniformity, and interparticle separation in the nonmagnetic SiO_2 matrix should produce films that have improved superparamagnetic properties. This will allow thinner coatings with higher Fe concentrations on sharper tips, with the goal of simultaneously improving sensitivity and resolution.

Sensitive detection of magnetic field distribution using scanning interference electron microscope (invited) (abstract)

Y. Yajima, Y. Takahashi, K. Kuroda, and Y. Sugita
Central Research Laboratory, HITACHI, Ltd., Kokubunji, Tokyo 185, Japan

We have implemented interference imaging mode as well as Lorentz imaging mode on a scanning transmission electron microscope (HITACHI HF-2000 with a scanning option; 200 kV accelerating voltage).[1] In the interference mode, a pair of mutually coherent fine probes scan simultaneously across the region of magnetic induction. By monitoring the relative phase change occurring in the probe pair, the variation of the magnetic flux bound by the probe trajectories can be sensed by the universal unit of e/h ($-|e|$: electron charge and h: Planck's constant). The combined use of this imaging mode with the Lorentz mode which is based on the detection of the probe deflection by Lorentz force facilitates detailed analyses of fringing field around magnetic materials and magnetic induction inside magnetic films. The microscope described above is particularly suited for the study of magnetic storage devices whose microscopic magnetic properties are drawing much attention recently. We show here the results of its application to the observation of field distributions near the MR (magnetoresistive) heads and induction distributions associated with high density longitudinal and perpendicular recording media.

Magnetization reversal process in TbCo-biased spin valves

J. N. Chapman and M. F. Gillies
Department of Physics and Astronomy, University of Glasgow, Glasgow G12 8QQ, United Kingdom

P. P. Freitas
INESC, R. Alves Redol 9-1, 1000 Lisbon, Portugal

The magnetization reversal processes in the free and the pinned layers of TbCo-biased spin valves have been studied in a highly modified transmission electron microscope. Reversal of the free layer in the presence of a field antiparallel to the biasing direction proceeds by a complex domain process with 360° walls forming frequently. In the presence of substantially higher fields, the pinned layer reverses by creep of highly irregular walls through the structure. By studying image grey levels, an estimate of the average orientation of the induction vector in the TbCo layer is made. © *1996 American Institute of Physics.* [S0021-8979(96)57208-2]

I. INTRODUCTION

Spin valves of the form M1/Cu/M2/TbCo have been grown which display magnetoresistances of 4%–8% and sensitivities of >1%/Oe.[1,2] For the work reported here M1 and M2 were either Permalloy (Py) or Permalloy with approximately 1.5 nm of cobalt (Py/Co) at each interface with the Cu spacer layer. Typical layer thicknesses were 6, 2.5, 6, and 10 nm for the M1, Cu, M2, and TbCo layers, respectively, while the composition of the TbCo layer lay in the range 32–35 at. % Tb. The enhanced magnetoresistance is found when the magnetizations in the free (M1) and pinned (M2) layers are oppositely directed; for our samples this occurred over an applied field range from ≈10 to ≈250 Oe. Here we describe how Lorentz microscopy has been used to study the magnetization reversal process in both the free and the pinned layers. The former relates directly to the noise behavior when the spin-valve material is used as a sensor while the latter provides information on the nature of the coupling between the M2 and TbCo layers. Essential for the experiments undertaken is the ability to form magnetic images at high spatial resolution with the specimen subjected to applied fields where the reversal processes of interest occur. This has been achieved using a highly modified Philips CM20 transmission electron microscope optimized for the study of magnetic materials.[3,4]

II. REVERSAL OF THE FREE LAYER

Figure 1 shows Fresnel images of the reversal of the M1 layer in a Py/Co spin valve deposited directly onto a Si_3N_4 window substrate. Domain walls appear as narrow dark and bright bands while the fact that there is significant dispersion of the magnetization within the domains themselves is revealed by the presence of ripple contrast. The numbers in the top left-hand corner of each image give the applied field in Oe. Note that magnetometry confirms that, over the field range shown in Fig. 1, only one of the magnetic layers reverses. As expected, the zero field state [Fig. 1(a)] is single domain as a result of weak ferromagnetic coupling between M1 and M2. The ripple enables the direction of magnetization, denoted by the white arrow, to be determined and fields in this sequence were applied antiparallel to the bias direction. As the field was increased, so did the magnetization dispersion until at a

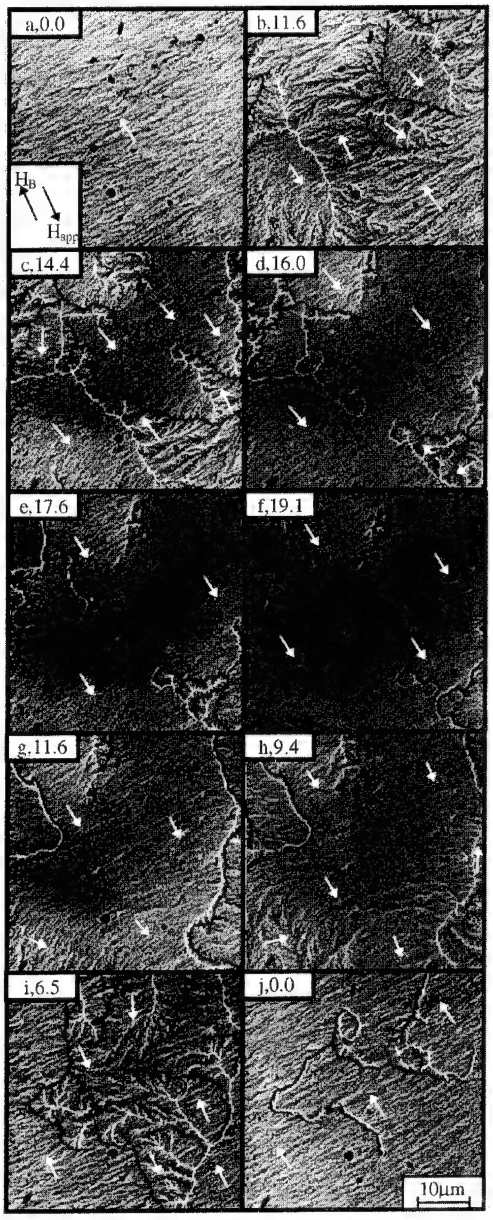

FIG. 1. Fresnel images showing the magnetization reversal of M1. Field values, in Oe, are given.

 0021-8979/96/79(8)/6452/3/$10.00

field of ≈11 Oe [Fig. 1(b)] magnetization reversal occurred over a few small areas within the film. Domain boundaries tended to be irregular and observation of the microscope viewing screen showed that they moved jerkily to expand the area of reverse domains [Fig. 1(c)]. Figures 1(d)–1(f), however, show that full antiparallel alignment was difficult to achieve due to the large number of 360° walls which formed in the final stages of the reversal process. These structures proved to be very stable and fields in excess of 100 Oe were required for their annihilation. Reduction of the applied field [Figs. 1(g)–1(j)] led to a return of the magnetization in M1 to its original orientation. It was observed that areas which had been last to reverse under an increasing field tended to be the first to return to their original orientation as the field was reduced. Once again complex erratic domain structures were involved and, while the majority of the spin valve returned to its original parallel state, a number of 360° walls remained when the applied field was removed completely [Fig. 1(j)].

A broadly similar reversal mechanism was observed for Py spin valves, the main differences being that magnetization dispersion and wall irregularity were both markedly reduced. Thus, as with spin valves pinned by FeMn,[5] the reversal of the so-called free layer is very different and much more complex than that of an equivalent isolated magnetic layer of the same composition and thickness. The coupling introduced by the presence of the M2 layer clearly modifies the domain processes involved and acts to stabilize highly charged structures such as 360° walls whose presence is less common in isolated layers.

III. REVERSAL OF THE PINNED LAYER

At much higher fields (≈250 Oe), where the M1 layer is fully reversed and aligned with the applied field, the reversal of magnetization in the M2 layer has been studied. Figure 2 shows a sequence of Fresnel images recorded at constant field but increasing time. The reversal proceeds by the "creep" of a small number of very irregular domain walls through the M2 layer. Figure 3 shows a higher magnification image from which it is apparent that changes in wall direction occur on a submicron scale. (Note that the fine approximately circular structures are not of magnetic origin.) Wall irregularity on a submicron scale is not usually associated with Py films and is indicative of the strong influence being exerted by the TbCo to which M2 is exchange coupled. Variation of the magnitude of the field changes the rate at which the reversal takes place but not the mechanism. Analysis of image sequences recorded on video under different applied fields suggests that there exists a single well-defined energy barrier which must be overcome.[6] The M2 reversal mechanism is quite different from that of M1 and also from reversal of the pinned layer in FeMn-biased spin valves reported elsewhere.[5]

Further information on the coupling between the M2 and TbCo layers can be gleaned from the use of differential phase contrast (DPC) Lorentz microscopy.[7] The advantage of this technique is its high linearity which allows quantitative information on the induction distribution to be derived. Figure 4(a) shows a DPC image of a spin valve in a remanent

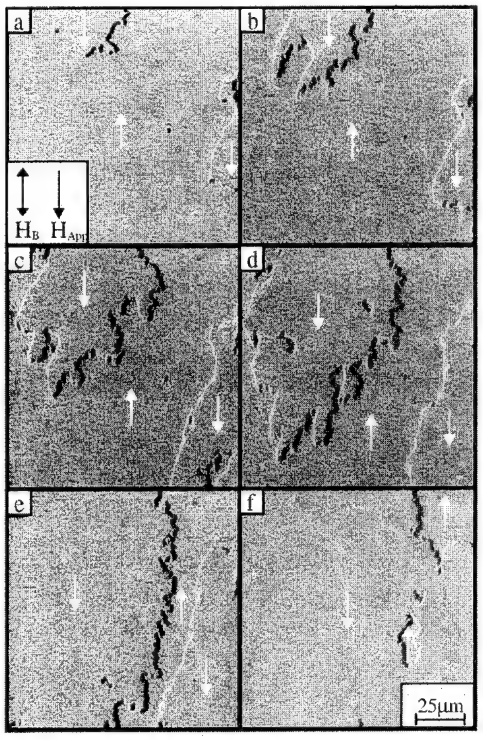

FIG. 2. Fresnel images showing the creep of an irregular domain wall through M2 under constant field (≈250 Oe).

state following the application of a large vertical field. Different grey levels are observed in different parts of the image and these can be interpreted with the help of Fig. 4(b). Note that the orientation of magnetization in the M2 and TbCo layers represents a simplification of models discussed in Refs. 1 and 8.

Following application of the large vertical field, Fig. 4(a) shows that the in-plane component of magnetization in different parts of the pinned layer is oppositely directed. Hence, domain walls are present. Well away from the interface, in

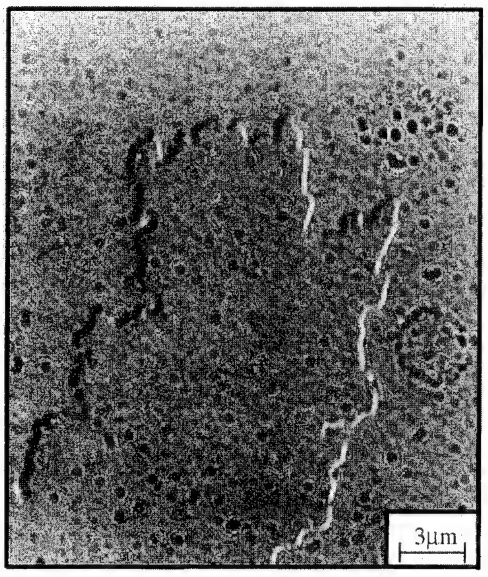

FIG. 3. High-magnification Fresnel image of a domain wall in M2.

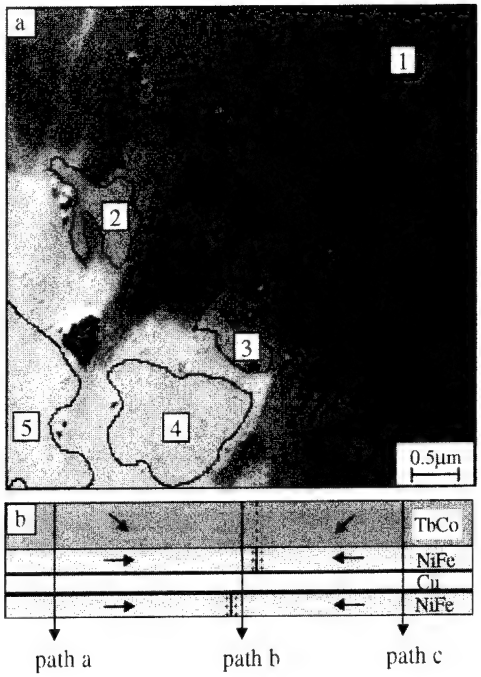

FIG. 4. (a) DPC image of a spin valve following application of a large vertical field; (b) schematic of different electron trajectories through the induction distribution shown in (a).

region 1 and in regions 4 and 5, it is assumed that the electrons follow paths of the kind denoted "a" and "c," respectively, in Fig. 4(b). The grey levels in the DPC image corresponding to these regions are characteristic of the electron having been deflected in the same sense by the magnetization in M1 and M2 and by any in-plane component of magnetization in the TbCo layer; however, in regions close to the domain boundary, such as 2 and 3 of Fig. 4(a), a further grey level is observed. Here we surmize that while there is weak coupling between M1 and M2 it is insufficiently strong for the walls in the two layers to coincide completely, the offset being introduced to reduce the overall magnetostatic energy. Hence the deflection experienced by the electron beam as it passes through such regions (path "b") is reduced in magnitude as the magnetization directions in M1 and M2 are oppositely directed, producing a cancelling effect. Comparison of the mean grey levels from the three different types of region confirms the presence of an in-plane component of induction in the TbCo and allows its magnitude to be calculated. Based on the simplified magnetization distribution of Fig. 4(b) a value of 22° to the vertical is deduced for the orientation of the induction vector in the TbCo layer for a spin valve whose pinning layer contained 32 at. % Tb. More rigorously the analysis provides a measure of the in-plane component of induction throughout the TbCo layer averaged along an electron trajectory. A value corresponding to 38% of the saturation induction is obtained, although no information can be derived about its distribution throughout the layer thickness.

IV. CONCLUSIONS

The ability to image magnetic structures at high spatial resolution in a magnetic field selected by the experimenter has allowed us to investigate in detail the magnetization reversal mechanisms in the free and pinned layers of TbCo-biased spin valves. Use of different Lorentz imaging modes allows information not only on the domain geometry but also the quantitative distribution of induction throughout the structure to be derived.

Direct observation of domain walls in NiFe films using high-resolution Lorentz microscopy

Bunsen Y. Wong and David E. Laughlin
Department of Materials Science and Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213

A novel approach to observe the interaction between magnetic domain wall and nanoscale microstructural features is demonstrated. The method is based on Focault mode Lorentz microscopy and utilizes a Gatan energy image filter to provide additional magnification. A postexperimental image processing technique was applied to separate lattice diffraction from that induced by magnetic domains. The effect of NiFe thickness on the width of a 180° Néel wall has been studied. It was found that the thickness dependence has a similar profile to the theoretically predicted trend but the actual wall thickness is smaller than the calculated values. © *1996 American Institute of Physics.* [S0021-8979(96)57308-6]

I. INTRODUCTION

Magnetic properties of materials are closely associated with the magnetic domain configurations and the interaction between domain walls and microstructural features. Techniques such as Lorentz microscopy in both the conventional and scanning transmission mode,[1,2] spin polarized scanning electron microscopy,[3] and magnetic force microscopy[4,5] have been developed to address these issues. However, these techniques are unable to resolve the microstructure-domain interactions on a nanoscale such as those in thin films. In this work, we report on a novel technique utilizing a Gatan energy image filter (GIF) and based on Focault mode Lorentz microscopy which can resolve both fine magnetic domains and microstructural features. A schematic of the GIF unit attached to the transmission electron microscope (TEM) is shown in Fig. 1. In the present study, the function of the GIF is twofold as follows.

(1) Conventional Lorentz microscopy requires a field-free objective lens which generally limits the image magnification to 3000×. The magnetic magnifying lenses (×18.75) and the charge-coupled-device (CCD) camera (~×8) contain within the GIF can provide additional magnification power which helps achieve a theoretical resolution of 1 nm in this technique.

(2) The elastically scattered electrons which have undergone magnetic phase change can be separated from the inelastically scattered electrons by using the energy filter slit. Hence, a higher signal-to-noise ratio in the magnetic image can be obtained. We have applied this technique to study the effect of film thickness on the 180° domain-wall width in sputter-deposited NiFe thin films in order to demonstrate the capacity of this new technique.

II. EXPERIMENTAL PROCEDURES

$Ni_{81}Fe_{19}$ films of thicknesses ranging from 7 to 35 nm were deposited on NaCl substrates by rf diode sputtering. The Ar sputtering gas pressure was 5 mTorr and a forward power of 50 W was used. The films were then floated off the substrates onto 3 mm Cu TEM grids. The domain-wall profiles and domain structures were studied using Focault mode Lorentz microscopy inside a JEOL 4000EX microscope operating at 400 kV and attached to a GIF unit. Images were recorded with a CCD camera. Postexperimental image analysis was carried out with the interactive data language (IDL) image processing software so that the interference between magnetic and crystalline diffraction contrast can be minimized and an acute domain-wall profile can be determined.

III. RESULTS AND DISCUSSION

The magnetic domain contrast of two antiparallel domains in a 28-nm-thick NiFe film are shown in Figs. 2(a) and 2(b) along with the corresponding bright-field (BF) image in Fig. 2(c). The location of two reference grains is marked by arrows in the respective images. The average grain size of the lattice diffraction contrast can be clearly observed in the BF image which enables one to discern the grain morphology and other microstructural features. Hence, any interaction between domain boundaries and fine microstructural features can be easily made.

In the Focault mode, the displaced aperture intercepts one of the magnetically diffracted beams and results in black and white contrast within the TEM image. This variation in intensity outlines the local magnetization. In between the magnetic domains, a continuous gray contrast which represents the extent of the domain wall can be observed. In order

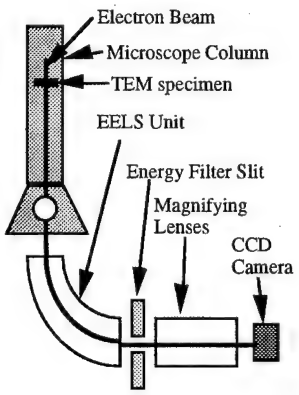

FIG. 1. A schematic of the GIF unit in relation to the TEM.

 0021-8979/96/79(8)/6455/3/$10.00

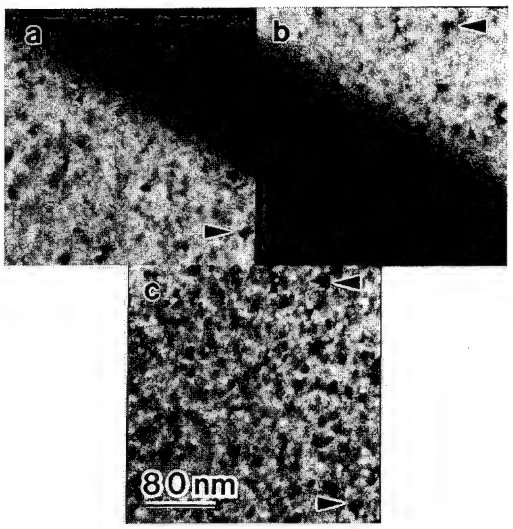

FIG. 2. (a),(b) Lorentz images of antiparallel domains in a 28-nm-thick thin film. (c) Corresponding BF image.

to determine the width of the 180° Néel wall, an integrated intensity profile across the image and perpendicular to the domain wall was obtained and the result is plotted in Fig. 3. This profile consists of three linear regimes and is an indirect representation of the magnetization direction within the image. The wall width is determined by the intercepts of the three linear regions as shown in Fig. 3. Similar Lorentz images for a 90° Néel wall in the same specimen are depicted in Fig. 4 and reference grains are marked with respect to the BF image. The gray regions in each frame represent domains which have half of their magnetization component blocked by the aperture whereas the origin of the black and white domains is similar to that explained above.

The Lorentz images that have been shown so far consist of diffraction contrast of both crystalline, i.e., granular, and magnetic nature. Hence, to assess the most appropriate profile of the domain wall, it is necessary to reduce the contribution from lattice diffraction within the image to a minimum. This is achieved through a postexperimental image processing technique and the path taken is illustrated in Fig. 5. In Figs. 5(a) and 5(b), an as-exposed Lorentz image is accompanied by its BF image, respectively. A negative or inverse of the BF image is shown in Fig. 5(c). In order to curtail the effect of lattice diffraction, intensity from the BF

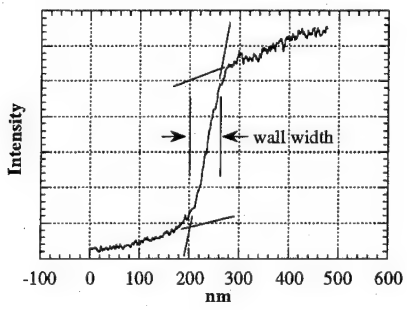

FIG. 3. Intensity trace across the 180° domain wall in 28 nm NiFe film.

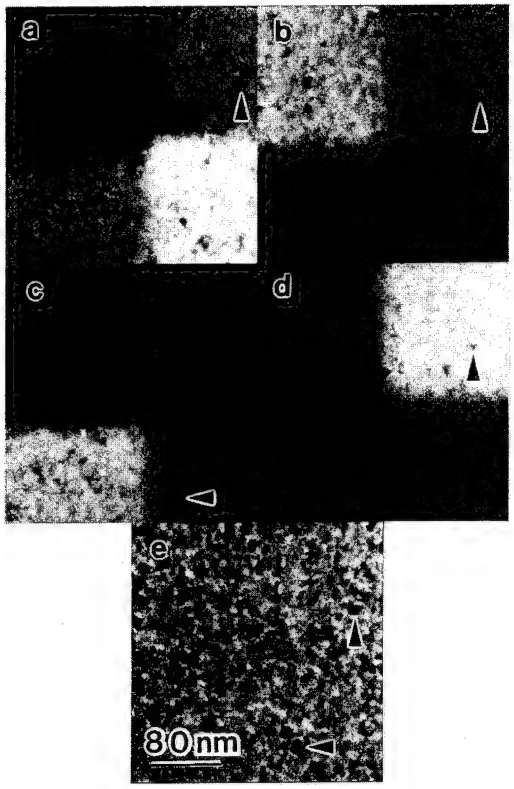

FIG. 4. (a)–(d) Lorentz images of 90° domains in a 28-nm-thick NiFe thin film with different components of the aperture blocked. (e) Corresponding BF image.

negative is added to the Lorentz image to achieve a more uniform contrast and the final processed image is shown in Fig. 5(d). The lattice diffraction within the white domain is reduced but not completely eliminated; however, the contrast in the black domain has deteriorated modestly after the image processing. The intensity profiles across the 180° Néel wall for the as-exposed and processed images are shown in

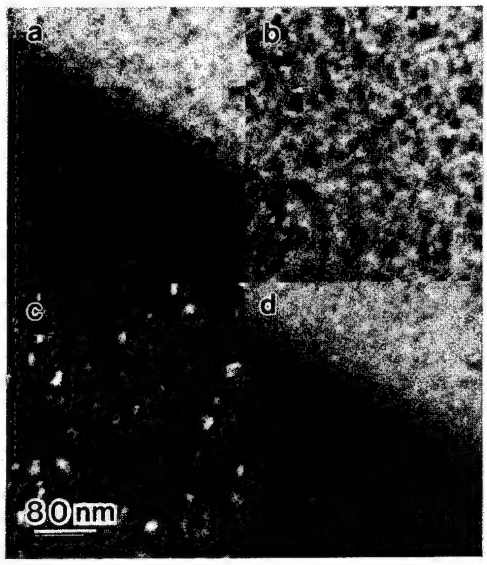

FIG. 5. (a) Lorentz images of a 28-nm-thick NiFe thin film. (b) Corresponding BF image. (c) Inverse of BF in (b). (d) Processed Lorentz image of (a).

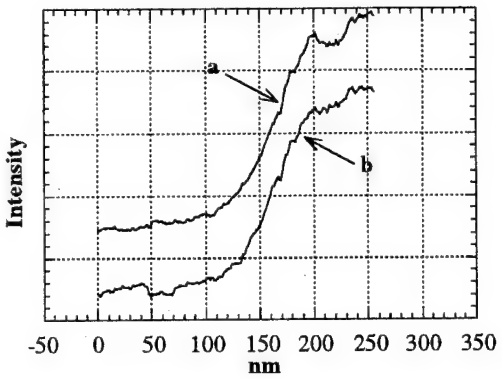

FIG. 6. Intensity profile across a 180° domain wall in a 28-nm-thick NiFe film: (a) as exposed and (b) processed images.

Fig. 6. The reduction in the intensity variation within the white domain has lead to a better definition of the domain-wall width. By combining the two profiles, the 180° Néel wall width in NiFe films of various thicknesses has been measured and the results are plotted in Fig. 7. The dependence of wall width on film thickness is similar to the theoretical profile[6] but the actual measured values are smaller than the calculated ones. They do, however, agree with other experimental observed values.[7]

IV. CONCLUSIONS

The dependence of 180° Néel wall width on the thickness of NiFe films has been measured by high-resolution Focault mode Lorentz microscopy. This new technique incorporates the magnification capacity of the GIF unit and has been demonstrated to achieve image resolution in the nanometer range. In addition, the lattice diffraction contrast can be reduced by applying postexperimental image processing technique which resulted in better magnetic contrast and a more accurate domain-wall profile.

Numerical micromagnetics in hard magnetic and multilayer systems (invited)

T. Schrefl and J. Fidler
Institut für Angewandte und Technische Physik, Technical University of Wien, Wiedner Hauptstrasse 8-10, A-1040 Vienna, Austria

Micromagnetic finite element calculations using a magnetic vector potential to treat long-range dipolar interactions describe the interactive magnetization processes which determine the magnetic properties of fine-grained magnetic materials. Micromagnetic models give a quantitative treatment of the correlation between the microstructure and the magnetic properties of melt-spun $Nd_2Fe_{14}B$ magnets and of Co/Pt multilayers. In nanocrystalline permanent magnets, intergrain exchange interactions cause nonuniform magnetic states which increase the remanence and act as nucleation sites. Remanence increases with decreasing grain size. Remanence enhancement of about 15% with respect to noninteracting particles can be achieved for an average grain size $D \leqslant 20$ nm. On the other hand, the nucleation field reduces to about 20% of the anisotropy field. Once a reversed domain has been nucleated, strong internal stray fields cause the expansion of the domain over several grains. The nucleation field of Co/Pt multilayers increases with improving texture. Spatial fluctuations of the magnetocrystalline anisotropy energy create barriers for domain wall motion. The pinning field of reversed domains increases with increasing misalignment and with increasing grain size. The quality of texture and the grain size significantly influence the jaggedness of domains in Co/Pt multilayers. Large grains and strong deviations of the easy directions from the film normal deteriorate the smoothness of domains and increase the transition width. [S0021-8979(96)27308-3]

I. INTRODUCTION

The macroscopic magnetic properties of a ferromagnetic material result from the microscopic arrangements of magnetic moments. The distribution of the magnetization significantly depends on the microstructure and on interparticle interactions. Since micromagnetism describes magnetization processes on a significant length scale of several nanometers, micromagnetic models provide a quantitative treatment of the correlation between the microstructure and the magnetic properties. During the last decade numerical micromagnetics has become an important tool to investigate the effects of microstructural features on the magnetic properties of modern magnetic materials.[1–5]

Generally, numerical micromagnetic models addressed two basic problems: (i) the calculation of the switching field in particles with nonuniform magnetic ground states, and (ii) calculation of the effects of interparticle interactions on the magnetic properties. The nonlinear micromagnetic energy functional allows a rigorous calculation of nucleation fields only for ellipsoidal particles.[6] Polyhedral particles show nonuniform demagnetizing fields and in turn exhibit inhomogeneous magnetic states. Bertram and Schabes[7] numerically derived nonuniform reversal modes for a ferromagnetic cube. Assuming a uniform magnetization within the individual particles, Zhu[1,2] and Fukunaga[8] studied the effects of interparticle interactions on the magnetic properties in magnetic recording media and in permanent magnets, respectively.

This work reviews micromagnetic concepts for the calculation of interaction effects while taking care of nonuniform magnetic states within single particles. In order to model magnetic inhomogeneities, each particle has to be divided into smaller finite elements. On the other hand, collective processes can only be observed for a sufficiently high number of particles. The concurrent modeling of nonuniform magnetic states and of interparticle interactions requires a considerably high number of variables. For large-scale problems the direct evaluation of the stray field energy becomes impracticable, since the demagnetizing field at a given point depends on the magnetization at all grid points. Introducing a magnetic scalar or a magnetic vector potential eliminates long-range terms from the micromagnetic energy functional.[9]

Section II describes the micromagnetic and numerical background of the simulation model. Section III treats the magnetization reversal process in nanocrystalline $Nd_2Fe_{14}B$ magnets. Section IV presents three-dimensional calculations of the magnetic properties and the domain structures in Co/Pt multilayers.

II. NUMERICAL MICROMAGNETICS FOR LARGE PARTICLE SYSTEMS

A theoretical treatment of magnetization processes starts from the total magnetic Gibb's free energy. If one neglects magnetoelastic effects, the magnetic Gibb's free energy Φ_t of a ferromagnetic specimen in an applied field is the sum of the exchange energy, the magnetocrystalline anisotropy energy, the stray field energy, and the magnetostatic energy of the magnetic polarization $\mathbf{J}_s$ in an external field $\mathbf{H}_{ext}$:[10]

 0021-8979/96/79(8)/6458/6/$10.00

$$\Phi_t = \Phi_{ex} + \Phi_K + \Phi_s + \Phi_H . \tag{1}$$

For uniaxial magnetic materials, where the direction of $\mathbf{J}_s$ may be described by the angle α between $\mathbf{J}_s$ and the easy axis the energy contributions are given by

$$\Phi_{ex} = \int A\{(\nabla\vartheta)^2 + (\nabla\varphi)^2 \sin^2\vartheta\} d^3r, \tag{2}$$

$$\Phi_K = \int \{K_1 \sin^2\alpha + K_2 \sin^4\alpha\} d^3r, \tag{3}$$

$$\Phi_s = -\frac{1}{2}\int \mathbf{J}_s \cdot \mathbf{H}_d \, d^3r = \frac{\mu_0}{2}\int \mathbf{H}_d \, d^3r, \tag{4}$$

$$\Phi_H = -\int \mathbf{J}_s \cdot \mathbf{H}_{ext} \, d^3r. \tag{5}$$

Here K_1, K_2 are the anisotropy constant, and A is the exchange constant. Using the polar angle φ and the azimuth angle ϑ to represent $\mathbf{J}_s$, automatically fulfils the nonlinear constraint, $|\mathbf{J}_s| = J_s$, during minimization. A second nonlinearity arises from the stray field energy which is the magnetostatic energy of $\mathbf{J}_s$ in its self-demagnetizing field $\mathbf{H}_d$. All energy terms but the stray field energy depend only locally on the magnetic polarization. The long-range terms can be eliminated from the total magnetic Gibb's free energy, introducing a magnetic vector potential $\mathbf{A}$. The micromagnetic energy functional can be written in the following form[11]

$$W[\mathbf{J}_s, \nabla\times\mathbf{A}] = \Phi_{ex} + \Phi_K + \Phi_H + \frac{1}{2\mu_0}\int (\nabla\times\mathbf{A} - \mathbf{J}_s)^2 \, d^3r. \tag{6}$$

For any arbitrary continuous vector $\mathbf{A}$ which decays at infinity at least as fast as $1/r$, the last term of Eq. (6) is an upper bound for the stray field energy. The minimization of Eq. (6) with respect to $\mathbf{J}_s$ and $\mathbf{A}$ leads to local minima which are in one to one correspondence to those of the total magnetic Gibb's free energy (1) and makes $\mathbf{A}$ equal to the actual magnetic vector potential.

Since the functional $W[\mathbf{J}_s, \nabla\times\mathbf{A}]$ depends only on local variables and their derivatives, its minimization can be easily performed within the framework of the finite element method. Fredkin and Koehler[12] originally applied a magnetic vector potential in micromagnetic finite element calculations, in order to investigate magnetization processes in irregular shaped particles.

In a similar way, a magnetic scalar potential can be used to eliminate long-range terms from the total magnetic Gibb's free energy. However, introducing a magnetic scalar potential leads to a saddle-point problem. Generally, mixed type finite element methods associated with saddle point problems are numerically unstable unless special discretization schemes are applied.[13]

For the investigation of melt-spun magnets, we assume a geometry where the easy axes of the grains as well as the magnetization are constrained to a plane. The magnetization is taken to be uniform in the direction perpendicular to this plane. Because of translation symmetry along the direction perpendicular to the plane containing the easy axes, only in plane magnetization processes need to be considered. The magnetic polarization and the demagnetizing field depend only on two Cartesian coordinates. Therefore, the vector potential $\mathbf{A}$ reduces to a one component potential. Reference calculations in three dimensions show that this two-dimensional model is valid for nanocrystalline magnets.[14]

The linear interpolation of magnetization angles and of the magnetic vector potential on triangular finite elements gives an algebraic minimization problem. A preconditioned quasi-Newton conjugate gradient method[15] solves for the magnetization and the magnetic vector potential simultaneously at all nodal points of the finite element mesh. The hysteresis properties directly result from subsequent minimum energy solutions for decreasing and increasing applied fields.[16] The last term of Eq. (6) is an integration over the whole space which is evaluated using the "parallelepipedic shell transformation" proposed by Brunotte, Meunier, and Imhoff.[17] This bijective transformation maps the external space into a shell enclosing the parallelepipedic interior domain. Details of the implementation of this transformation in a three-dimensional micromagnetic finite element code are given in Ref. 18. In two-dimensional calculations the vector potential reduces to a one component potential $\mathbf{A} = (0,0,A_z)$ and thus all terms associated with A_x, A_y, vanish. In order to validate the method, the authors calculated the stray field energy of a uniformly magnetized cube and the nucleation fields of ellipsoidal particles. The relative error in the stray field energy was found to be less than 2%.[18] The same accuracy was obtain for the nucleation fields of ellipsoids in three-dimensional calculations and for the nucleation fields of infinitely extended elliptic cylinders in two-dimensional calculations. Since the nucleation field of ellipsoids depends on the shape anisotropy, these results verify the stray field calculation using a magnetic vector potential and a spatial transformation to treat the external space.

Special finite elements are used to model the multilayer structure in Co/Pt multilayer recording media. Such special elements take into account the energy but have no volume.[19] Thus, ill-conditioned matrices due to poor aspect ratio volume elements can be avoided. Since a Co layer contains only two atomic layers, the magnetization is assumed to be constant in the direction of the film normal. The stray field energy of the Pt layer can described in the very same way as the energy of a thin air gap in magnetostatic finite element calculations.[19] The use of this technique is justified, because the Pt-layer thickness is considerably smaller than the domain width which is in the order 200 nm.[20] Figure 1 summarises the approximations due to the use of special finite elements for modeling Co/Pt multilayer systems. In order to reduce the number of unknowns, the incomplete gauge formulation,[21] $\mathbf{A}\cdot\mathbf{z} = 0$ ($\mathbf{z}$ is the film normal), is used. For the calculations periodic boundary conditions are applied at the edges of a quadratic sample. A coordinate transformation in the direction of the film normal maps the exterior space onto some additional layers that account for the stray field energy in the exterior space.

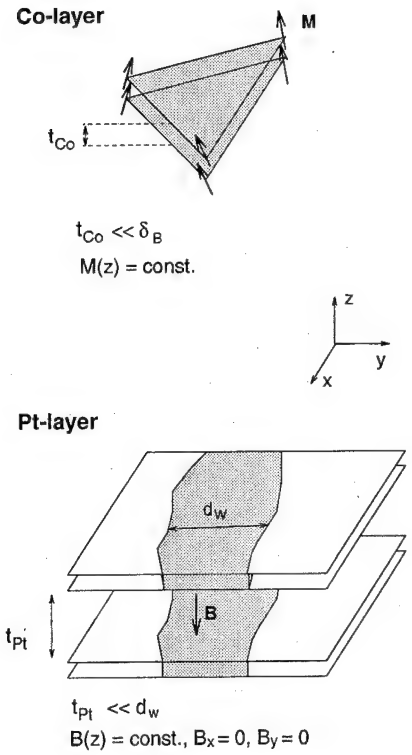

FIG. 1. Special finite elements to model Co/Pt multilayer structures. The Co-layer thickness, t_{Co}, and the Pt-layer thickness, t_{Pt}, are small as compared to the domain wall width of Co, δ_w, and the extension of domains, d_w, respectively.

III. NANOCRYSTALLINE $Nd_2Fe_{14}B$ MAGNETS

In nanocrystalline permanent magnets the grain diameter approaches the order of the domain wall width. Thus, the magnetization of several grains becomes strongly correlated increasing the remanence with respect to noninteracting particles. Several authors[22–24] reported an enhanced remanence in melt-spun Nd–Fe–B magnets being composed of nanocrystalline homogeneous grains without any nonmagnetic phases separating adjacent grains. Owing to intergrain exchange interactions the remanence considerably exceeds the value

$$J_r = J_s \langle \cos \theta \rangle, \tag{7}$$

given by the Stoner–Wohlfarth theory[6] for noninteracting particles. Here, θ is the angle between the saturation direction and the easy axes and $\langle\ \rangle$ denotes an ensemble average. According to Eq. (7) $J_r/J_s = 0.5$ for an assembly of noninteracting, randomly oriented particles, whereas J_r/J_s is $2/\pi = 0.64$ for microstructures with in plane random texture.

Modeling of the solidification process yields realistic two-dimensional microstructures of melt-spun Nd–Fe–B magnets.[25] The particles of randomly oriented easy axes are coupled by short-range exchange and long-range magnetostatic interactions. For calculations the material parameters of $Nd_2Fe_{14}B$ at $T = 300$ K [$K_1 = 4.3 \times 10^6$ J/m^3, $K_2 = 0.65 \times 10^6$ J/m^3, $A = 7.7 \times 10^{-12}$ J/m, $J_s = 1.61$ T (Ref. 26)] have been used. The grain size has been varied between 10 and 40 nm.

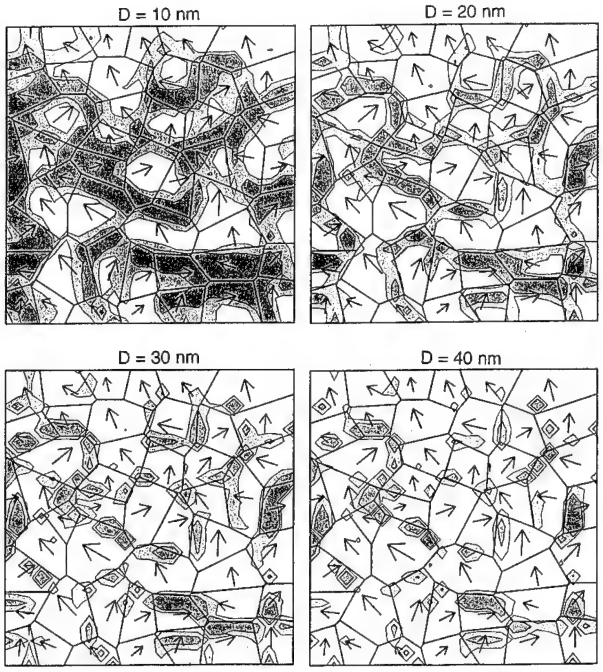

FIG. 2. Nonuniform magnetic states near grain boundaries for different average grain diameter D. The shaded areas denote the regions where the magnetic polarization deviates from the local easy axis by more than 10° and more than 20°, respectively.

Figure 2 clearly demonstrates the effect of intergrain exchange interactions on the magnetization distribution in nanocrystalline permanent magnets. The competitive effects of intergrain exchange interactions and magnetocrystalline anisotropy cause the magnetization to deviate from the local easy axis near the grain boundaries. The emphasized areas in Fig. 2 indicate the regions where $\mathbf{J}_s$ deviates from the local easy axes by more than 10° and 20°. The domain wall width $\delta_B = \pi\sqrt{A/K_1}$ restricts the extension of magnetic inhomogeneities. As a consequence the volume fraction of the nonuniform magnetic states becomes smaller for larger grain size. Only magnetic moments which deviate from the local easy

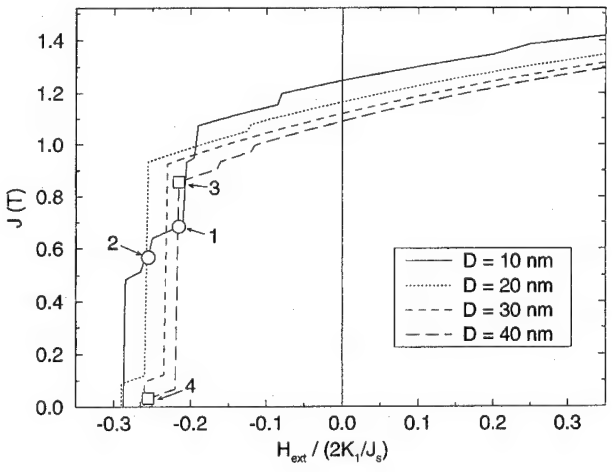

FIG. 3. Demagnetization curves as a function of the average grain diameter D. The circles refer to the stable equilibrium states plotted in Fig. 4.

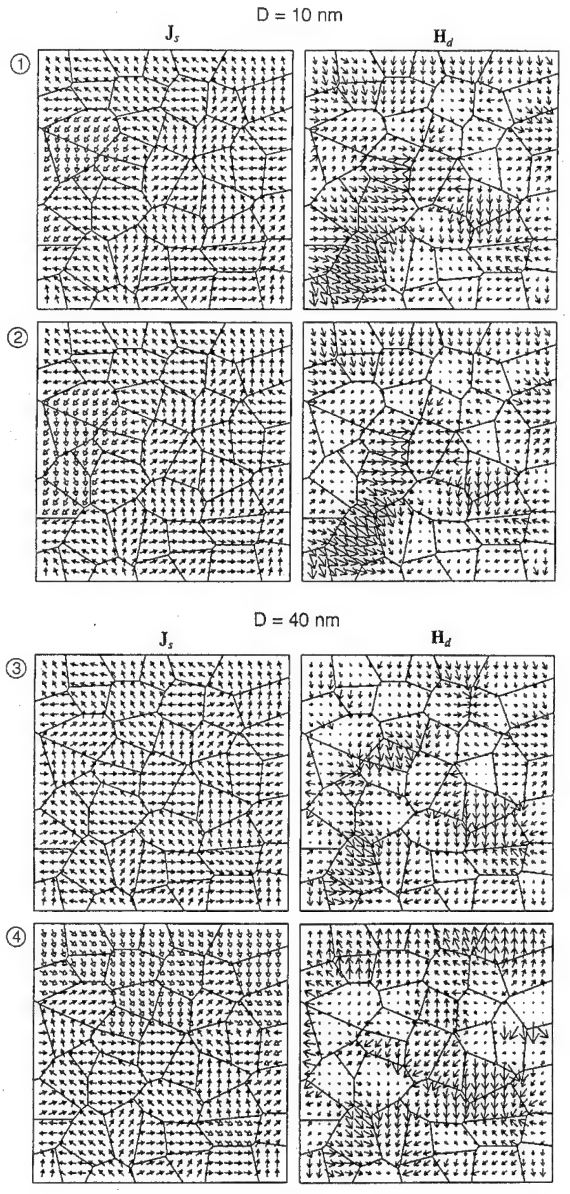

FIG. 4. Spin arrangements (left-hand side) and demagnetizing field (right-hand side) of a stable equilibrium states for different average grain size. (1) $\mu_0 H_{ext}=1.45$ T, $D=10$ nm; (2) $\mu_0 H_{ext}=1.72$ T, $D=10$ nm; (3) $\mu_0 H_{ext}=1.45$ T, $D=40$ nm; (4) $\mu_0 H_{ext}=1.72$ T, $D=40$ nm. axis can increase the remanence. Therefore, the remanence of nanocrystalline permanent magnets deteriorates with increasing grain size. The enhancement of the remanence with respect to noninteracting particles changes from 22% to 6%, as the average grain diameter varies between 10 and 40 nm.

Figure 3 compares the demagnetization curves for increasing grain size. The coercive field varies in the range from $H_c=0.29\times(2\ K_1/J_s)$ to $H_c=0.26\times(2\ K_1/J_s)$ and thus is significantly smaller than the Stoner–Wohlfarth value of 0.48 $(2\ K_1/J_s)$. Whereas the demagnetization curve for a mean grain size of $D=10$ nm shows several small steps, the steps become larger with increasing grain size. Intergrain exchange interactions and strong demagnetizing fields at sharp corners initiate magnetization reversal in the vicinity of the

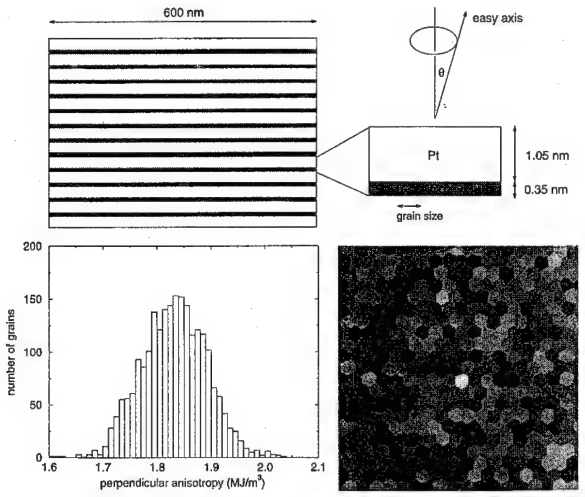

FIG. 5. Cross section of a Co/Pt multilayer structure and distribution of perpendicular anisotropy. The anisotropy constants of the top Co layer are mapped as gray scale with full bright referring to $K_u=1.6$ MJ/m^3 and full dark referring to $K_u=2.1$ MJ/m^3.

grain boundaries.[27] For an average grain size of 10 nm, the stray field energy and the exchange energy are approximately equal in magnitude. Magnetization reversal remains localised despite strong demagnetizing fields near the boundary of reversed domains, because the reversal of neighboring grains requires to overcome an energy barrier due to the exchange energy. The exchange energy decreases with increasing grain size reaching only 30% of the stray field energy for $D=40$ nm. Magnetization reversal may take place at less expense of exchange energy and thus strong demagnetizing fields easily expand reversed domains. Figure 4 compares stable equilibrium states at different external field for $D=10$ nm and $D=40$ nm.

IV. Co/Pt MULTILAYERS

Co/Pt multilayer structures are excellent candidates for high-density magneto-optic recording media.[28] Besides Lorentz electron microscopy,[29] micromagnetic modeling reveals the effects of microstructural features on the magnetic properties of Co/Pt multilayers. Figure 5 characterizes the structural properties of the multilayer system used for the calculations. The graphs show the cross section of the multilayer, the distribution of perpendicular anisotropy, and the grain structure. The maximum deviation angle θ between the easy axis and the film normal is a measure for the texture. The grains in different layers match in the film normal. Both, easy directions and perpendicular anisotropy constants vary from grain to grain and from layer to layer. The shape of each layer is rectangular. Periodic boundary conditions are applied. The polarization of Pt atoms next to the Co layers increases the magnetic polarization per unit volume Co by about 30%.[30] A nonvanishing magnetic polarization in the Pt layers gives rise to weak interlayer exchange coupling in addition to magnetostatic interactions. Table I summarizes the material properties used for the simulations.

Figure 6 presents the numerically calculated demagnetization curves for three different microstructures. The curves

show a step decrease at the nucleation field owing to the formation of reversed domains. As the domain wall pinning becomes the governing mechanism, magnetization reversal proceeds with a finite slope of the demagnetization curve. The nucleation field decreases from sample A to C. Both, increasing misalignment and increasing grain size cause a slight reduction of the nucleation field. Spatial fluctuations of the magnetocrystalline anisotropy energy from grain to grain hinder domain wall motion. The pinning field of domain walls increases with decreasing quality of texture and with increasing particle size. Figure 7 compares the domain patterns of samples A, B, and C at different applied fields. Magnetization reversal starts at few nucleation sites. The successive expansion of reversed domains significantly lowers the stray field energy. Numerical calculations for sample B show that an initially reversed domain of about 10 nm diam leads to the growth of an almost circular domain with an extension of 240 nm.

The jaggedness of domain walls significantly depend on the quality of texture and the grain size. Figure 8 shows numerically calculated bubble domains for samples A, B, and C. The equilibrium magnetic states have been calculated starting from an initially reversed magnetization within a cir-

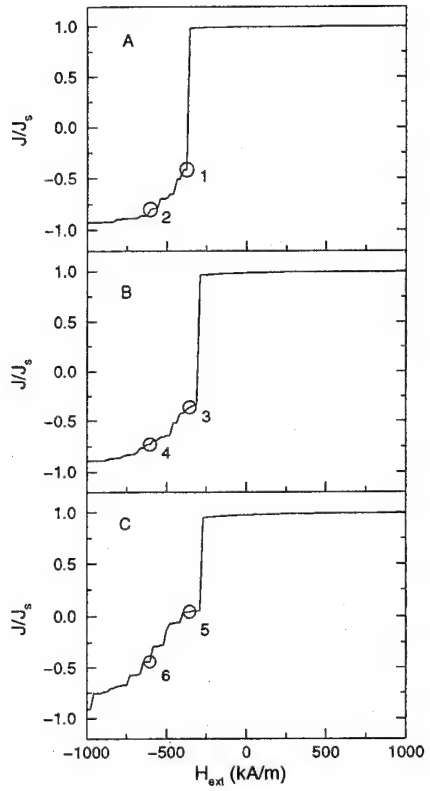

FIG. 6. Demagnetization curves of Co/Pt multilayers with different microstructural properties: (A) $\theta=5°$, $D=10$ nm; (B) $\theta=10°$, $D=20$ nm; (C) $\theta=10°$, $D=30$ nm. The numbers refer to the magnetization patterns given in Fig. 7.

cular region of 300 nm diam. The magnetization component parallel to the film normal has been averaged over 36 radial directions, in order to calculate the wall profiles of Fig. 8. Sharp transitions and smooth domain walls are found in sample A. The transition width and the domain wall jaggedness increase with decreasing quality of texture and increasing grain size.

V. CONCLUSION

A finite element method using a vector potential to treat long-range dipolar interactions proved to be effective in calculating interactive and cooperative magnetization processes in fine-grained magnetic materials. Nucleation of reversed domains and subsequent domain wall motion determines the hysteresis properties of melt-spun $Nd_2Fe_{14}B$ magnets and Co/Pt multilayers. In nanocrystalline permanent magnets intergrain exchange interactions enhance the remanence and initiate magnetization reversal under the influence of an external field. In Co/Pt multilayers only few nucleation sides are sufficient to form reversed domains with an extension in the order of 300 nm. The pinning field of domains increases with decreasing quality of texture and with increasing grain size.

Simulation of three-dimensional nonperiodic structures of π-vertical Bloch line and 2π-vertical Bloch line in magnetic garnet

M. Redjdal and F. B. Humphrey
Department of ECS Engineering, Boston University, 44 Cummington St., Boston, Massachusetts 02215

The dynamics of three-dimensional nonperiodic structures in magnetic garnet have been investigated using large scale numerical simulations. The width of a single π-vertical Bloch line (πVBL) at equilibrium has been measured to be twice the analytical Bloch line width $\pi(A/2\pi M_s^2)^{1/2}$, where A is the exchange energy constant and M_S the spontaneous magnetization. A 2πVBL has been shown to be 1.5× wider than a πVBL. A comoving technique is used to track a single domain wall with a single πVBL when a 5 Oe field is applied perpendicularly to the surface of the film. At dynamic equilibrium, the VBL to wall velocity ratio is equal to ten, smaller than the value found for a simulated loosely spaced chain of πVBLs. A 2πVBL is split into two single πVBLs when an in-plane field is applied in the same direction as that of the center spin of the 2πVBL. No motion of the surface spins is observed for the first 10 ns when a 30 Oe field is applied although considerable spin distortion occurs in the wall center. When the field is turned off after 8 ns, the relaxing distortion drives the surface spins apart. The containment due to 2π horizontal Bloch line formation during the process is demonstrated.
[S0021-8979(96)27408-X]

I. INTRODUCTION

Domain wall structures in magnetic garnet have been investigated using a large scale simulation method.[1] Bagnérés *et al.* showed that magnetization distortions play a critical role in the dynamics of periodically spaced chains of π-vertical Bloch lines (πVBLs) and 2πVBLs.[2–4] Patterson *et al.* investigated horizontal Bloch line (HBL) formation and its effect on wall motion.[5]

Most of the analytical investigations of the static and dynamic characteristics of wall structure have been based on a periodic arrangement of Bloch lines (BLs) in an infinitely long planar wall. Bloch line width was calculated using energy minimization[6] and by balancing exchange and demagnetizing forces.[7,8] The equilibrium distance between Bloch lines is in the order of $\sqrt{\pi A}/M_s$,[7] where A is the exchange energy constant and M_s, the spontaneous magnetization. No distinction was made between single πVBL and 2πVBL. The dynamics of periodic uncompressed Bloch lines in a planar wall with infinite length yielded a VBL to wall velocity ratio equal to $\pi\sqrt{Q}/2\alpha$, where Q is the quality factor and α, the damping parameter.[9] Using numerical simulation, Nakatani calculated the static structure of a πVBL using a very coarse three-dimensional lattice that drastically reduced the effect of the demagnetizing field.[10] Bagnérés used a much larger computer with a finer lattice to show that a πVBL structure is characterized by in-plane angle twists with a 2π twist at one surface, a π twist through the center line halfway between the surfaces and no twist at all at the other surface.[2]

In this article, the Landau–Lifshitz–Gilbert (LLG) equation is solved numerically to measure the widths of a πVBL and a 2πVBL in a single domain wall at equilibrium. A πVBL was moved gyrotropically by applying a field perpendicular to the surface of the film. A co-moving technique is used to track both the domain wall and its structure so as to center the coordinate system on the structure. A 2πVBL is split into two single πVBLs by applying an in-plane field. It is shown that the distortions drive the VBLs apart. The containment due to HBL formation slows the process.

II. TECHNIQUE

The simulations were performed by solving the LLG equation numerically in an xyz Cartesian lattice with 32 ×256×32 nodes, or 262 144 grid points. At each grid point, the simulation takes as input a characterization of the phenomenological magnetic parameters exchange, anisotropy, magnetostatic interactions, and saturation magnetization, together with an initial magnetization distribution and prescribed external field. Since free boundary conditions are used, a three-dimensional fast Fourier transform is combined with zero padding to evaluate the demagnetizing field in the isolated sample. The simulations were performed on the Connection Machine system CM5.

Initial magnetization distributions are based on analytical solutions for the azimuthal angle Θ and in-plane angle Ψ. The spin system is relaxed by solving the LLG equation with zero external field. The equilibrium is reached when the angular velocity of the fastest spin is in the order of 0.01 GHz which implies that the highest effective field acting on any spin in the system is no more than 0.2 Oe.

A co-moving technique is applied to the case where the domain wall (in yz plane) with a single πVBL is subjected to a constant field in the Z direction. A predictor-corrector algorithm is used to align the velocity of the coordinate system with that of the domain wall such that the πVBL is always kept in the center of the viewing frame. Such a system requires that the wall with the VBL be located accurately in both the x (for the moving wall) and y direction (for the VBL). The instantaneous velocity of the domain wall is directly tied to the total sum of M_z spins in the entire sample. The instantaneous velocity of the πVBL is calculated using the M_y spin component of the magnetization located in a region that contains the domain wall only. The wall velocity and πVBL velocity can be accurately calculated. The simu-

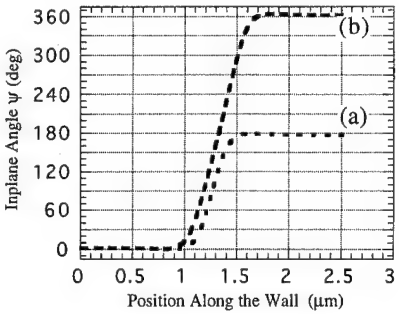

FIG. 1. In-plane angle ψ at the middle of the wall center slice as a function of position along the domain wall; (a) πVBL and (b) 2πVBL.

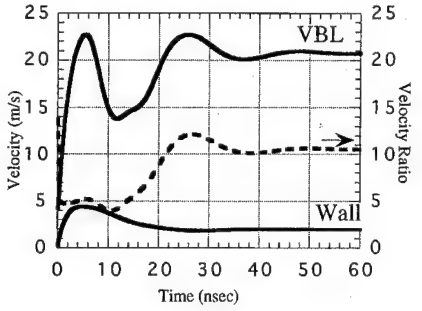

FIG. 2. Instantaneous velocity of a πVBL and a domain wall when the domain wall is driven by a 5 Oe bias field (α=0.2). The dashed curve shows the instantaneous πVBL to wall velocity ratio.

lation volume is 0.32 μm×2.56 μm×1.28 μm with a nodal ratio of 1:1:4. The maximum integration step is 1 ps. Typically, each nanosecond of simulation time requires about 1 h of CPU time.

The material parameters are exchange constant, $A=3.0\times10^{-7}$ ergs/cm; anisotropy field, $H_k=1860$ Oe; saturation magnetization, $4\pi M_s=452$ G; Gilbert damping constant, $\alpha=0.2$; gyromagnetic ratio, $\gamma=-0.01$ Oe^{-1} ns^{-1}.

III. RESULTS AND DISCUSSION

The equilibrium magnetization configuration for a wall containing a single πVBL or 2πVBL has been calculated numerically. Figure 1 shows the in-plane angle Ψ along a line in the middle of the sample and the wall center slice. The wall center slice is represented by the wall surface for which the magnetization component M_z is zero. The center spin line is represented by a line of spins midway between the surfaces of the material. For πVBL, the center spin undergoes a 180° rotation starting at the domain wall with one chirality and ending at the domain wall with the opposite chirality. The 2πVBL starts and ends in domain walls with the same chirality through a 360° rotation of its center spin. The width is determined by extrapolation of the linear portion of the curve to 0° and 180° for the πVBL and to 0° and 360° for the 2πVBL. The simulated width is 0.41 μm for a πVBL and 0.59 μm for a 2πVBL.

The πVBL simulated value compares better with the calculated equilibrium distance of 0.27 μm for the periodic arrangement of Bloch lines[7] and Hayashi's simulated πVBL (Ref. 10) than with the analytical result based on Bloch line width parameter.[6] According to Thiaville,[11] the measured πVBL width is 0.45 μm in a 7 μm thick sample. These results suggest that the πVBL width is independent of the thickness of the material.

Figure 2 shows the instantaneous velocity and the velocity ratio of a πVBL and a domain wall for the first 60 ns of motion under the influence of a 5 Oe field normal to the surface of the material. It can be seen that the wall velocity develops a slight overshoot then settles to a steady state velocity after ~20 ns. However, the πVBL takes twice as long to reach steady state motion after undergoing a relatively large oscillatory transient state. Finally, a steady state velocity ratio of 10 is reached after 60 ns. For loosely spaced periodic chains of πVBLs, Bagnérés[4] measured a VBL to wall velocity ratio of 14. We measure a smaller velocity ratio presumably because the motion of a single πVBL is slowed by the curvature inherent to the presence of the single VBL structure in a plane wall. This makes the velocity ratio even further from the analytically predicted value of 16 for uncompressed BLs in a planar wall.[9]

Figure 3 shows the contours of in-plane angle ψ of the magnetization in the wall center slice. The contour lines correspond to ±15°, ±45°, ±75°, ±105°, ±135°, and ±165° for ψ. The in-plane angle ψ is 0° or 180° in the direction perpendicular to the wall. These values are shown by the dotted lines in the shaded areas which represent regions where the magnetization is within ±15° of the direction perpendicular to the wall. In the light shaded areas close to the center along the wall, the magnetization lies within ±15° from the direction parallel to the wall.

Figure 3(A) shows a section of the wall slice center, 2.56 μm long, with a single 2πVBL at equilibrium. The 2πVBL has a 2π twist at all levels through the thickness of the material with a notable compression of the twist at both surfaces. For convenience, the distance between the dotted lines is defined as the "half-width." It can be seen that the contours are very regular and symmetric in the surrounding domain walls. The in-plane angle ψ varies at a rate close to 6° per node along the wall and through the thickness of the wall.

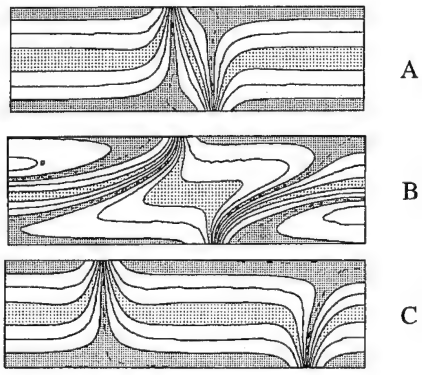

FIG. 3. Contours of the magnetization in-plane angle ψ in the wall containing a 2πVBL for: (A) the initial state, (B) after 8 ns when an in-plane field of 30 Oe has been applied, (C) almost at equilibrium at 100 ns after the field was turned off at 8 ns.

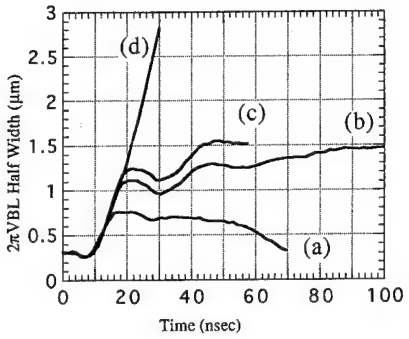

FIG. 4. 2πVBL half-width as a function of time when a 30 Oe pulse field is applied for: (a) 5 ns, (b) 8 ns, (c) 9.5 ns, and (d) 30 ns.

When a 30 Oe in-plane field is applied in a direction opposite to the chirality of the domain walls but in the same direction as that of the center spin of the 2πVBL, the contours become distorted. It can be seen that after 8.0 ns, as shown in Fig. 3(B), most of the distortion takes place at the center of the wall while the compressed twists, weighing down the domain wall at the surfaces, appear not to have moved. Horizontal Bloch lines form in the surrounding domain walls where the spins undergo a supplementary twisting due to the in-plane field. The pulse field is turned off at 8.0 ns. As the structure relaxes toward its equilibrium state, HBLs disappear. Slowly, the 2πVBL structure splits. Figure 3(C) shows the equilibrium configuration at a simulation time of 100 ns or 82 ns after the field is turned off. The separation distance is 1.5 μm, about three times a πVBL width. Bagnérés *et al.* measured a separation equilibrium distance equal to 1.2 μm for a loosely spaced and periodic chain of πVBLs.[2]

Figure 4 shows the half-width, distance between the center positions of the compressed twists at the surfaces, as a function of time for a 2πVBL when a 30 Oe in-plane field is applied. In curve (a), the pulse field is applied for 5 ns. The compressed twists show no movement during this time or for the first 10 ns. They start moving apart between 10 and 15 ns with no field applied, settle at a plateau of 0.7 μm until ~65 ns, and finally settle back to the equilibrium configuration at 70 ns without splitting the 2πVBL. Curve (b) shows the results when the pulse field is 8 ns long. It shows similar behavior to case (a) for the first 15 ns but the compressed twists break apart around 19 ns, undergo an oscillatory behavior and then proceed further apart to split the 2πVBL. Again, all motion is observed when no field duration is applied. Similarly, in curve (c), for which the pulse field is 9.5 ns, the compressed twists settle at an equilibrium distance close to 1.5 μm: the splitting of the structure into two single πVBLs has taken place. Curve (d) shows the half-width when the in-plane field is applied continuously. It can be seen that curves (b) and (c) are similar to curve (d) between 10 and 20 ns although (d) has a field applied while (b) and (c) have none. The formation of HBLs in the domain walls, on each side of the 2πVBL structure, presumably contributes to the containment of the latter. It implies that the distortions inside the structure are balanced by the formation of HBLs for the duration of the transient phase.

IV. CONCLUSION

It is shown that equilibrium structures of πVBLs and 2πVBLs are distinct. The 2πVBL is only 1.5× wider than a πVBL instead of twice. A velocity ratio of 10 was measured. This ratio is lower than the analytically predicted value of 16 for uncompressed Bloch lines. It was also demonstrated that in splitting a 2πVBL, it is as easy to use the distortions due to a short pulse as using a field. The containment due to horizontal Bloch line formation slows down the process.

Co–Cr–Ta thin film media produced by transfer deposition are known to be highly anisotropic. Earlier experimental work shows these films achieve the maximum theoretically possible δI in the parallel direction but small deviation from zero transverse to the sputtering direction. A thin film micromagnetic model has been extended to simulate this highly anisotropic behavior. It was found that anisotropic exchange coupling was insufficient to account for the anisotropic behavior. Good agreement with experiment has been obtained using an approach which modifies the exchange coupling *and* the magnetostatic interaction. The large values of δI are ascribed to difficulties in the production of the ac demagnetized state. © *1996 American Institute of Physics.*
[S0021-8979(96)27508-X]

I. INTRODUCTION

Transfer deposition has the advantage that it is a continuous method of production. However, sputtered Co–Cr–Ta thin film media prepared by transfer deposition have been shown to be highly anisotropic from the δI curves parallel to and transverse to the transfer direction.[1] Furthermore, measurements of modulation of the read/write performance of disks show the anisotropy is strongly dependent upon the track orientation[2] although this has not been related to the magnetization processes within the film. The motion of the substrate past the sputtering target leads to the formation of a "bowed columnar structure" in the transfer direction which leads to the high planar anisotropy.[1]

We have attempted to simulate the anisotropic behavior by studying the effects of the model parameters which are dependent upon the microstructure. The best description of the experimental data is found by introducing a small anisotropy in the microstructure resulting in an anisotropy of both the exchange and the magnetostatic coupling.

II. MICROMAGNETIC MODEL

A thin film micromagnetic model which includes anisotropy, Zeeman, magnetostatic and exchange energy for N grains on a hexagonal lattice[3] has been extended to study the origins of the difference in remanence properties between the parallel and transverse directions.

In an initial study, "anisotropic exchange coupling" was introduced to account for the anisotropic behavior, but despite giving the correct bulk properties, this was insufficient to account for the maximum δI.

In the magnetic layer, the bowed columnar structure causes a larger grain area to be in contact with adjacent grains along the transfer direction whereas transverse, the grains will be less affected. In the simulation, this has been interpreted as reduced interactions (both magnetostatic and exchange) in the transverse direction and has been incorporated into the model by expanding the lattice in the transverse direction. We use an exchange coupling term based on that introduced by Zhu and Bertram,[4] modified by Walmsley *et al.*[5] which includes a separation term to allow for irregular structures.

III. RESULTS

An extensive series of computations has been carried out which cannot be completely reported here because of space limitations. Instead, we report those data which were instrumental in leading to a good theoretical description of the experimental data. Although the fit cannot be considered completely unambiguous, the hypothesis involved seems reasonable and the model predictions lead to experimentally verifiable predictions, particularly the importance of ac erasure in δI measurements.

The thin film was represented by 56×68 grains on a hexagonal lattice. The grain diameter and thickness are in the range 40–50 nm.

A relatively small expansion ($<10\%$) was required to provide sufficient anisotropy. For a strongly interacting system though, this gave an unrealistic longitudinal squareness (>0.99) so 10% of the grains (chosen at random) were considered exchange decoupled to reduce the squareness, which had negligible effect on the co-operative behavior of the film.

Hysteresis loops have been computed for both in-plane orthogonal directions for 5 degrees of exchange coupling, $C^*=0.0,0.1,...,0.4$ and three interaction field parameters, $h_i=0.2$, 0.4, and 0.6. The parameter h_i controls the magnetostatic energy and is defined as $h_i=H_i/H_k$, where $H_i=M_sV/d^3$ with d the grain diameter (prior to expansion). Loops were computed for two expansion factors, $E_y=1\%$ and 5%, but results presented here are with the latter only.

Figure 1 shows the squareness for the parallel and transverse directions for $E_y=5\%$ and the three interaction field parameters as a function of exchange coupling. For each curve there is an increase of squareness with C^*, as expected. The small transverse expansion gives rise to a significant anisotropy in the magnetostatic interactions. This is

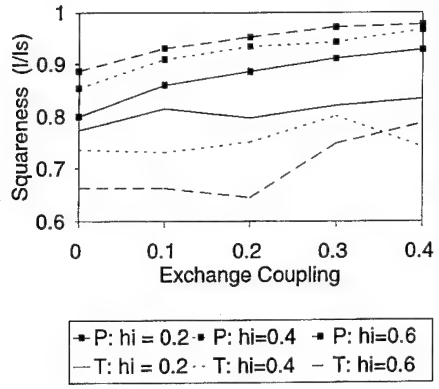

FIG. 1. Effect of exchange coupling on squareness for the two orthogonal directions.

reflected in the squareness which is enhanced parallel and decreased transverse by the magnetostatic interactions. The coercive states from the two orthogonal directions are very different. In the parallel direction, stripe domains dominate along the field direction because of the large exchange coupling and the reduced demagnetizing effect of nearest neighbors. Transverse, the magnetic microstructure consists of vortices which are formed to reduce the stray field.

A high degree of exchange coupling together with a large magnetostatic term is required to give the strong cooperative reversal which occurs experimentally. In fact, with $C^*=0.4$, $h_i=0.6$ and a 5% expansion, the hysteresis loops are in good agreement with experimental data in both parallel and transverse directions.

With these parameters, the dc-demagnetization curves, ac erased states, and IRM curves were computed. Experimentally, samples were demagnetized by rotation in a slowly reducing dc field and further demagnetized by slowly moving across a bulk eraser. If the measured sample moment was too large, the process was repeated a number of times until it fell below 1% of saturation. Difficulty in obtaining a demagnetized state in the simulation was also experienced. We have developed a technique for ac erasure based on simulated annealing, described more fully in Ref. 3, which assumes that the ac erased state is the magnetic ground state. The final ac erased state is strongly dependent upon the rate of annealing. A slow annealing schedule, corresponding to carefully erasure, has previously been followed[3] which leads to a demagnetized state with low system energy which is well correlated, with the formation of large scale structures in the magnetic state. An increased annealing rate leads to a higher system energy, shorter range correlations and less well correlated regions.

The ac erasure was carried out at four rates of erasure. The average grain energy for each erased state for increased annealing rate was −6.9, −6.5, −6.3, and −6.1 kV, the increase in energy being consistent with increasing imperfect demagnetization. A section of the final erased state for the slowly annealed is given in Fig. 2(a) and the most rapidly annealed in Fig. 2(b).

Figure 3 shows the IRM curves for the four ac erased states. The small sample size of 3808 grains causes large changes in the IRM and hence δI curves. In order make the

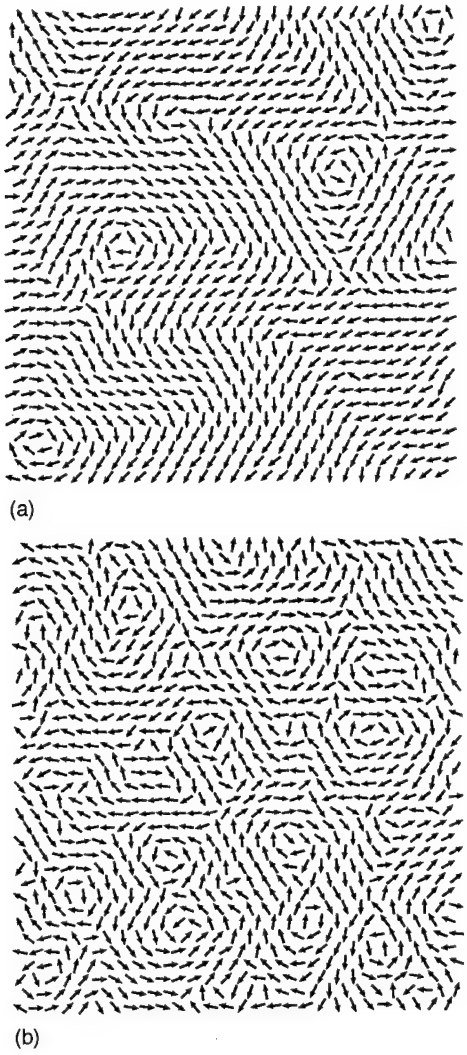

FIG. 2. Section of two ac erased states for (a) slowly (b) rapidly annealed.

interpretation of these curves easier but without changing their form, a moving average over three field steps was performed. The IRM curves are all zero in small fields indicating the stability of the ac erased state. The highest energy erased state reaches saturation remanence at the lowest field

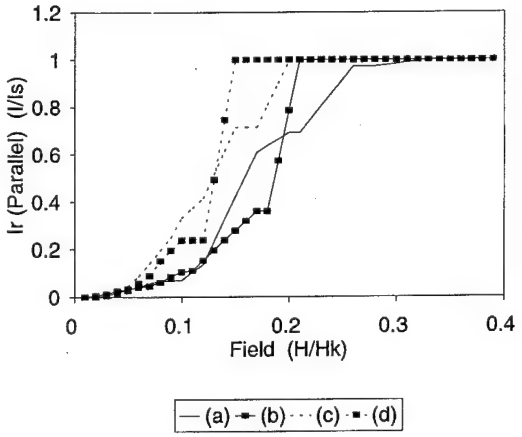

FIG. 3. IRM curves from four ac erased states.

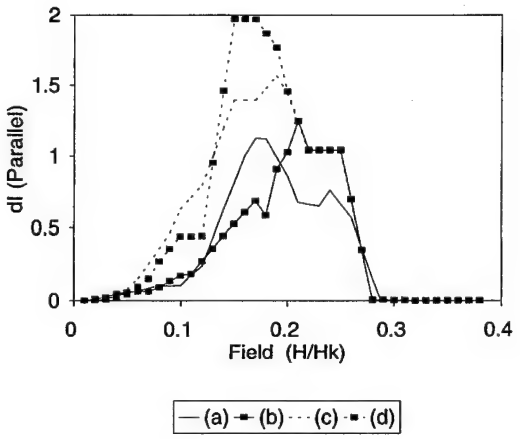

FIG. 4. Corresponding δI curves.

with others reaching it at larger applied fields. Using these IRM curves, the δI curves were calculated and are given in Fig. 4.

Due to the strong exchange coupling which allows the sample to resist a large negative applied field, all the δI curves are positive, but the maximum δI of 2 (required for complete agreement with experiment) is achieved only by the highest energy sample. The other samples which are of lower energy, reach saturation remanence at a field below which the sample has started to become demagnetized. This suggests that the form of the IRM curve is central to the δI plot. In particular, the erasure process has a strong bearing on the value of δI, as also stated previously.[6]

IV. CONCLUSION

The highly anisotropic behavior of sputtered Co–Cr–Ta thin film media prepared by transfer deposition has been simulated by extending a previous thin film model. In order to simulate the effect of the bowed columnar structure on the magnetic properties, the lattice was expanded transverse to the transfer direction. Comparison with experiment showed this to be the most satisfactory and consistent way to simulate the anisotropic magnetic behavior. The latter indicates the effect of disorder in the microstructure on the bulk magnetic properties. A high degree of exchange coupling and magnetostatic interaction was required to give strong cooperative reversal. An expansion factor of 5% gave the high planar anisotropy. It was found that a certain degree of disorder was required to reduce the squareness, and this was introduced by exchange decoupling 10% of the grains at random. These parameters gave the correct bulk hysteresis loop properties. A rapid annealing schedule was followed to simulate the imperfect erasure which is known to occur experimentally and the resulting δI curves are in good agreement with the experimental curves, demonstrating the importance of a consistent and reproducible method of ac erasure in δI measurements.

The Jiles–Atherton theory is based on considerations of the dependence of energy dissipation within a magnetic material resulting from changes in its magnetization. The algorithm based on the theory yields five computed model parameters, M_S, a, α, k, and c, which represent the saturation magnetization, the effective domain density, the mean exchange coupling between the effective domains, the flexibility of domain walls and energy-dissipative features in the microstructure, respectively. Model parameters were calculated from the algorithm and linked with the physical attributes of a set of three related melt-quenched permanent magnets based on the $Nd_2Fe_{14}B$ composition. Measured magnetic parameters were used as inputs into the model to reproduce the experimental hysteresis curves. The results show that two of the calculated parameters, the saturation magnetization M_S and the effective coercivity k, agree well with their directly determined analogs. The calculated a and α parameters provide support for the concept of increased intergranular exchange coupling upon die upsetting, and decreased intergranular exchange coupling with the addition of gallium. [S0021-8979(96)27608-2]

I. INTRODUCTION

The various relationships between structure and properties in permanent magnet materials are usually explored by experimental methods. With a few notable exceptions,[1,2] these relationships have not yet been extensively explored by theoretical modeling. We present here an inaugural investigation of the results which link model parameters calculated from an algorithm based on the Jiles–Atherton theory[3] with the physical attributes of a set of three related melt-quenched and thermomechanically treated permanent magnets based on the $Nd_2Fe_{14}B$ composition. Interpretations of the information thus yielded provides substantial insight into the hypothesized reversal mechanisms and internal coupling found in these magnets.

II. THE HYSTERESIS MODEL ALGORITHM

The Jiles–Atherton model[4–6] of hysteresis is based on consideration of the dependence of energy dissipation on change in magnetization, the principal cause of hysteresis in multidomain specimens. Consideration of the underlying mechanisms has produced two differential equations which represent the irreversible differential susceptibility and reversible differential susceptibility. The solution of these differential equations leads to a normal sigmoidal-shaped hysteresis curve, when combined with an appropriate choice of function for the anhysteretic magnetization. The algorithm requires input of nine experimentally measured parameters: The coercivity H_{ci}, the remanence B_R, the initial normal susceptibility χ'_{in}, the initial anhysteretic susceptibility χ'_{an}, the differential susceptibility at the coercive point $\chi'_{H_{ci}}$, the differential susceptibility at remanence χ'_{B_R} and the coordinates (H_m, M_m) of the loop tip, as well as the differential susceptibility of the initial magnetization curve at the loop tip, χ'_m.[4] The algorithm yields five computed model parameters, M_S, a, k, α, and c. The physical interpretation of these five model parameters is given as follows.

M_S is the saturation magnetization of the material, and thus the validity of this parameter is very easy to check, either by experimental means or by obtaining the data from references. The units of M_S are A/m or emu/cc.

The a parameter is sometimes referred to as the "effective domain density." The model parameter a is derived from an analogy to the Langevin expression[7] for the anhysteretic magnetization M_{an} as a function of both temperature T and field H for a paramagnet:

$$M_{an}(H,T)=M_S\times[\coth(H/a)-(a/H)], \tag{1}$$

where $a=k_BT/(\mu_0\langle m\rangle)$; M_S is the saturation magnetization and k_B is Boltzmann's constant. However, in the Jiles–Atherton theory, the spin entity $\langle m\rangle$ is not an atomic magnetic moment $m=n\mu_B$, where μ_B is the Bohr magneton, as in the original Langevin expression. Rather, it represents the moment from a mesoscopic collections of spins that we refer to as an "effective domain;" each "effective domain" possesses a collective magnetic moment $\langle m\rangle$. These effective domain entities may or may not correspond to actual magnetic domains; the units of a are in A/m or Oe.

k gives a measure of the quasistatic energy dissipation via the expression $k=(1/\mu_0)\times dE/dM$, with μ_0 as the permeability of free space and dE/dM the change in energy per change in magnetization. In the case of a material for which the coercivity is controlled by domain-wall pinning, this expression is related to effect of pinning sites on the progress

 0021-8979/96/79(8)/6470/3/$10.00

TABLE I. Sample descriptions and model parameter results calculated from the Jiles–Atherton algorithm.

Sample identification	Bulk composition	Processing	M_S (emu/cc)	a(Oe)	k(Oe)	α	c
HP1553	$Nd_{13.75}Fe_{80.25}B_6$	Hot pressed (MQ-2)	1080	13920	8825	3.168	0.885
DU1418	$Nd_{13.75}Fe_{80.25}B_6$	Die upset (MQ-3)	1000	1247	4100	0.742	0.485
DU2162	$[Nd_{13}(Fe_{0.95}Co_{0.05})_{81}B_6]_{0.996}Ga_{0.004}$	Die upset (MQ-3)	1100	3748	8246	1.472	0.885

of the hysteresis. In soft materials k is approximately equal to the coercivity H_{ci}; in hard materials it is equal to a modified form of the coercivity:[8]

$$k=\frac{M_{an}(H_c)}{1-c}\times\left\{\alpha+\frac{1}{\chi'_{max}-\left(\frac{c}{1-c}\right)\times\frac{dM_{an}(H_c)}{dH}}\right\}. \quad (2)$$

M_{an} is the anhysteretic magnetization as defined in Eq. (1); the units of k are A/m or Oe. An explicit expression for k has not been derived for the case where the coercivity is controlled by the nucleation of reversed domains; however, in general it is to be expected that k should increase when the density of domain reversal sites decreases.

α is a dimensionless quantity that describes the mean interaction field experienced by the effective domains, in a manner completely analogous to the Weiss molecular field: $H_{ex}=\alpha M$, where M is the magnetization.

The dimensionless model parameter c gives a measure of the relative magnitude of the reversible magnetization contribution to the total magnetization, and is defined by the expression $\chi'_{in}=c\chi'_{an}$.

III. RESULTS

The hysteresis loops that provided the experimental inputs to the model algorithm were obtained from three related, melt-quenched and thermomechanically processed magnets obtained from General Motors R. & D. Center. The bulk compositions of the magnets are given in Table I, along with some processing details. The samples were measured at $T=350$ K using a Quantum Design MPMS SQUID magnetometer with the furnace insert. The sample measurement configuration and subsequent data analysis is described in detail in Ref. 9.

Iterations of the parameter-determination algorithm produced the results presented in Table I. In general, the fits between the calculated and the experimental hysteresis loops were very good, being in error by less than 5% of the whole of the hysteresis curve. Figures 1(a)–(c) show the calculated hysteresis loops superimposed upon the measured loops. The calculated saturation magnetization values, M_S, agree well with the experimentally determined ones. The model parameters, a, k, and α, show very interesting variations from sample to sample, especially as the sample HP1553 was die upset to become DU1418. The parameters a and α, representative of the density of "effective domains" and the operative interdomain coupling, respectively, decreased sharply with die upsetting. These quantities recovered somewhat in the sample DU2162, doped with cobalt and gallium. The value of the k parameter, illustrating the average pinning

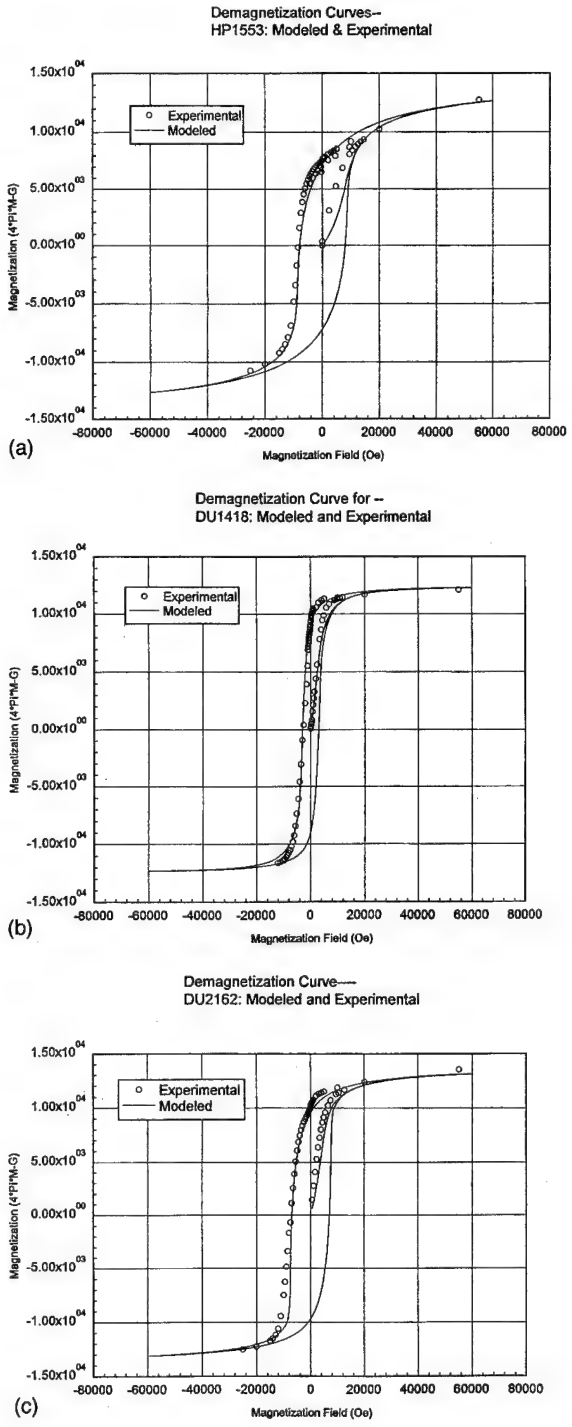

FIG. 1. (a) Hysteresis loops for sample HP1553 ($Nd_{13.75}Fe_{80.25}B_6$), modeled and experimental. (b) Hysteresis loops for sample DU1418 ($Nd_{13.75}Fe_{80.25}B_6$), modeled and experimental. (c) Hysteresis loops for sample DU2162 ($[Nd_{13}(Fe_{0.95}Co_{0.05})_{81}B_6]_{0.996}Ga_{0.004}$), modeled and experimental.

strength of the inhomogeneities in the materials, is roughly the same in HP1553 and DU2162, but is approximately half that value in DU1418.

IV. DISCUSSION

In order to lend physical insight to the calculated model parameters, a review of recent microstructural and magnetic characterization of the samples is necessary. The process of die upsetting a hot-pressed sample introduces drastic changes within the microstructure. A melt-quenched and hot-pressed sample typically consists of a dense collection of mostly equiaxed grains with dimensions on the order of 100 nm. Preliminary transmission electron microscopy (TEM) investigations performed at Brookhaven National Laboratory indicate that the grain size dispersion of HP1553 is small. Some researchers have found an additional phase in the microstructure, identified by electron diffraction as $Nd_5Fe_2B_5$.[10] An intergranular phase has also been identified at the grain boundaries[11] of hot-pressed samples and is reported to have a composition close to the eutectic composition in the Nd–Fe binary system, $Nd_{70}Fe_{30}$.

With die upsetting, the grains not only increase in size, but they become highly anisotropic. The die-upset structure consists of platelet-shaped grains of the 2–14–1 phase stacked along the press direction, the 2–14–1 tetragonal c axis. A thin intergranular phase has also been identified in these magnets, but the nature and composition of this phase is in dispute. Mishra *et al.*[11,12] report that the intergranular phase is crystalline (fcc), seems to uniformly coat all grains, and has a composition close to $Nd_{70}Fe_{30}$. Recent results, obtained with high resolution TEM methods[9,13] using a nominal 5 Å probe size, have demonstrated the existence of an amorphous grain boundary phase present in DU1418 and a related sample, die-upset PrFeB. Based on a sampling of 30 grain boundaries, the phase clearly shows an enrichment of iron in the grain boundary region relative to the grain itself; it does not evenly wet all surfaces of the deformed 2–14–1 main phase particles, but is found mainly on those boundaries parallel to the c axis.

Magnetic studies performed on DU1418 at elevated temperatures[9] show a linear development of both remanence and coercivity with applied field after thermal demagnetization, consistent with the phenomena of nucleation of reverse domains. The coercivity and remanence in HP1553 and DU2162 also show this same linear dependence. It has been postulated that the iron-rich grain boundary phase may act as a reverse grain nucleation site of lowered anisotropy, as well as providing a means to exchange couple the constituent grains.[9]

The above results lend interpretation to the calculated model parameters. The decrease in the a parameter from the relatively high value of 13920 Oe in HP1553 to the low value of 1247 Oe in DU1418 represents a decrease in the density of effective domains, as described in Sec. II. This decrease is consistent with a change in the microstructure that promotes exchange coupling among the grains in the die-upset sample, as would be expected if a significant portion of intergranular phase changed in composition from rare-earth rich to iron rich. The increase of the a parameter in DU2162, the sample doped with both cobalt and gallium, relative to that of DU1418, is consistent with a certain amount of exchange decoupling between the grains that serves to produce a greater density of "effective domains." Many researchers[14–17] believe that the addition of gallium to 2–14–1-based magnets segregates to the grain boundary phase; such a segregation would be expected to decrease the intergranular coupling by diluting the magnetic properties of the intergranular phase. Consistent with the above discussion, the variation of calculated k parameters can be ascribed to the difficulty in the nucleation of reversed grains. This difficulty may be traced to a dearth of Fe-rich, low-anisotropy rich regions in the microstructures of HP1553 and DU2162 of the proper dimensions to allow nucleation of reverse domains upon the application of a magnetizing field to a thermally demagnetized sample.

The calculated α parameters indicate that the coupling between the "effective domains" in HP1553 is somewhat stronger than that found in DU2162, and is much stronger than that found in DU1418. Such a result may be attributed to differences in the chemistry, thickness and occurrence of the iron poor intergranular and triple-point junction phases found in each material; the iron-rich intergranular phases presumably exist within the volume of the "effective domain" and do not contribute to α. Work is presently underway to thoroughly characterize the grain boundary phases in these materials using advanced TEM methods.

Superconducting hysteresis and the Preisach model

I. D. Mayergoyz
Electrical Engineering Department, University of Maryland, College Park, Maryland 20742

The critical state (Bean) model for superconducting hysteresis is discussed for arbitrary specimen shapes and complex flux distributions. It is demonstrated that this model exhibits the "wiping out" property and "congruency" property of minor hysteresis loops. This leads to the conclusion that the critical state model is a particular case of the Preisach model. For this reason, it is suggested to use the Preisach model for the description of superconducting hysteresis in very general situations.
 [S0021-8979(96)41508-2]

High-field (hard) type-II superconductors exhibit magnetic hysteresis. This hysteresis occurs because the motion of flux filaments is pinned by various deffects. The critical state model has been proposed[1–3] to treat the magnetic hysteresis of hard superconductors. This model is based on the assumption of ideal (sharp) resistive transition which is described by a rectangular (step wise) **E** vs **J** relation. This implies that persistent currents up to a critical current density j_c are always induced in superconductors. The critical state model has been further generalized[4] to take into account a dependence of critical current density on magnetic field.

It has been shown[5,6] that the critical state model for superconducting hysteresis is a very particular case of the classical Preisach model which has been traditionally used for the description of hysteresis in magnetic materials. This result has been established for one-dimensional flux distributions and specimens of simple shapes (plane slabs, circular cross-section cylinders). For these cases, explicit analytical expressions for magnetic field distributions within the superconductors are readily available, and they have been instrumental in the discussion presented in the aforementioned references.

The purpose of this article is to demonstrate that the critical state model is a particular case of the Preisach model for specimens of arbitrary shapes and complex flux distributions. For these specimens, analytical machinery for the calculation of magnetic fields within the superconductors does not exist. Nevertheless, it is shown below that the superconducting hysteresis (as described by the critical state model) still exhibits the "wiping out" property and the "congruency" property of minor hysteresis loops. These properties constitute the necessary and sufficient conditions for the applicability of the classical Preisach model.[6,7] This leads to the conclusion that the critical state model is indeed a particular case of the Preisach model. This fact suggests that the "first-order transition curves," which are used for the identification of the Preisach model, may emerge as standard experimental data for the identification of superconducting hysteresis and evaluation of hysteretic losses in superconductors.

To start the discussion, consider a superconducting cylinder of arbitrary cross section subject to the uniform external field $\mathbf{B}_e(t)$ whose direction does not change with time and lies in the plane of superconductor cross section (Fig. 1). We will choose this direction as the direction of axis x. As the time varying flux enters the superconductor, it induces screening (shielding) currents of density $\pm j_c$. The distribution of these superconducting screening currents is such that they create the magnetic field which at any instant of time completely compensates for the change in the external field $\mathbf{B}_e(t)$. Mathematically it can be expressed as follows:

$$\delta B_e(t)+B_i(t)=0. \tag{1}$$

Here $\delta B_e(t)$ is the change in $B_e(t)$, while $B_i(t)$ is the field created by superconducting screening currents, and equality (1) holds in the region interior to these currents.

It is clear that $\delta B_e(t)\geqslant 0$ when $B_e(t)$ is monotonically increased, and $\delta B_e(t)\leqslant 0$ when $B_e(t)$ is monotonically decreased. By using this fact and (1), it can be concluded that there is a reversal in the direction (polarity) of superconducting screening currents as $B_e(t)$ goes through its maximum or minimum values.

With these facts in mind, consider how the distribution of superconducting currents is generically modified in time by temporal variations of the external magnetic field. Suppose that, starting from zero value, the external field is monotonically increased until it reaches its maximum value M_1 at some time $t=t_1^+$. This monotonic variation of $B_e(t)$ induces a surface layer of superconducting screening currents. The interior boundary of this current layer extends inwards as $B_e(t)$ is increased [see Fig. 2(a)], and at any instant of time this boundary is uniquely determined by the instantaneous values of $B_e(t)$. Next, we suppose that the above monotonic increase is followed by a monotonic decrease until $B_e(t)$ reaches its minimum value m_1 at some time $t=t_1^-$. For the time being it is assumed that $|m_1|<M_1$.

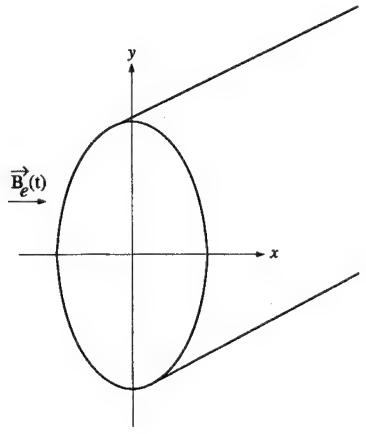

FIG. 1. A superconductor subject to the external magnetic field.

 0021-8979/96/79(8)/6473/3/$10.00

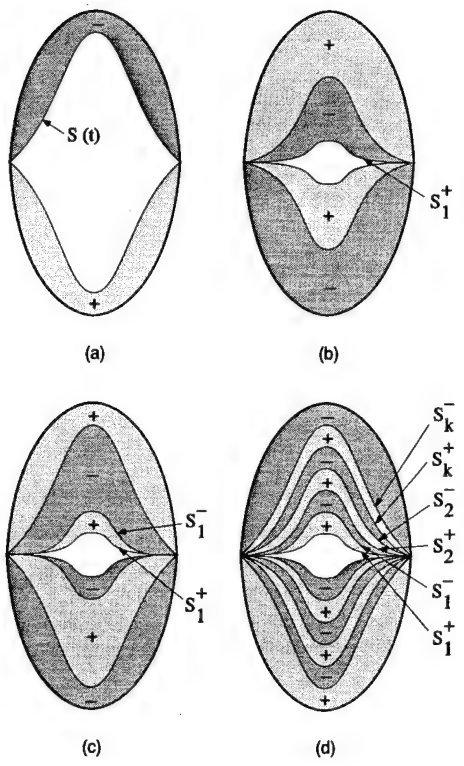

FIG. 2. Superconducting current distributions.

As soon as the maximum value M_1 is achieved, the inward progress of the previous current layer is terminated and a new surface current layer of reversed polarity (direction) is induced [see Fig. 2(b)]. This new current layer creates field $B_i(t)$ which compensates for monotonic decrease in $B_e(t)$ in the region interior to this current layer. For this reason, it is clear that the interior boundary of the new current layer extends inward as $B_e(t)$ is monotonically decreased. It is also clear that this boundary is uniquely determined by the instantaneous value of $\delta B_e(t)$, and, consequently, by the instantaneous value of $B_e(t)$ for any specific (given) value of M_1. Now, suppose that the above monotonic decrease is followed by a monotonic increase until $B_e(t)$ reaches its new maximum value M_2 at some time $t=t_2^+$. For the time being, it is assumed that $M_2<|m_1|$. As soon as the minimum value m_1 is achieved, the inward progress of the second current layer is terminated and a new (third) surface layer of superconducting screening currents of reversed polarity is introduced to counteract the monotonic increase of the external field [see Fig. 2(c)]. This current layer progresses inward until the maximum value M_2 is achieved; at this point the inward progress of the current layer is terminated. As before, the instantaneous position of the interior boundary of this layer is uniquely determined by the instantaneous value of $\delta B_e(t)$, and, consequently, by the instantaneous value of $B_e(t)$ for a specific (given) value of m_1.

By generalizing the previous line of reasoning, the essence of the critical state model can be summarized as follows. Each reversal in the external magnetic field results in the formation of a surface layer of superconducting screening currents. This layer extends inward with time until another reversal value of the external field is reached. At this point, the inward progress of the previous superconducting current layer is terminated and a new inward extending current layer is formed. The previously induced layers of persisting superconducting currents stay still and they represent past history of the temporal variations of the external field. This past history leaves its mark upon future distributions of superconducting currents.

Thus, it can be concluded that at any instant of time there exist several (many) layers of persisting superconducting currents [see Fig. 2(d)]. These persisting currents have opposite polarities (directions) in adjacent layers. The interior boundaries S_k^+ and S_k^- of all the layers (except the last one) remain still and they are uniquely determined by the past extremum values M_k and m_k of $B_e(t)$, respectively. The last induced current layer extends inward as the external field changes in time monotonically.

The magnetic moment $\mathbf{M}$ of the superconductor is related to the distribution of the superconducting screening currents as follows:

$$\mathbf{M}(t)=\int\int_S[\mathbf{r}\times\mathbf{j}(t)]ds, \tag{2}$$

where the integration is performed over the superconductor cross section.

In general, this magnetic moment has x and y components. According to (2), these components are given by the expressions:

$$M_x(t)=\int\int_S yj(t)ds, \tag{3}$$

$$M_y(t)=-\int\int_S xj(t)ds. \tag{4}$$

It is clear that if the superconductor cross section is symmetric with respect to x axis, then only the x component of the magnetic moment is present. In the absence of the above symmetry, two components of the magnetic moments exist.

It is apparent from the previous discussion that the instantaneous values of $M_x(t)$ and $M_y(t)$ depend not only on the current instantaneous value of the external field $B_e(t)$ but on the past extremum values of $B_e(t)$ as well. This is because the overall distribution of persisting superconducting currents, j, depends on the past extrema of $B_e(t)$. Thus, it can be concluded that relationships $M_x(t)$ vs $B_e(t)$ and $M_y(t)$ vs $B_e(t)$ exhibit *discrete* memories which are characteristic and intrinsic for rate independent hysteresis. It is worthwhile to note that it is the hysteretic relationship $M_x(t)$ vs $B_e(t)$ that is typically measured in experiments by using, for instance, a vibrating sample magnetometer (VSM) with a one pair of pickup coils. By using a VSM equipped with two pairs of orthogonal pickup coils, the hysteretic relation between $M_y(t)$ and $B_e(t)$ can be measured as well.

It is important to stress here that the property of rate independence of superconducting hysteresis can be traced back to the assumption of ideal (sharp) resistive transitions. This connection is especially clear for superconducting specimens of simple shapes (plane slabs or circular cross-section cylinders subject to coaxil and uniform external mag-

netic fields). For such specimens, the explicit and single-valued relations between the increments of the external field and the location of inward boundaries of superconducting layers can be found by resorting only to the Ampere's Law.[1–3] It is also worthwhile pointing here that in the case of gradual resistive transitions, customary described by the "power" law, the property of rate independence of superconducting hysteresis does not hold anymore.[8–10] For this reason, it can be conjectured that the gradual resistive transitions may be at least in part responsible for the rate dependence of hysteresis that has been observed for high-T_c superconductors and that is usually and exclusively attributed to creep.

Now, we return to the above description of the critical state model. It is clear from this description that a newly induced and inward extending layer of superconducting currents will wipe out (replace) some layers of persisting superconducting currents if they correspond to the previous extremum values of $B_e(t)$ which are exceeded by a new extremum value. In this way, the effect of those previous extremum values of $B_e(t)$ on the overall future current distributions will be completely eliminated. According to (3) and (4), the effect of those past extremum values of the external magnetic field on the magnetic moment will be eliminated as well. This is the "wiping out" property of the superconducting hysteresis as described by the critical state model.

Next, we proceed with the discussion of the "congruency" property. Consider two distinct variations of the external field, $B_e^{(1)}(t)$ and $B_e^{(2)}(t)$. Suppose that these two external fields have different past histories and, consequently, different sequences of local past extrema, $\{M_k^{(1)}, m_k^{(1)}\}$ and $\{M_k^{(2)}, m_k^{(2)}\}$. However, starting from some instant of time they vary back-and-forth between the same reversal values. It is apparent from the description of the critical state model and expressions (3) and (4) that these two identical back-and-forth variations of the external field will result in the formation of two minor loops for hysteretic relation $M_x(t)$ vs $B_e(t)$ [or $M_y(t)$ vs $B_e(t)$]. It is also apparent from the same description of the critical state model that these two back-and-forth variations of the external field will affect in the *identical* way the *same* surface layers of a superconductor. Unaffected layers of the persistent superconducting currents will be different for $B_e^{(1)}(t)$ and $B_e^{(2)}(t)$ because of their different past histories. However, according to (3) and (4), these unaffected layers of persistent currents result in constant in time ("background") components of the magnetic moment. Consequently, it can be concluded that the same *incremental* variations of $B_e^{(1)}(t)$ and $B_e^{(2)}(t)$ will result in equal *increments* of M_x (and M_y). This is tantamount to the congruency of the corresponding minor loops. Thus, the congruency property is established for the superconducting hysteresis as described by the critical state model.

The experimental testing of the "congruency" and "wiping out" properties has been recently undertaken[11] and it has been found that these properties are in good compliance with experimental data for tested superconductors.

It has been established[6,7] that the "wiping out" property and the "congruency" property constitute the necessary and sufficient conditions for the representation of actual hysteresis nonlinearities by the Preisach model. Thus, the description of the superconducting hysteresis by the critical state model is equivalent to the description of the same hysteresis by the Preisach model. The question can be immediately asked, "What is to be gained from the above result?" The answer to this question can be stated as follows. There is no readily available analytical machinery for the calculation of the interior boundaries of superconducting current layers for specimens of arbitrary shapes. For this reason, the critical state model does not lead to the mathematically explicit results. The application of the Preisach model allows one to circumvent these difficulties by using some experimental data. Namely, for any superconducting specimen, the "first-order transition" curves can be measured and used for the identification of the Preisach model[6] for the given specimen. By using these curves, complete prediction of hysteretic behavior of the specimen can be given at least at the same level of accuracy and physical legitimacy as in the case of the critical state model. In particular, cyclic and "ramp" losses can be explicitly expressed in terms of the first-order transition curves.[6]

The above result can be also useful whenever numerical implementation of the Bean model is attempted. Indeed, the numerical realization of the Bean model can be appreciably simplified by computing only the "first-order transition" curves and then by using these curves for the prediction of hysteretic behavior for arbitrary piece-wise monotonic variations of the external field.

In conclusion, I wish to thank Professor G. Friedman from UIC for many helpful discussions. This research is supported by the U.S. Department of Energy, Engineering Research Program.

A model for magnetomechanical hysteresis and losses in magnetostrictive materials

A. Bergqvist
Electric Power Engineering, Royal Institute of Technology, S-10044 Stockholm, Sweden

G. Engdahl
Power Engineering, ABB Corporate Research, S-72178 Västerås, Sweden

A phenomenological hysteresis model for the magnetomechanical constitutive law in highly magnetostrictive materials is proposed. Magnetization and strain are represented using a set of noninteracting particles. Any change in magnetization or strain in individual particles is assumed to be obstructed by a counterforce analogous to mechanical dry friction. Comparisons have been made with experiments performed on Terfenol-D under varying field and/or stress with satisfactory results. © *1996 American Institute of Physics.* [S0021-8979(96)41608-9]

I. INTRODUCTION

Computer simulations play an increasingly important role in device design. In applications involving highly magnetostrictive materials such as Terfenol-D, it is necessary to have constitutive models relating bulk magnetization M and strain S to magnetic field H and mechanical stress T. Such materials exhibit nonlinearity, which is significant except for processes in the small-signal domain, and hysteresis which can contribute considerably to the losses in a device.

In this context, it is more important that a model agrees well with experiments and is computationally simple and efficient rather than giving a detailed description of the microscopic processes involved. Also, in a real device, the waveforms of field and stress in the active material are usually not known *a priori* so a model must allow for both field and stress to be arbitrary functions of time. A model which merely gives for instance the behavior under a fixed mechanical stress is here useless. In this work, we present a phenomenological uniaxial magnetomechanical hysteresis model, using the same approach as in a recent model for magnetic vector hysteresis.[1]

II. THE MODEL

In the Jiles–Atherton theory,[2] it is reasoned that ferromagnetic hysteresis is due to a friction-like force opposing any changes in magnetization. This notion is adopted here; however the friction is in this work assumed to act analogously to mechanical dry friction, a.k.a. Coulomb friction. We will briefly present the basic properties of Coulomb friction, which is discussed in more detail in standard works on mechanics.[3]

One intuitive formulation of Coulomb friction that emphasizes the parallels with magnetism is as follows: Suppose we have an object on a surface, subjected to gravity, normal force, and a controllable force P. Its potential energy V is proportional to its height above the ground and is indirectly a function of the horizontal coordinate x. It is straightforward to show that the horizontal component of the sum of gravitational force and normal force is $-\partial V/\partial x$. Without friction, there would be a single-valued relation between applied force P and position x given by the condition that the total force $P-\partial V/\partial x$ is zero. However, if there is Coulomb friction, the object will not move unless $|P-\partial V/\partial x|$ reaches some threshold value, here called P_F. In that case, the $P-x$ relation will be a hysteresis curve with a width $2P_F$. Figure 1 shows a typical example. The relation can be formulated more precisely as follows: As long as $|P-\partial V(x)/\partial x|\leqslant P_F$ there is a metastable state. If the force changes to a new value P' such that $|P'-\partial V(x)/\partial x|>P_F$, then the position will change to a new value x' such that $|P'-\partial V(x')/\partial x|=P_F$.

If the force and position are vectors in two or more dimensions, there are a couple of complicating factors. One is that the friction may be anisotropic, so that the threshold value P_F is a function, not necessarily simple, of the direction of the force $(\mathbf{P}-\nabla V)$. We may say that there is no change in position $\mathbf{x}$ as long as $(\mathbf{P}-\nabla V)$ belongs to some metastability region which in the isotropic case is a circle. Another aspect is that when the force does reach the threshold value, it is not apparent in what direction the movement is in, although in the isotropic case, it should be parallel to $(\mathbf{P}-\nabla V)$.

Let us now see how we can adopt Coulomb friction for the description of magnetomechanical hysteresis. Suppose we have a pseudoparticle with magnetization m, strain s, and a free energy f that depends only on m and s. There is a clear analogy between such a particle and a mechanical system with an object on a surface, in that the mechanical system is governed by minimization of $V(\mathbf{x})-\mathbf{P}\cdot\mathbf{x}$, while, due to the principle of entropy maximization, for the particle it is the potential $g=f(m,s)-Hm-Ts$ that strives towards a minimum.[4] We now assume that the relation between (H,T)

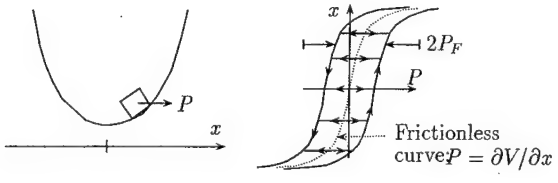

FIG. 1. An object on a surface subjected to an applied force P and Coulomb friction. The figure to the right shows the resulting relation between P and position x.

 0021-8979/96/79(8)/6476/3/$10.00

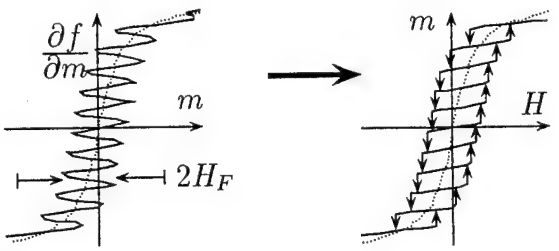

FIG. 2. Relation between H and m when the free energy $f(m)$ contains a small ripple. Dotted curves show behavior without ripple.

and (m,s) is analogous to the relation between **P** and **x** in the presence of Coulomb friction. In other words, for a given (m,s), there exists a region such that as long as (H,T) stay within the region, there is no change in (m,s).

Formally, such behavior can be reproduced by stating that f is the sum of a convex function $f_{an}(m,s)$, corresponding to anhysteretic behavior, and a small ripple $f_F(m,s)$, and then apply the principle of minimization of g. The ripple introduces a large number of densely distributed local minima for g. As an example we may consider a purely magnetic case with $f_F=-(H_F/N)\cos(Nm)$, where N is large. The relation between H and m can then be derived[4] and is illustrated in Fig. 2. As $N\to\infty$, the magnetization curve asymptotically becomes equivalent to the $P-x$ relation of Fig. 1. Therefore, if f contains a ripple component, Coulomb friction-type behavior emerges naturally. The aforementioned aspects of anisotropic friction can likewise be represented and are then related to the shapes and locations of the small potential wells of f_F in some complicated manner.

We proceed to define the two auxiliary quantities $\tilde{H}=\partial f_{an}/\partial m$, $\tilde{T}=\partial f_{an}/\partial s$. Since without friction we would have $H=\partial f_{an}/\partial m$, $T=\partial f_{an}/\partial s$, it is natural to write

$$(m,s)=[M_{an}(\tilde{H},\tilde{T}),S_{an}(\tilde{H},\tilde{T})], \tag{1}$$

and label (M_{an}, S_{an}), which are the inverse of $(\partial f_{an}/\partial m,\partial f_{an}/\partial s)$, the anhysteretic curves.

The shape of the metastability region could conceivably be estimated from experiments. For simplicity however, we here assume it to be elliptical. This can be expressed through the inequality

$$H_F^{-2}(H-\tilde{H})+T_F^{-2}(T-\tilde{T})^2\leq 1. \tag{2}$$

H_F and T_F are adjustable parameters corresponding to the half width of purely magnetic hysteresis loops and purely mechanical hysteresis loops, respectively.

Concerning the direction in which changes occur, we again simplify and assume that a change in $(\tilde{H},\tilde{T})$ is parallel to $(H-\tilde{H},T-\tilde{T})$. In other words,

$$(\Delta\tilde{H},\Delta\tilde{T})=\Delta\xi(H-\tilde{H},T-\tilde{T}), \tag{3}$$

where $\Delta\xi$ is adjusted so that after a change in $(\tilde{H},\tilde{T})$, the left-hand side of (2) is exactly 1. It is a straightforward algebraic exercise to show that

$$\Delta\xi=1-[H_F^{-2}(H-\tilde{H})^2+T_F^{-2}(T-\tilde{T})^2]^{-1/2}. \tag{4}$$

An incremental algorithm for determining (m,s) for any variation of (H,T) can now be formulated as follows: Suppose that at some moment we have known values (H,T) and $(\tilde{H},\tilde{T})$ and that (H,T) are then changed by a small amount. With the new (H,T) values and the old $(\tilde{H},\tilde{T})$ values, we check if (2) is fulfilled. If it is, there is no change in $(\tilde{H},\tilde{T})$; otherwise $(\tilde{H},\tilde{T})$ are updated using (4) and (3). Thereafter, (m,s) are found from (1).

We can also determine the energy loss q for arbitrary processes. The change in loss is the difference between changes in work and stored energy, $\Delta q=H\Delta m+T\Delta s-\Delta f$. Noting that f_F is always very small and using Taylor expansions and the definitions of $\tilde{H}$ and $\tilde{T}$, gives $\Delta f\approx\Delta f_{an}\approx\tilde{H}\Delta m+\tilde{T}\Delta s$. Dividing by Δt and taking the limit, we find

$$\dot{q}=(H-\tilde{H})\dot{m}+(T-\tilde{T})\dot{s}. \tag{5}$$

It is easy to realize that for any cyclic process, the net loss is the sum of the areas of the closed magnetic and mechanical hysteresis loops $\oint(H\,dm+T\,ds)$. It is also straightforward to show that $\dot{q}\geq 0$ at all times. This can be derived from the fact that f_{an} is convex and that $(\dot{\tilde{H}},\dot{\tilde{T}})\propto(H-\tilde{H},T-\tilde{T})$. The details are excluded.

The type of pseudoparticle described exhibits basic qualitative properties of magnetomechanical hysteresis. However, the minor loop behavior, which as seen in Fig. 1 consists merely of horizontal lines connecting major loop branches, is too simple to be satisfactory. To get a better agreement, with real behavior, we consider an assembly of such particles, differing only by the magnitude of the friction. Thus they have the same nonhysteretic properties, the same ratio between magnetic and mechanical friction, etc. To express this, we associate each particle with a dimensionless positive scalar α. For a given particle, H_F and T_F are multiplied by α in Eqs. (2) and (4). The net magnetization and strain are written

$$M=\int_0^\infty M_{an}[\tilde{H}(\alpha),\tilde{T}(\alpha)]\zeta(\alpha)d\alpha, \tag{6}$$

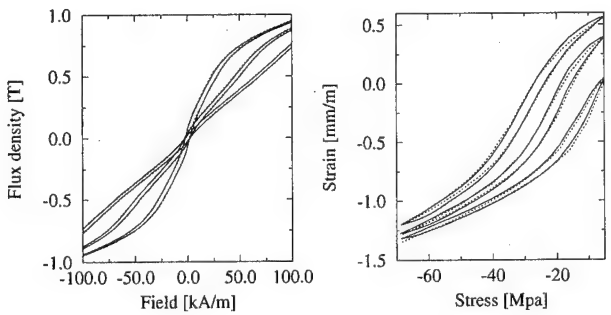

FIG. 3. Flux density vs magnetic field for constant values of T and strain vs stress for constant values of H. Solid lines=calculations, dotted lines =experiments.

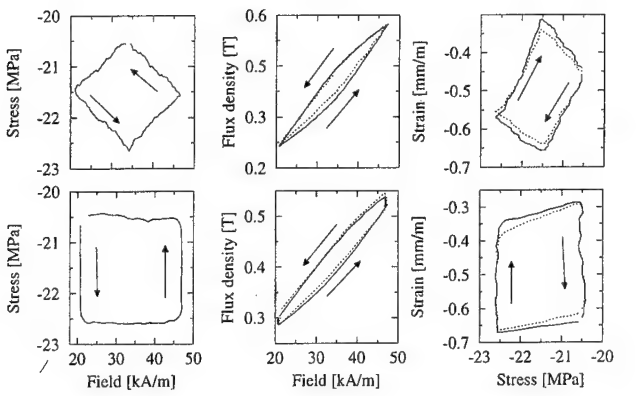

FIG. 4. Magnetic and mechanical work for two processes. Upper row, process A; lower row, process B. Diagrams to the left show controlled stress-field trajectories. Solid lines=calculations, dotted lines=experiments.

$$S=\int_0^\infty S_{\mathrm{an}}[\tilde{H}(\alpha),\tilde{T}(\alpha)]\zeta(\alpha)d\alpha. \tag{7}$$

Here $\tilde{H}(\alpha)$ and $\tilde{T}(\alpha)$ are the values of $\tilde{H}$ and $\tilde{T}$ for a particle with frictional multiplier α and $\zeta(\alpha)$ is a weight distribution giving the volume fraction for the corresponding particle. It satisfies the normalization condition $\int_0^\infty \zeta(\alpha)d\alpha=1$. In a numerical implementation, we must use a finite number of particles and approximate (6) and (7) by sums.

It is straightforward to show that if either field or stress is kept constant, the model behaves like the classical Preisach model[5] (CPM) with a particular configuration of parameters. However, the present work should not be viewed as a mere reformulation of the CPM since the CPM is only defined for a single scalar independent variable and the proper generalization to the case of several variables is far from clear.

III. DETERMINATION OF PARAMETERS

To use the model, we need a method for determining material parameters from experiments. The parameters involved are the anhysteretic functions $M_{\mathrm{an}}(H,T)$ and $S_{\mathrm{an}}(H,T)$, the distribution $\zeta(\alpha)$, and the friction constants H_F and T_F. We will in this work not actually model the anhysteretic curves, but estimate them entirely from experiments in the following manner: If we define $M^+(H,T)$ and $M^-(H,T)$ as the values of M along the upper and lower branches of a saturation loop with respect to H under constant T, an approximation that appears to be quite accurate is

$$M_{\mathrm{an}}(H,T)\approx 1/2[M^+(H-H_c,T)+M^-(H+H_c,T)].$$

$S_{\mathrm{an}}(H,T)$ can be similarly estimated.

$\zeta(\alpha)$ is for convenience assumed to be the sum of a Gaussian and a Dirac delta function

$$\zeta(\alpha)=A\ \exp[-(\alpha-1)^2]+\lambda\,\delta(\alpha). \tag{8}$$

Here A is given by normalization and λ is an adjustable parameter. The second term in this expression gives a fully reversible contribution since $\alpha=0$ corresponds to the frictionless case. In a small minor loop, any changes are due to this component since particles with $\alpha>0$ then have minor loops that are only horizontal lines as seen in Fig. 1. We can therefore determine λ as the ratio between the slope of a small minor loop for some arbitrary (H,T) and the slope of the anhysteretic curve for the same (H,T).

H_F and T_F finally can be found from for instance magnetic and mechanical losses. For a major M,H loop under constant T, the loss contribution from a particle is clearly $4\alpha H_F M_s$ where M_s is the saturation magnetization. The total loss of a major loop is therefore $[4H_F M_s\int_0^\infty \alpha\zeta(\alpha)d\alpha]$ which is proportional to H_F. In this manner, H_F can be adjusted to fit a measured magnetic loss. Similarly, T_F can be estimated from a measured mechanical loss $\oint T\,dS$ under constant H.

IV. RESULTS AND CONCLUSION

Computations have been compared to experiments done on a sample of Terfenol-D. The experimental equipment has been described in Ref. 6. Parameter values were $\lambda=0.48$, $H_F=2.56$ kA/m, $T_F=1.6$ MPa. Figure 3 shows some results when either field or stress is kept constant. In Fig. 4 are shown two cases, labeled A and B, of simultaneously or alternatively changing field and stress. These are examples of how magnetic energy can be converted to mechanical energy. The supplied positive net magnetic work is $W_H=\oint H\,dB$ giving a negative net mechanical work $W_T=\oint T\,dS$. The net total work $W_H+W_T\geq 0$ is dissipated. The relative loss $(W_H+W_T)/W_H$ was measured to be 65% and 42% for cases A and B, respectively, while model calculations gave 57% and 45%. This shows that hysteresis losses are very significant for these processes and that they are quite well estimated by the model.

It is found that the model shows a fair accuracy for processes when field, stress, or both are changing in time and that this is achieved at a modest cost in terms of computational complexity and experimental characterization of a material.

J. González
Facultad de Quimica–UPV/EHU, 20009 San Sebastian, Spain

The relaxation at constant applied field and temperature of a simple magnetic system is evaluated in the framework of the micromagnetic approximation and using a Monte Carlo algorithm. Our results, and particularly, those corresponding to the time evolution of the probability of magnetic moment reversal, evidence remarkable differences with the classical Arrehnius–Néel predictions. These differences are linked to the fact that relaxation proceeds through the formation of structures involving a large number of degrees of freedom. © *1996 American Institute of Physics.* [S0021-8979(96)28608-4]

I. INTRODUCTION

The phenomenology of thermally activated demagnetization is discussed by assuming that the magnetic system under consideration can be described in terms of a distribution of noninteracting, local two-level subsystems,[1,2] each one relaxing according to the Arrehnius–Néel kinetics.[3] This assumption is based on the occurrence of energy barriers, linked to the effective anisotropy and preventing the system from evolving from the remanence-type states to reversed ones. In the framework of this approach it could, in principle, be possible to correlate the so-called magnetic viscosity data, that is, the time evolution of the magnetization measured at constant applied field and temperature, with some characteristics of the distribution of energy barriers and eventually with the intrinsic and extrinsic properties originating those barriers.[4]

Nevertheless, the two-level subsystems approach is only acceptable if the process of temperature induced overcoming of the local barriers can be described in terms of a reduced number of degrees of freedom, that is, considering a mechanism of the coherent rotation type.[5] Since with a few exceptions, coherent rotation cannot quantitatively account for the magnetization reversal of real materials, the appropriateness of the approach should then be scrutinized in detail. Also, and importantly, recent experimental[6,7] and simulation[8,9] works have evidenced the occurrence in simple systems of significant departures from the predictions of the two-level Arrehnius–Néel relaxation kinetics.

The aim of the present work is to examine, in the framework of the micromagnetic approximation, a simple magnetic relaxation case: that corresponding to identical, noninteracting individual magnetic entities having many degrees of freedom.

II. DESCRIPTION OF THE MODEL

An individual relaxing unit (a "particle," see inset in Fig. 1) consists of a chain of 100 parallel infinite planes. This size is, at least, one order of magnitude larger than the different correlation lengths associated with the considered values of the model parameters describing the intrinsic magnetic properties of our system and, therefore, our results are only weakly dependent on the "particle" size. For the sake of simplicity, intraplane and interplane exchange constants are considered infinite and finite, respectively, which makes up our model one-dimensional, although the magnetic moments representing each plane are allowed to orient in three dimensions.

The intrinsic magnetic properties of the "particle" are defined by the exchange-to-anisotropy ratio, $a=Ad^{-2}/K$ (where A, d, and K are the exchange constant, the interplanar distance, and the anisotropy constant, respectively) and by the square of the magnetization-to-anisotropy ratio, $m=\mu_0 M_s^2/2K$ (where M_s is the saturation magnetization). We considered values for these parameters ($a=5$, $m=0.15$, and $d=2.5\ 10^{-10}$ m) corresponding to highly anisotropic materials. The internal energy of the system included terms corresponding to the anisotropy energy (local, uniaxial), the Zeeman energy (local, unidirectional), the exchange energy (first neighbors) as well as the magnetic energy (many-body interaction although in one dimension it can be reduced to a local form). Explicitly, the total internal energy E_T writes as

$$E_T \propto \frac{1}{2}\sum_{j=1}^{N} \sin^2(\arccos(u_{m_i}\cdot u_z)) + H_{\mathrm{app}}\sum_{j=1}^{N} u_{m_i}\cdot u_z - a\sum_{j=1}^{N-1}(u_{m_i}\cdot u_{m_{(i+1)}}) + m\sum_{j=1}^{N}(u_{m_i}\cdot u_y)^2.$$

Here u_{mi}, u_y, and u_z are unit vectors along the directions of the moment at the ith position in the chain and along the OY and the OZ axes of our reference system, respectively (both

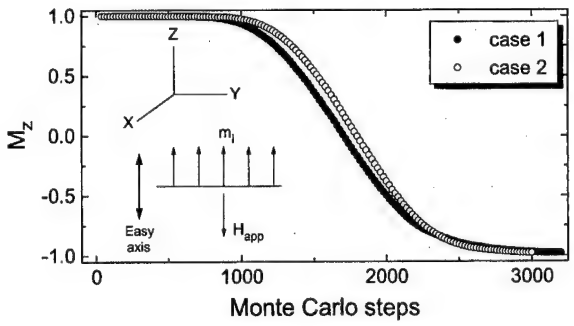

FIG. 1. Evolution with the number of MCS of the reduced total moment corresponding to the relaxation shown in Figs. 2(a) and 2(b).

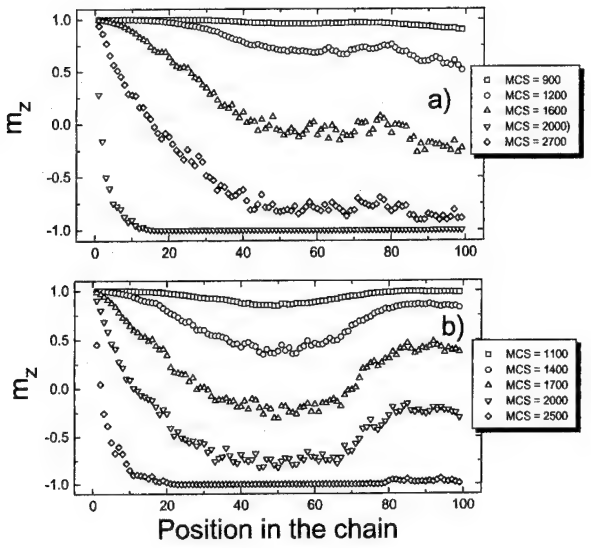

FIG. 2. Two examples of system configurations observed along the relaxation processes and corresponding to (a) case 1 and (b) case 2 (see text).

the easy axis and the demagnetizing field are applied along the OZ axis). The coefficient $H_{app}=\mu_0 M_s H/2K$ gives the applied field, H, reduced to the anisotropy field. The evolution of this total internal energy is followed by a Monte Carlo algorithm with Metropolis dynamics[10] in a canonical ensemble at a temperature corresponding to 2×10^{-4} of the maximum anisotropy energy attainable by the system. Regarding the use of this stochastic method, we should remark that we define a Monte Carlo step (MCS) as the process corresponding to the consecutive introduction of random modifications in all the degrees of freedom of the system (the bound for the modification of the two angles defining the direction of every moment in the system was arbitrarily chosen as 9×10^{-3} rads). If the attempt frequency (that is the time rate at which a real system can modify its degrees of freedom) is known (through independent physical arguments) the number of MCS can be converted into time units. In all the cases, the relaxation proceeds from a saturation state in which the magnetization of the "particle" points along the easy axis and antiparallel to the applied field.

III. RESULTS AND DISCUSSION

In Figs. 2(a) and 2(b) we present two different examples of the evolution with the number of MCS of the configuration of a "particle" during its relaxation at a constant reduced field $H_{app}=1.1$ (we have plotted the component along the easy axis direction of the magnetic moments forming the system as a function of their position in the chain). Relaxation proceeds through the formation of a nucleus of out-from-the-easy axis moments which can be originated either at one of the ends of the chain [case 1, Fig. 2(a)] or in any other position inside it [case 2, Fig. 2(b)]. The moments in those nuclei reverse rapidly their direction forming one (case 1) or two (case 2) structures similar to 180° domain walls which sweep the "particle" leading to the reversal of its total moment.

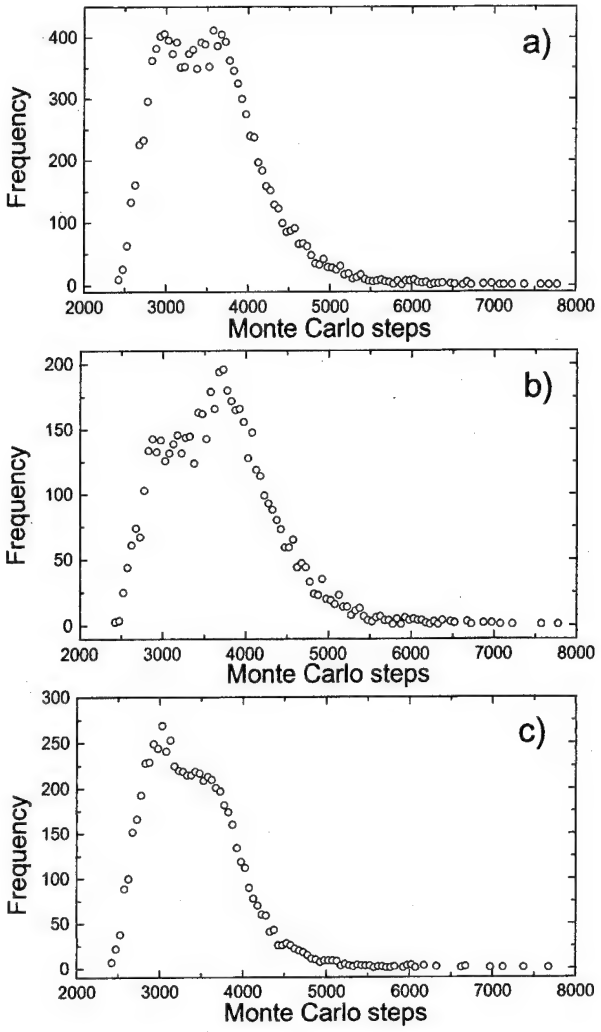

FIG. 3. Distributions of reversal events (a) total; (b) subdistribution corresponding to case 1; and (c) subdistribution corresponding to case 2.

The evolution with the number of MCS of the OZ components of the reduced total moment of the "particle" corresponding to these relaxation processes are shown in Fig. 1. As it is clear from this figure, in both cases, a range of "time" (MCS) exists in which the fluctuations on the orientation of the magnetic moments forming the "particle" do not lead to any change of the macroscopic state of the system. During this "time" range the system is slowly evolving towards the formation of the nucleus which is responsible for the onset of the global reversal but since that nucleus has a domain wall-type structure, its formation cannot be described as a sequential process but as a collective one, requiring the coupling of many degrees of freedom.

In order to get statistical information about the number of MCS required to observe the reversal of the "particle" (or equivalently, to observe a relaxation process in a system formed by many identical, noninteracting particles), we run 1.3×10^4 independent relaxations. The results of this simulation are presented in Fig. 3(a) where we show the distribution of reversal events (characterized as corresponding to the achievement of the negative saturation) as a function of the

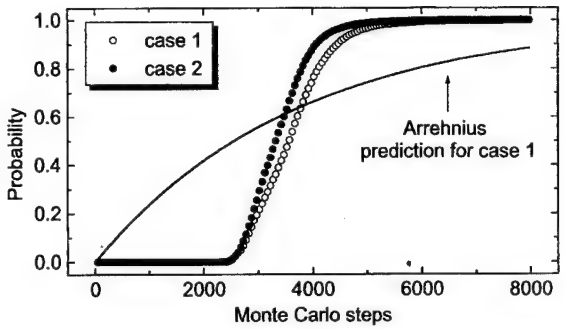

FIG. 4. Probabilities of total moment reversal after a given number of MCS corresponding to cases 1 and 2. The Arrehnius prediction corresponding to case 1 (see text) is also shown.

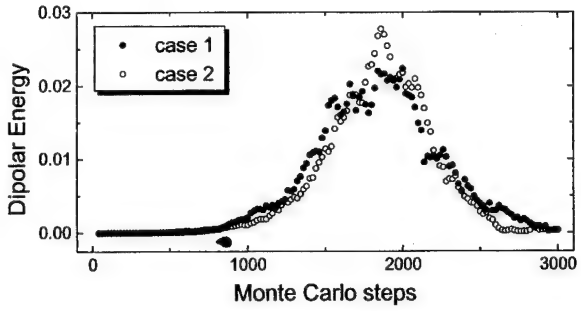

FIG. 5. Two examples of the evolution with the number of MCS of the dipolar energy of the system corresponding to cases 1 and 2.

number of MCS (the data in the figure have been smoothed by adjacent averaging).

As it is apparent from the figure the distribution presents two resolvable peaks. By identifying, during the relaxation process, the nucleation site, we were able to decompose the total distribution of reversal events in the two subdistributions shown in Figs. 3(b) and 3(c) and corresponding to the 1 and 2 nucleation cases, respectively.

In Fig. 4 we have plotted the probabilities of total moment reversal after a given number of MCS corresponding to the two types of nucleation we have detected. These probabilities are obtained, by integration, from the results in Figs. 3(b) and 3(c). In both cases, the reversal probabilities are zero in the initial range of MCS, indicating a remarkable difference with the classical Arrehnius–Néel description of relaxation for which that probability is different from zero for arbitrarily small times[3] {for the sake of comparison with the Arrehnius–Néel predictions, we present in Fig. 4 the curve $[1-\exp(-\mathrm{MCS}/\langle \mathrm{MCS1}\rangle)]$ where $\langle \mathrm{MCS1}\rangle$ is the average value corresponding to the case 1 subdistribution, Fig. 3(b)}. Interestingly, the "waiting time" corresponding to both subdistributions (i.e., the range of MCS for which the reversal probability is zero) seems to be very similar (same probability for both nucleation sites) which allows us to distinguish the observed phenomenology from a real bifurcation (occurrence of inequivalent trajectories linking the initial and final states). Then, we identify the origin of the two maxima in the total distribution of reversal events [Fig. 3(a)] with the presence during relaxation of one or two domain wall-like structures, moving in the last case in opposite sense and requiring a different number of MCS to sweep the system. This point is illustrated in Fig. 5 where we show two particular examples of the evolution with the number of MCS of the dipolar energy stored by the system during relaxations taking place through both modes of nucleation. Accordingly with our idea, the number of MCS required to achieve complete reversal of the total magnetic moment was larger in case 1 (one wall) than in case 2 and the difference of MCS between both relaxation cases is compatible with that observed between the two peaks of the total distribution.

IV. CONCLUSIONS

From our results we can conclude that thermally activated relaxation proceeds, similarly to hysteresis, through a sequence of the type nucleation-domain wall(s) formation—domain wall(s) propagation. Each one of this events envolves a limited number of the moments in our system but a high number of degrees of freedom. As consequence of this, the evolution with the number of MCS of the orientation of the total magnetic moment of the system cannot be described in terms of the Arrehnius–Néel kinetics since it is characterized by the occurrence of a "waiting time" during which the different degrees of freedom of the system collectively evolve towards the formation of the nucleus which is precusor of the global relaxation.

The $S=1/2$, nearest-neighbor, kinetic Ising model has been used to model magnetization switching in nanoscale ferromagnets. For this model, earlier work based on the droplet theory of the decay of metastable phases and Monte Carlo simulations has shown the existence of a size dependent spinodal field which separates deterministic and stochastic decay regimes. We extend the above work to study the effects of an oscillating field on the magnetization response of the kinetic Ising model. We compute the power spectral density of the time-dependent magnetization for different values of the amplitude and frequency of the external field, using Monte Carlo simulation data. We also investigate the amplitude and frequency dependence of the probability distributions for the hysteresis loop area and the period-averaged magnetization. The time-dependent response of the system is classified by analyzing the behavior of these quantities within the framework of the distinct deterministic and stochastic decay modes mentioned above. © *1996 American Institute of Physics.* [S0021-8979(96)27708-9]

I. INTRODUCTION

Hysteresis is a nonequilibrium phenomenon characteristic of metastable systems. The kinetic Ising model, for temperatures below its critical temperature T_c and at nonzero external fields H, exhibits a metastable phase. If $H(t)$ varies periodically in time, the response of the system, the magnetization $m(t)$, lags behind the forcing field, and hysteresis occurs. Previous studies of hysteresis have been performed, both for mean-field models and for the Ising model.[1,2] In both cases the hysteresis loop area, $A=-\oint m dH$, was found to have a power-law dependence on the frequency and amplitude of H for low frequencies. Also, the mean-field models exhibit a dynamic phase transition in which the period-averaged magnetization, $Q=(\omega/2\pi)\oint m dt$, changes from $Q\neq 0$ to $Q=0$.[3,4] Magnetization reversal in small ferromagnetic grains has been modeled with a kinetic Ising model in static fields.[5] Also, recent experiments on ultrathin ferromagnetic Fe/Au(001) films[6] have considered the frequency dependence of hysteresis loop areas, obtaining exponents that are consistent with those found for the two dimensional Ising model.[1]

The model used in our study is a kinetic, nearest-neighbor Ising ferromagnet on a square lattice with periodic boundary conditions. The Hamiltonian is given by $\mathscr{H} = -J\Sigma_{\langle ij\rangle}s_i s_j - H\Sigma_i s_i$, where $\Sigma_{\langle ij\rangle}$ runs over all nearest-neighbor pairs, and Σ_i runs over all $N=L^2$ lattice sites. The dynamic used in this work is the Glauber[7] single spin-flip Monte Carlo algorithm. The system is put in contact with a heat bath at temperature T, and each spin can flip from s_i to $-s_i$ with a probability given by[8]

$$W(s_i\rightarrow -s_i)=\frac{\exp(-\beta\Delta E_i)}{1+\exp(-\beta\Delta E_i)},$$

where ΔE_i gives the change in the energy of the system if the spin flip is accepted, and $\beta=1/k_B T$.

In contrast to earlier studies of hysteresis in Ising models, we have performed simulations in two distinct field regimes. It has recently been observed that the metastable phase in Ising models exposed to a static field H decays by different mechanisms, depending on H and the system size L.[9] For fields weaker than a T and L dependent dynamic spinodal field H_{DSP}, the mean lifetime τ of the metastable phase is comparable to the standard deviation in the lifetime. This field region is termed the stochastic or single-droplet (SD) region because decay of the metastable phase proceeds by random nucleation of a single critical droplet of the stable phase. For fields stronger than H_{DSP}, the mean lifetime of the metastable phase is much greater than the standard deviation in the lifetime. This field region is called the deterministic or multidroplet (MD) region because decay of the metastable phase proceeds by the nucleation, growth, and coalescence of many droplets of the stable phase. The study presented here is, to our knowledge, the first in which the effects of these two different decay mechanisms on hysteresis are considered.

In our simulations, a system of size L at temperature T is prepared with $m(0)=0$ and the up and down spins in random arrangement. Then, a sinusoidal field $H(t)=H_0\sin(\omega t)$ is applied, and the magnetization $m(t)$ is recorded. The field $H(t)$ is changed every attempted spin flip, allowing for a smooth variation. Using the $m(t)$ vs t data, we calculate

 0021-8979/96/79(8)/6482/3/$10.00

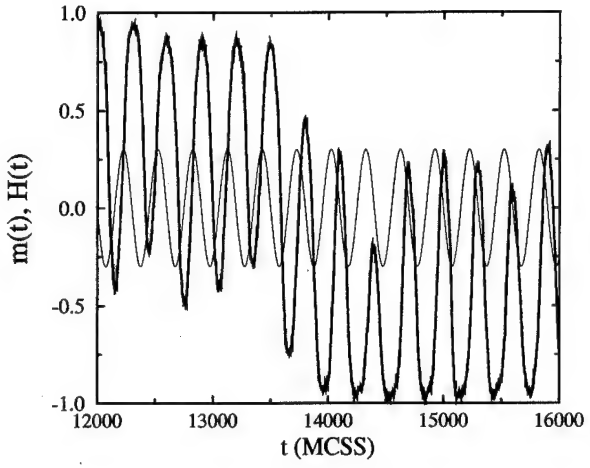

FIG. 1. Magnetization $m(t)$ and external field $H(t)$ vs time t in the MD region with $(2\pi/\omega)\approx 300$ Monte Carlo steps per spin (MCSS), $H_0=0.3J$, and the lifetime in static field $\tau_{\omega=0}\approx 75$ MCSS. The darker line shows $m(t)$ and the lighter line denotes $H(t)$. The total length of the time series is 16.9×10^6 MCSS. The ratio of the period of $H(t)$ to $\tau_{\omega=0}$ is ~ 4.

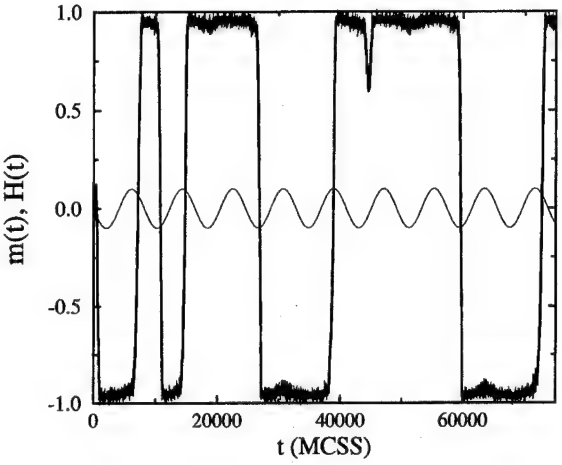

FIG. 2. Magnetization $m(t)$ and external field $H(t)$ vs time t in the SD regime with $(2\pi/\omega)=8192$ MCSS, $H_0=0.1J$, and $\tau_{\omega=0}\approx 2058$ MCSS. The darker line shows $m(t)$ and the lighter line denotes $H(t)$. The total length of the time series as well as the ratio of the period of $H(t)$ to $\tau_{\omega=0}$ are the same as in Fig. 1.

power spectral densities (PSD) and probability distributions for the loop area A and the period-averaged magnetization Q for different amplitudes and frequencies of $H(t)$.

II. RESULTS

Our results are presented so as to contrast the behaviors of the hysteretic magnetization response in the SD and MD regions. All of the results shown are for $L=64$ and $T=0.8T_c$. The simulations were performed at two field amplitudes H_0 and several frequencies ω. One value of H_0 was chosen such that for $\omega=0$, the system was clearly in the SD region. Similarly, the other value of H_0 was chosen such that the system was definitely in the MD region. While several frequencies were used, here we show results for a value of ω for which the magnetization switches many times over the course of the entire simulated time series [although not necessarily with the same periodicity as $H(t)$]. Figure 1 shows a portion of the time series in the MD regime, where the system switches over several periods from a state that oscillates with $Q>0$, to a state that oscillates with $Q<0$. In Fig. 2, a portion of the time series in the SD regime shows oscillations with Q near plus or minus the zero-field spontaneous magnetization, punctuated by random switching events that are completed within less than one period of the field oscillation. Here, once a critical droplet forms (in a Poisson process), the stable phase quickly takes over the system.

Figure 3 shows the PSDs for the entire time series of Figs. 1 and 2. The first peak in the MD data is at the driving frequency $f_{\mathrm{MD}}=(\omega/2\pi)$ of the external field. The higher-frequency peaks are located at integer multiples of f_{MD}. The first peak in the SD data is at the driving frequency f_{SD} of the external field. Here, the higher frequency harmonics are located at odd integer multiples of f_{SD}. Both the MD and SD data show large low-frequency components, indicating the slow dynamics of the magnetization reversal in both regimes. In the high-frequency part of the spectrum, the PSDs have slopes on the log–log plot of approximately minus two, corresponding to exponential short-time correlations.

Figure 4 shows the probability distributions of the hysteresis loop areas A for the data of Figs. 1 and 2. The distribution for the MD regime shows a single wide peak, since $m(t)$ lags behind $H(t)$ by a nearly constant phase factor. The distribution in the SD regime has a narrow peak near zero as $m(t)$ oscillates near the positive or negative spontaneous magnetization for most of the length of the run. The narrow peak between the scaled A values of 0.4 and 0.5 corresponds to the rapid switching of $m(t)$ via the nucleation of a single, critical droplet of the stable phase.

Figure 5 shows the distributions of the period-averaged magnetization Q for the data in Figs. 1 and 2. The distributions for both the SD and the MD regions show a double-peaked structure. The two sharp peaks in the SD data are due to $m(t)$ oscillating near the spontaneous magnetization values during most of the run. The distribution for the MD

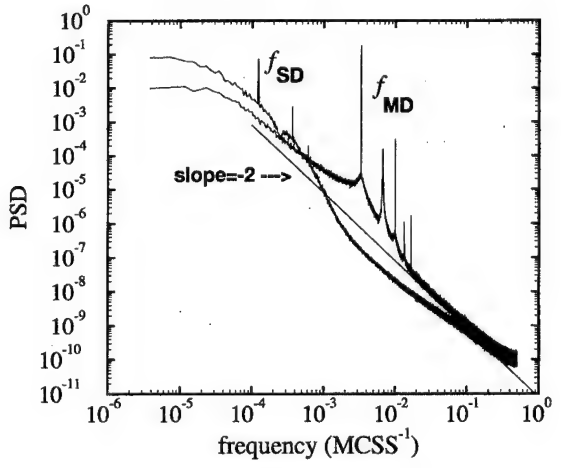

FIG. 3. PSDs for the time series of Figs. 1 and 2. The magnetization is sampled every 1.0 MCSS, so the Nyquist frequency is 0.5 MCSS^{-1}. The lowest frequency that can be resolved for both PSDs is 3.8×10^{-6} MCSS^{-1}.

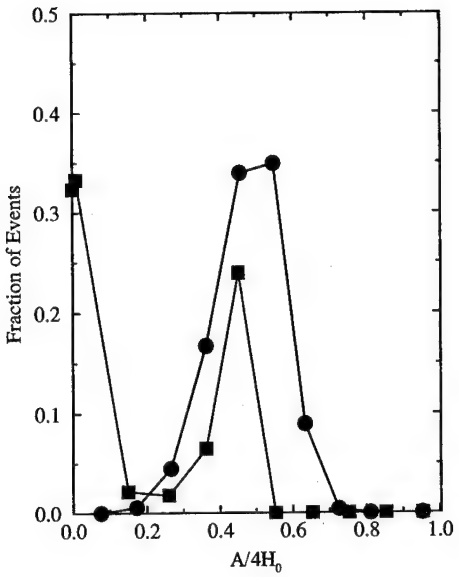

FIG. 4. Probability distributions of the hysteresis loop areas, $A=-\oint m dH$. A is calculated for the MD (●) and SD (□) regions from the data of Figs. 1 and 2. We have used bins of size 0.1 for the area values for both data sets. The value of the area used to plot each of the points is the mean value of the loop areas over a particular bin. Note that the loop areas have been normalized by $4H_0$, the maximum possible loop area. The number of events (periods) for the SD data and MD data is different; the MD distribution uses 56333 events and the SD distribution uses 2062 events.

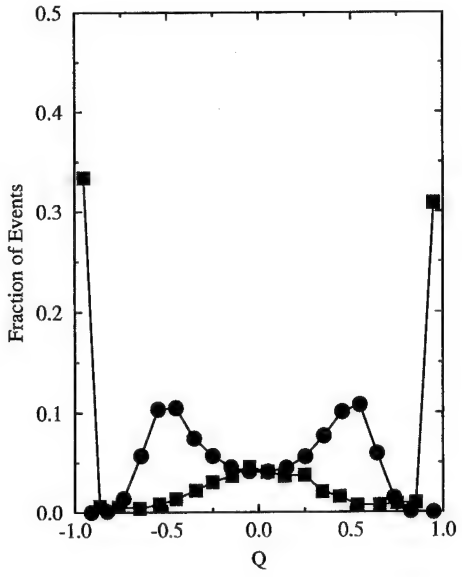

FIG. 5. Probability distributions of the period-averaged magnetization, $Q=(\omega/2\pi)\oint m dt$. Q is calculated for the MD and SD regions from the data in Figs. 1 and 2. The size of the bins used and the quality of the statistics are the same as in Fig. 4.

regime shows two peaks as well, but each peak is much wider than in the SD case. The positions of the peaks in both distributions have been found to be frequency dependent as well as amplitude dependent. In both cases the slight asymmetry of the distribution is an effect of the finite length of the time series.

III. CONCLUSION

Our results show distinct differences between the multidroplet region and the single-droplet region. This study shows that the nature of the response of an Ising system does not only depend on the competition between the two time scales: the oscillation period of the external field, and the lifetime of the metastable state. It also depends on the mode by which the system switches magnetization states, which depends not only on the field amplitude and frequency, but also on the temperature and system size.

Study of residual magnetization of hard steel samples

M. Saadi, F. Jellali, A. Delmas, and G. Quichaud
Laboratoire d'Electrotechnique des Universités Paris VI et XI, Université Paris sud, Bât. 214-91405 Orsay, France

This study forms part of a program trying to determine the position of a train on railway using magnetic spots. In this paper, we investigate the influence of the parameters of the exciting current pulse on the residual magnetization of a hard steel. In the case of a pulse of long duration and small amplitude, we show that the associated hysteresis problem can be reduced to the determination of a magnetic field distribution due to a fixed magnetization. We define this magnetic field distribution by means of a boundary integral equations method. For these conditions, the internal and external induction distributions are of the same order of magnitude. In contrast, for pulses of short duration (millisecond or less) and large amplitude, the eddy currents in hard steel lead to a remanent magnetization loop which is permanently trapped by the hysteresis phenomena. The residual external induction is always small, and is not representative of the large internal magnetization.
 [S0021-8979(96)27808-5]

I. INTRODUCTION

We are interested by the residual magnetism within a conducting ferromagnetic volume (F) in front of a solenoid (B) which carries a pulsed sinusoidal current. In this experiment, the volume (F) is a hard steel ball as shown in Fig. 1.

Practically, this work is related to the use of magnetic spots on railway[1,2] in the aim of localizing a train. For this application, the ball is replaced by a section of a rail. The time duration of the current pulses T_0 must be relatively short (less than millisecond) because of the high actual speed of the train (more than 300 Km/h). This leads us to specify the influence of T_0 on the residual magnetism of a hard steel.

II. SLOW MAGNETIZATION

We assume that the current pulse duration T_0 is long enough to neglect the induced current in the volume (F). This is equivalent to utilizing an insulating ferromagnetic material. The simplest representative case is the one represented in Fig. 2 where the magnetic induction $\mathbf{b}(t)$ produced by the solenoid is uniform in the absence of the ball. Indeed, the study is made easier by the known uniform internal demagnetizing field $-(1/3)\mathbf{J}$ in the sphere of uniform magnetization $\mathbf{J}$. Thus, the magnetic induction $\mathbf{B}(t)$ and the field $\mathbf{H}(t)$ in the sphere are still uniform and linked by the relation

$$\mathbf{B}(t)=-2\mu_0\mathbf{H}(t)+3\mathbf{b}(t). \tag{1}$$

So we are lead to determine the maximum induction B_0 seen by (F) and its residual induction b_r as shown in Fig. 3(a) where we have represented the curve $B(H)$ of a hard steel. This slow magnetization enables us to determine the Frölich's approximation of the ball's first magnetization curve:

$$B=\mu_0 H\left(1+\frac{2}{0.012+\mu_0 H}\right), \tag{2}$$

and the dependence of its coercive field H_c with regard to the applied magnetic induction peak B_v [Fig. 3(b)]. The maximal residual induction in the ball is then nearly $2\mu_0 H_c$. We note that induction values B_v of about 2 T could be obtained with an appropriate magnetic circuit.

In the practical case of a railway section, the residual magnetization is determined using as magnetic characteristic for $t>T_0/2$, the linear law

$$\mathbf{B}=\mathbf{M}_0+\mu\mathbf{H}, \tag{3}$$

where $\mathbf{M}_0$ is the magnetic polarisation at $t=T_0/2$. Yet, the vectorial hysteresis[3] problem becomes an easier permanent magnetization one. It is solved, in a classical way, using a boundary integral method. Then, we calculate a superficial magnetic charges density $\sigma(M)$ at the interface (s) between air and rail which is taken as a solution of the boundary integral equation:

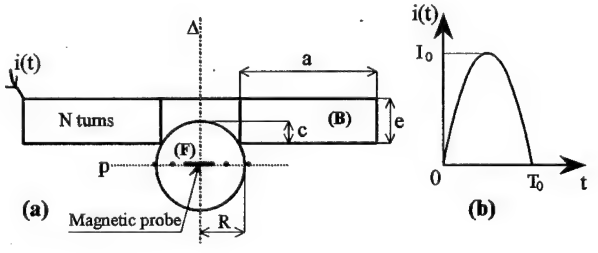

FIG. 1. (a) Experimental device; (b) current shape.

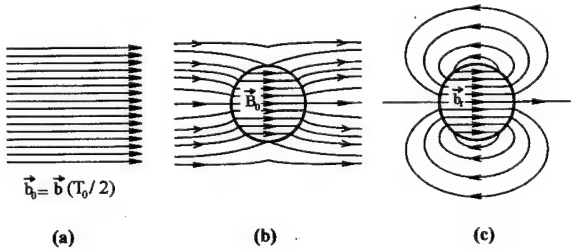

FIG. 2. Distribution of the induction; (a) without ball; (b) with ball at $t=T_0/2$; (c) residual induction at $t\gg T_0$.

 0021-8979/96/79(8)/6485/3/$10.00

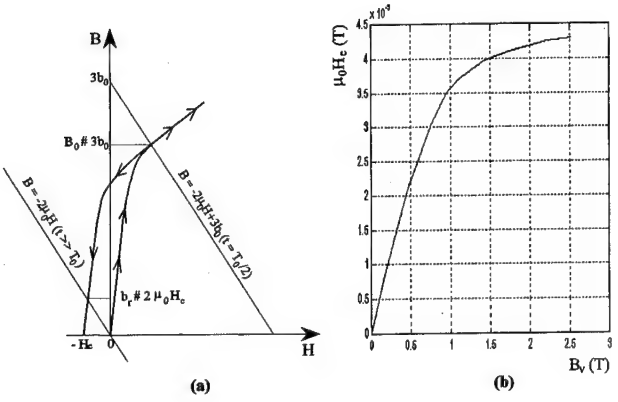

FIG. 3. (a) Determination of magnetization states of the ball; (b) the coercive field as a function of the maximum induction seen.

$$\frac{\mathbf{M}_0 \cdot \mathbf{n}}{\mu} + \frac{1}{4\pi} \int_{(F)} \frac{\mathbf{r} \cdot \mathbf{n}}{r^3} \rho_0(M) d\tau + \frac{1}{4\pi} \int_{(S)} \frac{\mathbf{r} \cdot \mathbf{n}}{r^3} \sigma(M) ds - \frac{\sigma(M)}{2} = 0, \tag{4}$$

associated with the constraint

$$\int_{(F)} \rho_0(M) d\tau + \int_{(S)} \sigma(M) ds = 0, \tag{5}$$

where $\rho_0 = -\text{div}\, \mathbf{M}_0/\mu$ is the known volume magnetic charge density in the rail. The residual field distribution in the air $\mathbf{h}_r(M)$ is then given by

$$\mathbf{h}_r = \frac{1}{4\pi} \left(\int_{(F)} \frac{\mathbf{r}}{r^3} \rho_0(M) d\tau + \int_{(S)} \frac{\mathbf{r}}{r^3} \sigma(M) ds \right). \tag{6}$$

We compute this method numerically in the case of a rail section of 60 cm long placed in front of the solenoid as shown in Fig. 4. In the particular conditions where the coercive field is 800 A/m and the peak induction is 1.2 T, we obtained the results shown in Figs. 5(a) and 5(b).

III. FAST MAGNETIZATION

The geometric parameters of Fig. 1 being as follows: $R=10$ mm, $a=51$ mm, $e=9$ mm, $c=4$ mm, the previous ball is submitted to current pulse of $T_0=400$ μs duration, and $I_0=3100$ A peak amplitude. The solenoid contains $N=22$ turns. The ball has been previously cut by electroerosion to two hemispheres according to an equatorial plane p (Fig. 1). We are then able to put two magnetic flux probes of axe Δ (Fig. 1) with respective radius $r_1=4$ mm, $r_2=6$ mm, between the hemispheres, the air gap being reduced to a minimum value. A third probe of radius $r_3=10$ mm has been put at the periphery of the ball.

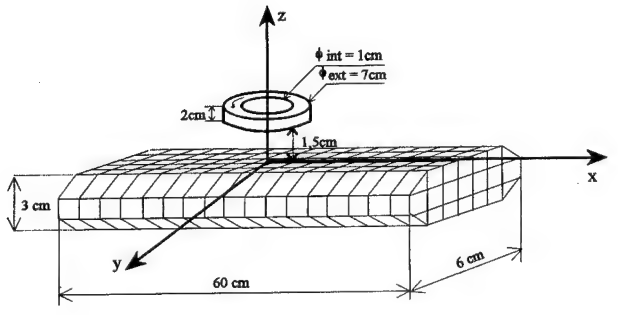

FIG. 4. Simulated model.

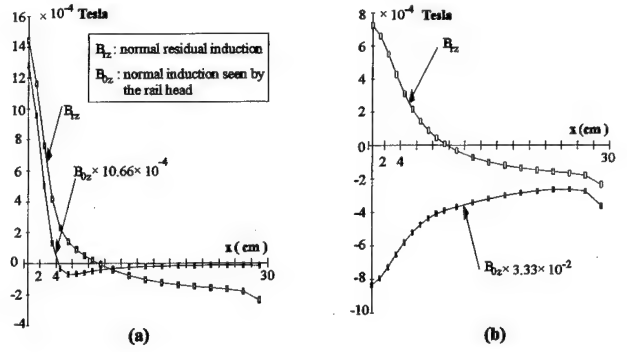

FIG. 5. Normal inductions B_{0z} and B_{rz} as functions of the rail head length x at $y=0.5$ cm for (a) the above face ($z=0$); (b) the bottom face ($z=-3$ cm).

The integration of the induced voltages record $v_1(t)$, $v_2(t)$, and $v_3(t)$ [Fig. 6(a)] in those probes gives, respectively, the flux evolutions $\varphi_1(t)$, $\varphi_2(t)$, and $\varphi_3(t)$ represented in Fig. 6(b). After this magnetization, the residual induction measured around the ball was in agreement with the behavior of the Fig. 2(c). The maximum value on the axe Δ, at the surface of the ball is 25×10^{-4} T. We have also measured a permanent attractive force of 47 N between the two hemispheres. This force would be negligible in the case of a slow magnetization because of the value of the steel's coercive field. The flux evolutions in the Fig. 6(b) show that at $t=300$ μs, the ball interior peak induction is relatively homogeneous with a value between 2 and 2.3 T.

In the hypothesis of a slow magnetization, this result would give a residual induction of 80×10^{-4} T instead of 25×10^{-4} T measured. This difference is due to the induced current which leads to the formation of a flux loop subsequently trapped in permanence by the magnetic hysteresis. This current is also at the root of the attractive force as well as the $\varphi_1(t)$ and $\varphi_2(t)$ bounds of 41 μWb and 75 μWb, for

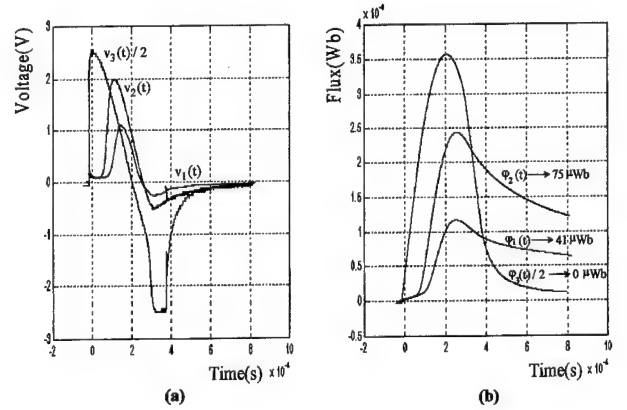

FIG. 6. (a) Induced voltages across the probes; (b) flux.

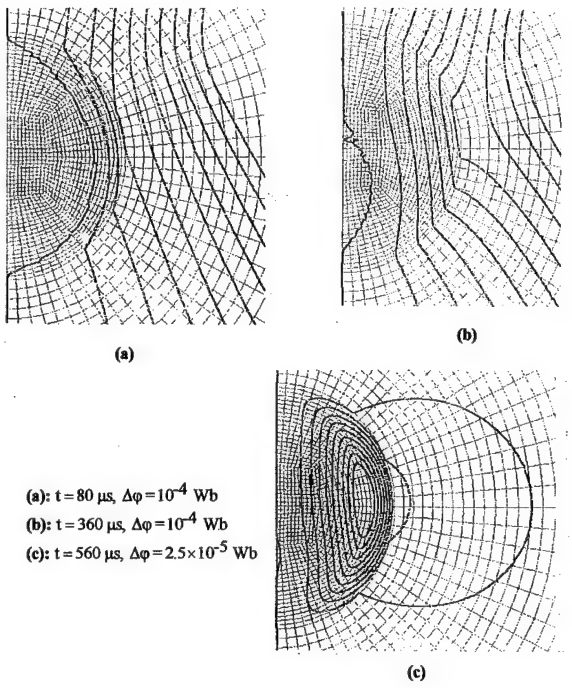

FIG. 7. Progressive penetration of the flux in the ball.

large t, than that practically null $\varphi_3(t)$, are representative of that trapped flux. They lead, in the p plane, to a mean residual induction of 0.8 T, in agreement with the 47 N force and the residual induction of a hard steel in taking into account of the parasitic air gap between both hemispheres. Taking into account only the steel's first magnetization curve and its electric conductivity $\sigma=4.17\times10^6(\Omega\,\mathrm{m})^{-1}$, we modeled the transient rating of the induction diffusion[4,5] in the ball for conditions close to the previous experimental ones.

In Fig. 7, we give the equiflux lines with step $\Delta\varphi$ for three instants. One sees the progressive flux penetration until $t=320$ μs when its distribution is relatively homogeneous and its density is close to 2 T. This result is in agreement with the experimental one shown in Fig. 6(b). Then, after the extinction of the excitation current, that flux is closed up within the ball and attenuates very slowly [Fig. 7(c)]. The induction normal component evolution, in the equatorial plane p, shown in Fig. 8, is also in agreement with these results.

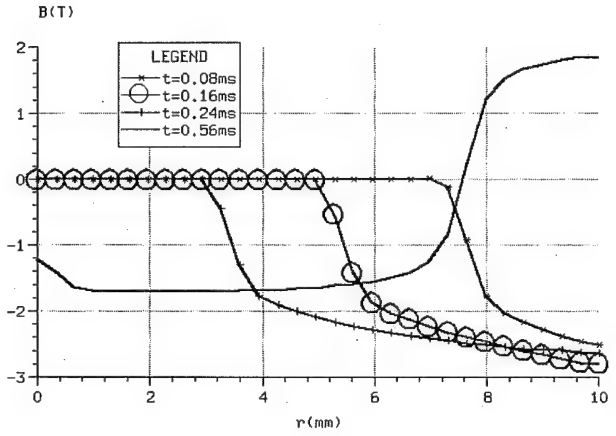

FIG. 8. The normal induction evolution at the plane p.

As it is difficult to take into account the vectorial hysteresis,[3,6] even if there are no induced currents, we have used the results of the above global simulation[7] to simulate the case of scalar hysteresis, taking into account the induction tangential component. In these conditions, the complete flux attenuation given by the global simulation does not appear, in agreement with the experiment.

IV. CONCLUSION

The experiment in conjunction with the modeling process shows the large variation of the internal residual magnetization of a conducting sphere with magnetic hysteresis, according to the excitation current duration. In fact, if for a slow magnetization, the sphere is nearly demagnetized, it has, in contrast, a magnetization close to its remanent one if the excitation peak current is short. We have also investigated[5] the trapped flux phenomena in disks cut out a rail head. Nevertheless, in that case, the comparison of the residual magnetization with the slow magnetization one is more delicate.

The magnetic reversal mechanism in perpendicularly oriented, premagnetized Co based thin film alloys, induced by ultra short magnetic field exposure of a few picoseconds duration has been studied.[1] Field pulses with a magnitude of several thousand Tesla were generated by the 50 GeV final focus electron beam at the Stanford Linear Accelerator Center (SLAC). Characteristic remanent domain patterns are observed in these films long after field exposure using polar Kerr microscopy.[2] Complete reversal of the magnetization is found to occur during a single spin precession event of 6.0 ps duration where the inplane-field amplitude is greater or equal to the macroscopically determined perpendicular anisotropy field. Further, a wide transition range, dividing the reversed and nonreversed regions is observed which is broken into a quasi periodic stripe domain structure with stripe-width 0.3 μm. As a main result of this experimental study we find that magnetization reversal on this time scale is solely governed by the intrinsic effective field, i.e., anisotropy- and demagnetization-field contributions, rather then by complex curling and buckling mechanisms.[3] Unique insight into fundamental spin reversal mechanisms and their ultimate speed in thin magnetic recording films is provided by these experiments. © *1996 American Institute of Physics.* [S0021-8979(96)70208-2]

A theoretical description of magnetic switching experiments in picosecond field pulses

L. He and W. D. Doyle
Center of Materials for Information Technology and Department of Physics and Astronomy, The University of Alabama, Tuscaloosa, Alabama 35487-0209

Siegmann *et al.* have reported that the magnetization in a perpendicularly oriented CoPt film with a uniaxial anisotropy field of 20 000 Oe was reversed when the film was exposed to a 20 000 Oe in-plane pulsed field lasting only 6 ps. From a calculation based on the Gilbert form of the Landau–Lifshitz equation (LLG), it is shown that the experimental result is consistent with the LLG model even for values of the damping constant α as larger as 0.5. The dependence of the switching time on the anisotropy field and the applied field are presented as a function of α and the angle β between the applied field and the easy axis. Experiments are suggested which could illuminate the damping mechanism at these very short times. © *1996 American Institute of Physics.*

INTRODUCTION

Studies of dynamic switching in magnetic materials[1] have been limited for experimental reasons to field pulse widths τ_H in the nanosecond regime or greater except in a few special cases.[2] Recently, in a beautifully conceived experiment, Siegmann *et al.*[3] demonstrated that the remanent state of a perpendicularly oriented film of CoPt could be switched by an in-plane field with $\tau_H=6$ ps produced by an electron beam focused to a few square microns. The anisotropy field H_K of the CoPt at room temperature was reported to be ~20 000 Oe and the magnitude of the pulsed field in the switched region where thermal effects were felt to be minimal was estimated to be ~20 000 Oe. Because this switching time is more than two orders of magnitude faster than those observed in more conventional systems, it is tempting to speculate that if the spin-lattice relaxation time are $\gg\tau_H$, then the usual damping mechanisms would be effectively inoperative during the field pulse and the magnetization would precess freely in the total effective field. In fact, the authors pointed out that the results were consistent with this assumption.

We have for some time been interested in the high speed switching of high coercivity materials and have studied solutions to the Gilbert form of the Landau–Lifshitz equation (LLG).[4] In this paper we apply that methodology to the present case assuming that in the center of the switched region, the film can be treated as a single domain, switching coherently. For the particular experimental conditions applicable to the CoPt film, we show that the reversal is consistent with LLG even for values of α as large as 0.5. Other experiments are suggested which could illuminate the damping process at these very short times.

THEORETICAL MODEL

The motion of the magnetization $\mathbf{M}$ with constant magnitude M_S is assumed to be described by the Gilbert form of the Landau–Liftshitz equation:

$$\frac{d\mathbf{M}}{dt}=-|\gamma|(\mathbf{M}\times\mathbf{H}_T)+\left(\frac{\alpha}{M_S}\right)\left(\mathbf{M}\frac{d\mathbf{M}}{dt}\right), \tag{1}$$

where $\gamma=1.76\times10^7$ rad/Oe s is the gyromagnetic ratio, α is the phenomenological damping constant and $\mathbf{H}_T$ is the total effective field acting on $\mathbf{M}$. The easy axis of the uniaxial film is taken to be along the z direction (Fig. 1). At $t=0$, with $\mathbf{M}$ at rest in the $+z$ direction, a pulse field which reaches a constant value H_A in a time Δt is applied in the $y-z$ plane at an angle β to the $+z$ direction and after a time τ_H is reduced to zero. The total effective field is $\mathbf{H}_T=\mathbf{H}_A+\mathbf{H}_K$ where $\mathbf{H}_K=H_{KZ}\hat{k}=H_K\cos\theta\hat{k}$ is an effective anisotropy field along the z direction. Following Gillette and Oshima,[5] the motion of $\mathbf{M}$ can be expressed as two coupled differential equations which can be integrated numerically. The fourth-order Runge–Kutta method with double precision was used to find solutions. The accuracy of the calculation was verified by letting $H_K=0$ and comparing the results for various values of step size to the analytical solutions for the isotropic case.[6] For step sizes between 10^{-5} and 10^{-3} ns, the error in M_Z/M_S was less than 10^{-7} for $\alpha=0.1$ over the entire switching time. In all the results described below, the step size was chosen to be 10^{-5} ns. The switching time τ defined as the time at which M_Z changes sign from positive to negative for the last time before the field is shut off, varied by less than 1% for $0\leqslant\Delta t\leqslant1$ ps. For convenience, Δt was taken to be zero.

RESULTS AND DISCUSSION

We first examine the switching process for $H_A=H_K=20\,000$ Oe, $\tau_H=6$ ps and $\beta=90°$, the conditions

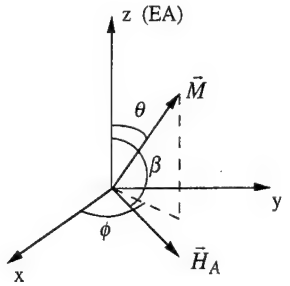

FIG. 1. Definition of the coordinate system used in this calculation. The uniaxial easy axis (EA) is along the z axis.

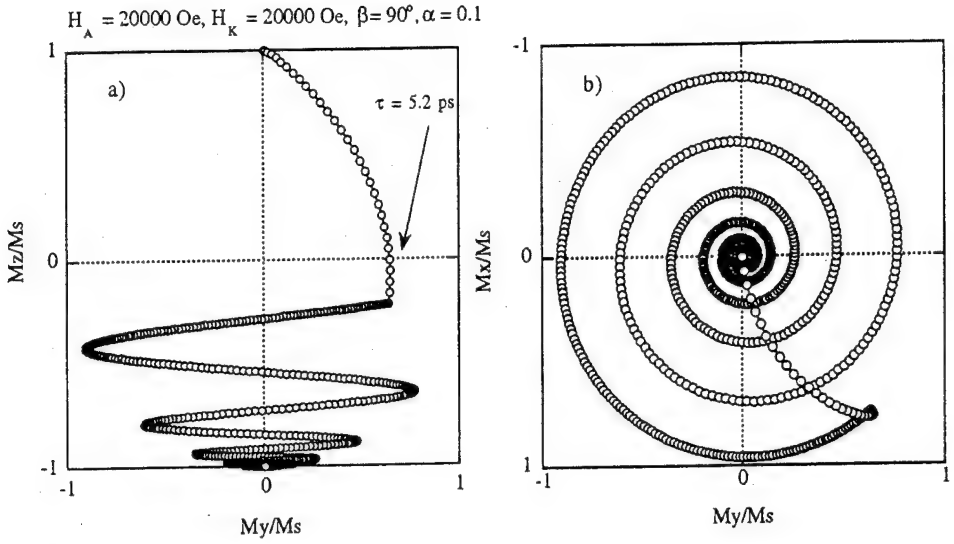

FIG. 2. The locus of the magnetization in terms of its reduced components (a) Mz/Ms vs My/Ms and (b) Mx/Ms vs My/Ms as a function of time for the anisotropy field H_K=20 000 Oe, the applied field H_A=20 000 Oe, the damping constant α=0.1 and the applied field at β=90° to the easy axis. The full circles are plotted every 0.2 ps.

estimated by Siegmann *et al.*[3] The locus of **M** in terms of its components are plotted every 0.2 ps in Fig. 2 as a function of time for α=0.1, a typical value for many materials.[1] Initially since $\mathbf{H}_T$ is at 45° to the $+z$ direction, **M** precesses out of $y-z$ plane. Since the damping torque which tries to align **M** with $\mathbf{H}_T$ is small, **M** precesses at a large angle to $\mathbf{H}_T$ and the polar angle θ increases rapidly. This reduces the value of the anisotropy field $H_K \cos\theta$ so that the direction of $\mathbf{H}_T$ moves quickly to and passed the $+y$ direction. This, in turn, drives **M** across the hard plane toward the $-z$ direction in 5.2 ps. When $\mathbf{H}_A$ is shut off after 6 ps, **M** continues to precess around $\mathbf{H}_K$ but spirals in slowly toward the $-z$ direction, taking about 82 ps for M_Z to reach $0.95M_S$.

If we test the sensitivity of τ to the value of α for the same conditions, we find (Fig. 3) that τ is relatively insensitive to α up to $\alpha\sim0.5$ above which τ increases rapidly. Thus the results of Siegmann *et al.*[3] in CoPt are consistent with the classical LLG model over a wide range of α and are not inconsistent with the inclusion of normal damping processes.

It should be noted that if $\mathbf{H}_A$ was not terminated after 6 ps, then **M** would continue to precess around the $+y$ direction and after ~18 ps, M_Z would become positive again. If $\mathbf{H}_A$ was then terminated, no change in the remanent state would be observed.

The value of τ vs the reduced field $h=H_A/H_K$ for several values of H_K with β=90° and α=0.1 are shown in Fig. 4. That the minimum critical field for switching is less than the equilibrium Stoner–Wohlfarth value of h=1 when $\alpha<1$ and Δt=0 had been pointed out previously.[4] For h greater than the minimum switching value, the value of τ decreases as H_K increases for constant h.

When $\beta\neq$90°, the switching time τ becomes much more sensitive to α, suggesting that experiments at other angles could illuminate the damping process more clearly. The de-

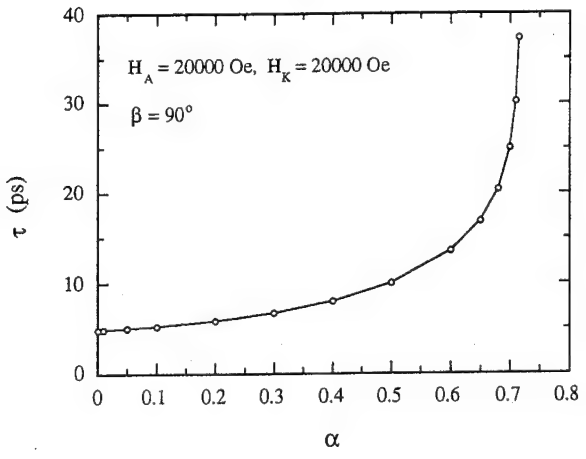

FIG. 3. The switching time τ vs dampling constant α for H_A=20 000 Oe and H_K=20 000 Oe with β=90°.

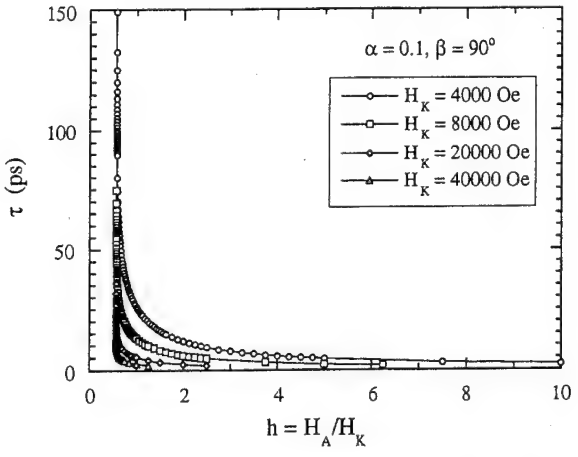

FIG. 4. The switching time τ vs the reduced field h for several values of the anistropy field H_K with α=0.1 and β=90°.

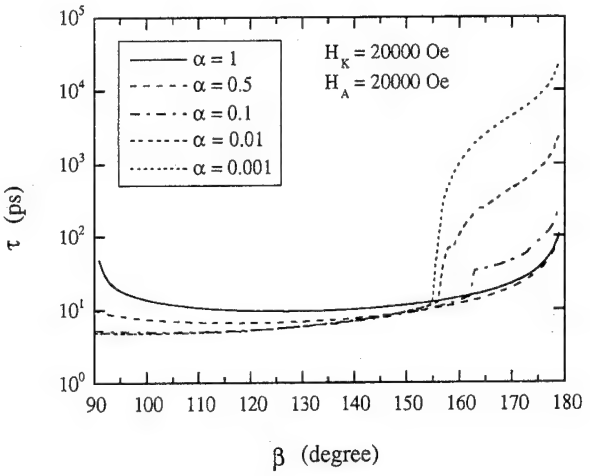

FIG. 5. The switching time τ vs applied field direction β for several values of the damping constant α with the anisotropy field H_K=20 000 Oe and the applied field H_A=20 000 Oe.

pendence of τ on β for several values of α with $H_A=H_K=20\,000$ Oe is shown in Fig. 5. For $\alpha=1$, τ approaches 100 ps when $\beta=90°$ or 180°, with a broad minimum at 130°. As α decreases, the minimum value of τ drops to less than 6 ps and shifts to $\beta=98°$ when $\alpha=0.001$. The values of τ increase less than 2% when $\beta=90°$ but monotonically to <100 ps as β approaches 180°. The increase in τ

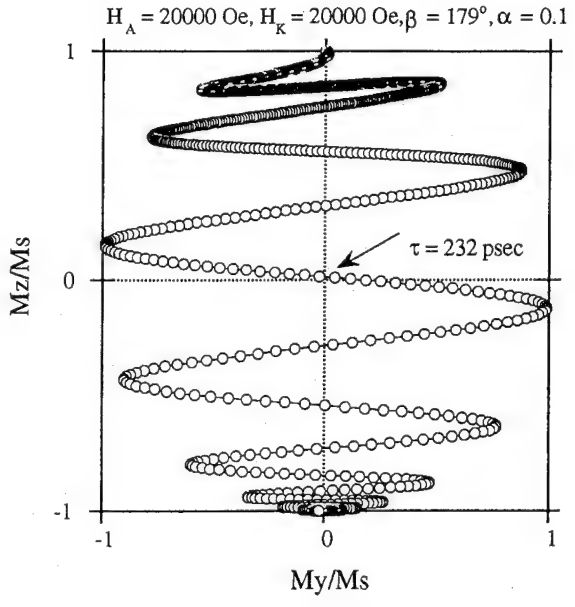

FIG. 6. The locus of the magnetization in terms of its reduced components Mz/Ms vs My/Ms as a function of time for the anisotropy field H_K=20 000 Oe, the applied field H_K=20 000 Oe and the damping constant α=0.1 with the applied field at β=179°. The full circles are plotted every 0.2 ps.

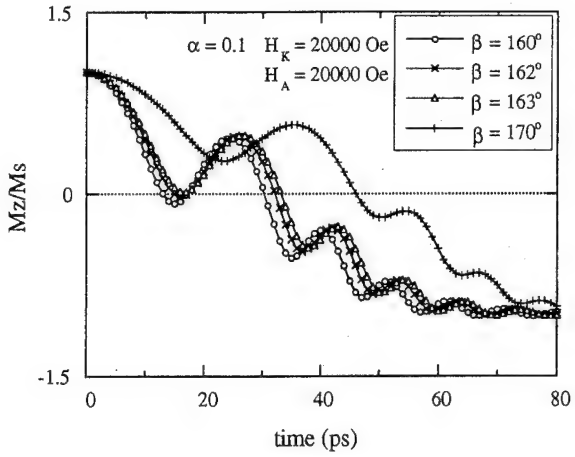

FIG. 7. The normalized component of magnetization Mz/Ms vs time for several values of applied field direction β for the anisotropy field H_K=20 000 Oe and the applied field H_A=20 000 Oe with damping constant α=0.1.

at small values of α as $\beta\rightarrow180°$ can easily be understood from Fig. 6 which shows that **M** precesses for several cycles before crossing the hard plane.

In Fig. 5 it can be seen that the switching time τ is discontinuous between $155°<\beta<165°$ when $\alpha<0.1$. This can be understood from a plot of M_Z/M_S vs time for different values of β with, for example, α=0.1 (Fig. 7). As β changes from 162° to 163°, the time at which the magnetization crosses the hard plane switches discontinuously from the first precession cycle to the second precession cycle.

The experimental beam conditions which determine the amplitude and length of the pulse field are presumably not easily changed. However, if the anisotropy field of the sample could be increased to 40 000 Oe and reliable measurements made nearer to the beam center where the pulse field would be larger, then τ near $\beta=90°$ would be 2.6 ps. A measurement of τ vs β with τ_H=6 ps should then be able to detect a critical switching angle (Fig. 5) from the effective value of α could be determined.

The reflectivity of circularly polarized (CP) soft x rays is a technique which combines the power of x-ray scattering and magnetic circular dichroism and allows the structural *and* magnetic characterization of heteromagnetic multilayers. In this technique, the energy and angular dependence of the differential reflectivity of left- and right-circularly polarized soft x rays at the relevant absorption edges of the constituent elements of the multilayers are measured. As examples the reflectivity curves for single films of Fe, Co, ordered and disordered $Fe_{50}Co_{50}$ alloys, and for a trilayer consisting of two single crystal $Fe_{30}Co_{70}$ films separated by an 8.7 Å Mn spacer layer media utilizing complex dielectric tensors with no free parameters show that the rich reflectivity curves can be used to determine the multilayer magnetic ordering, film thicknesses, interface quality, as well as differentiating between ordered and disordered alloys.

Giant magnetic effects in the *L*-edge extended x-ray absorption fine structure of 3*d* transition metals

V. Chakarian,[a] Y. U. Idzerda, and K. M. Kemner
Naval Research Laboratory, Code 6345, Washington, DC 20375

J.-H. Park, G. Meigs, and C. T. Chen
AT&T Bell Laboratories, 600 Mountain Avenue, Murray Hill, New Jersey 07974

A systematic extended x-ray absorption fine structure (EXAFS) study at the L edges of ferromagnetic Fe, Co, and Ni thin films has been conducted using circular polarized soft x rays. A very large helicity dependence has been observed in the L-edge EXAFS spectra. Surprisingly, in contradiction with prior works, these magnetic EXAFS results indicate a *nonlinear* dependence of this effect on the magnetic polarization of the scattering atom. The data further indicate that the dominant scattering paths responsible for the effect are different from those responsible for EXAFS. A discussion of the results in relation to the present understanding of the underlying mechanism and its ramifications to the existing theoretical frameworks is also presented. [S0021-8979(96)78508-5]

The possibility of adding *magnetic* selectivity to the scope of extended x-ray absorption fine structure (EXAFS) has prompted considerable interest in its spin-dependent counterpart, spin-polarized EXAFS (SPEXAFS) or, more appropriately, magnetic EXAFS (MEXAFS). MEXAFS is the natural extension of x-ray absorption magnetic circular dichroism (MCD) analysis beyond the near-edge region and into the extended fine structure region. Both MCD and MEXAFS are measures of the difference in the absorption of left- and right-circular polarized photons at the absorption edges of the material under investigation.

EXAFS is a mature, chemically selective spectroscopic method for local atomic structure determination.[1] On the other hand, MEXAFS, which is related to the magnetic short-range order, is still in its infancy. The lack of a first-principles theory allowing for the extraction of tangible quantitative material parameters and the added difficulty of the MEXAFS measurements due to the small size of the effect have hampered the generation of a deeper understanding of the underlying mechanism. Its origin is primarily the spin–orbit interaction of the core electrons and the exchange interaction between the spin–polarized photoelectron and the magnetically polarized neighboring atoms. The feasibility of MEXAFS was first demonstrated on $3d$ transition metal K-edge and $4f$ rare-earth L-edge measurements.[2] In later studies,[2–8] it was almost universally found that, for these edges, the size of the MEXAFS oscillations is linearly proportional to the spin moment of the scattering atom. Finally, in the case of the pure $3d$ metals Fe, Co, and Ni, it was found that the MEXAFS oscillations are in phase with the EXAFS oscillations, further supporting the notion that this effect is due primarily to the scattering from magnetic nearest neighbors.[6–8]

Until now, due to the lack of a suitable circular polarized photon source as well as the lack of an established data reduction procedure, this type of study has not been extended to the lower binding energy L edges of the transition metals. The standard EXAFS analysis is complicated by the small energy separation of the L_3 and L_2 edges in transition metals, causing the (M)EXAFS oscillations for these edges to overlap. Furthermore, the MEXAFS oscillations for the well separated L_3 and L_2 edges of rare-earth elements show identical structure, but of opposite sign, prompting prior investigators to suggest that, due to this cancellation, measurements at the overlapping L edges of the $3d$ elements would yield a negligible MEXAFS signal and hence be impractical.[4,6] Nevertheless, due to the strong dipole transition to the magnetically interesting $3d$ states, the MEXAFS effect may be much larger at the L edges of transition metals than their K edges, where the earlier studies were conducted. (Similar arguments apply to the M edges vs L edges of $4f$ rare earths.)

In order to test the above hypotheses and to demonstrate the feasibility of the MEXAFS measurements for the L edges of $3d$ transition metals, transmission MCD measurements extended to the EXAFS region have been performed for Fe, Co, and Ni thin films. Helicity dependent soft x-ray absorption spectra (XAS) were obtained by measuring the relative photon flux transmitted through the magnetic thin films using a photodiode mounted behind the sample. Details of the experimental procedures are described elsewhere.[9,10] Numerous scans were collected over a period of 25–30 h for each sample to improve the signal-to-noise quality of the data.[11]

The films were grown under ultrahigh vacuum conditions by e-beam evaporation from pure-metal sources onto $\sim$1-μm-thick semitransparent parylene $(C_8H_8)_n$, substrates. The film growth as well as the measurements were conducted at room temperature. The film thicknesses (about 250–300 Å) were independently determined by comparing the measured absorption to the calculated atomic photoabsorption cross sections and by *ex situ* x-ray fluorescence methods. *In situ* element-specific magnetic hysteresis measurements[12,13] show these films to display nearly square magnetization behavior with remnant magnetizations of 90%–100%. The structure of the deposited films can be inferred from the measured L-edge EXAFS oscillations. An analysis of the data indicates that the Fe, Co, and Ni films are most likely in the bcc, hcp, and fcc phases, respectively,[14] consistent with structural determinations for the evaporation of these materials on glass slides. In addition, the bcc struc-

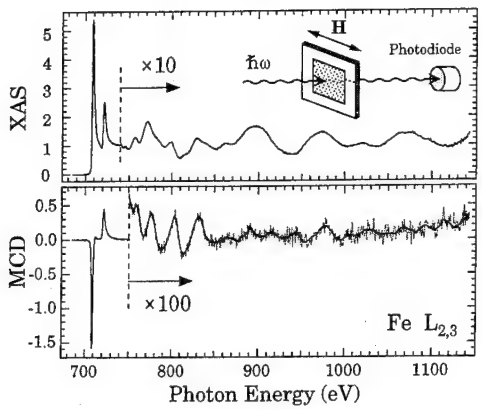

FIG. 1. The $L_{2,3}$ XAS (EXAFS) (top panel) and MCD (MEXAFS) (bottom panel) for the Fe thin film. The solid curve through the MCD data in the EXAFS region is the result of numerical smoothing and is provided as a guide to the eye. The experimental geometry for the acquisition of the helicity-dependent (M)EXAFS spectra is also shown.

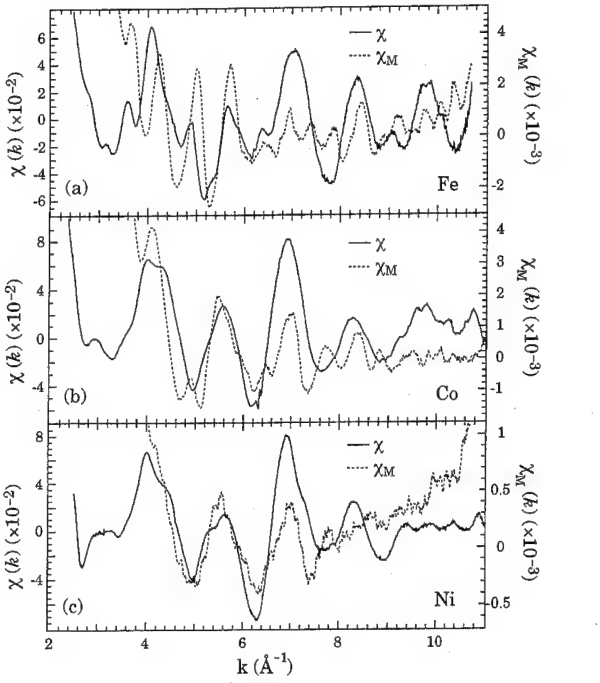

FIG. 2. The $L_{2,3}$ EXAFS, $\chi(k)$, and MEXAFS, $\chi_M(k)$, for Fe (top panel), Co (middle panel), and Ni (bottom panel) thin films. The numerically smoothed $\chi_M(k)$ data are shown for clarity.

ture of the Fe film was verified by K-edge EXAFS measurements for a Fe thin film similar to the one used in the L-edge work (after capping with a vanadium overlayer to prevent oxidation).[15]

The results for the Fe film are shown in Fig. 1. The figure shows the total absorptivity (XAS), $\mu(\omega)=\mu_+(\omega)+\mu_-(\omega)$, and the dichroic signal (MCD), $\delta\mu(\omega)=\mu_+(\omega)-\mu_-(\omega)$. The MCD spectrum was scaled to correct for the incomplete circular polarization of the photons and the photon incidence angle. A smoothly varying, single cubic-spline spin-independent continuum background function has been removed from the EXAFS region and the data were normalized in the usual way to yield a combined $L_{2,3}$ edge jump of unity after the L_2 edge.

A comparison of the results for Fe, Co, and Ni (M)EXAFS is possible after a standard conversion of the data to momentum space, as shown in Fig. 2.[16] Here $\chi(k)=[\mu(k)/\mu_0(k)]-1$ and $\chi_M(k)=\delta\mu(k)/\mu_0(k)$, where $\mu_0(k)$ is the spin-independent high-energy continuum background. Note that the intensity variations of the EXAFS oscillations are about $\pm 6\%$–7% of the edge jump. Considering that the measurements were made at room temperature and that the films are polycrystalline, this indicates a relatively large coherence length for the crystallites in the films. As is readily apparent in Fig. 2 there is a substantial difference between the detailed shapes of the EXAFS oscillations for Fe and for Co and Ni. This is due, in part, to the differences in the local atomic structure of these films (Fe: bcc; Co: hcp; Ni: fcc). The EXAFS for Co and Ni films are, as expected, strikingly similar. A further source of difference between the detailed shapes of the EXAFS for these films is due to the changes in the interference between the oscillations associated with the L_3 and L_2 edges (the energy separation between the two edges increases in going from Fe to Ni), which accounts for the minor differences between the Co and Ni EXAFS.

Although the EXAFS oscillations of the Fe, Co, and Ni films are of comparable intensity, the relative amplitude of the MEXAFS oscillations, compared to the EXAFS oscillations, changes dramatically in going from Fe to Ni. The results, summarized in Table I show that $\chi_M(k)/\chi(k)$ is $\pm 5\%$, $\pm 2.5\%$, and $\pm 0.5\%$ for Fe, Co, and Ni, respectively. Noting the magnitudes of the orbital and spin moments of bcc Fe, hcp Co, and fcc Ni, also shown in Table I, these measurements indicate that the size of the effect does *not* scale linearly with the spin (or with the orbital or total) moment of the scattering atom. It is important to note that these oscillations are up to 50 times larger than those observed at the K edge of Fe[2,3,5,8] and Co,[6] demonstrating the enhanced sensitivity of the L-edge absorption to the spin-dependent scattering potential of the neighboring atoms. Furthermore, contrary to the K-edge measurements, an inspection of the respective EXAFS and MEXAFS spectra readily indicates that the MEXAFS spectra are not in-phase with the EXAFS spectra and display higher frequency oscillations. This clearly indicates that the scattering paths that dominate MEXAFS oscillations are not the same as those which give rise to the EXAFS oscillations. Indeed, the shorter wavelength, higher frequency MEXAFS signal cannot be generated by nearest-neighboring single scattering paths, but is

TABLE I. Summary of experimental results, showing the relative size of the MEXAFS effect (χ_M) as compared to EXAFS (χ) at the $L_{2,3}$ edges of Fe, Co, and Ni thin films. Also shown for reference are the electron orbital (m_l) and spin (m_s) moments for each of these elements.

[a]Room temperature Einstein–de Haas gyromagnetic ratio measurements (Ref. 20).

dominated by longer scattering path lengths, most likely from multiple scattering events. Multiple scattering is consistent with both the higher frequency of the MEXAFS, and the nonlinear dependence of the MEXAFS oscillations with the magnetic moment of the scattering center.

In principle, full multiple-scattering EXAFS formalisms which incorporate the appropriate circular polarized selection rules and correct spin-dependent atomic potentials should completely reproduce these spectra, including their amplitude dependence. Theoretical treatments of this type have been attempted,[17] with particularly good agreement for the half-filled shell of Gd.[18] Although variations of the spin-dependent portion of the atomic potential results in only small differences in the individual helicity dependent EXAFS spectra, the *difference* of the two spectra measured with opposite light helicity (the MEXAFS spectra) is quite sensitive to the method of inclusion of the spin–orbit interaction of the core electrons which generate the small energy differences in the spin-dependent potentials. In fact, the detailed comparison of the measured MEXAFS spectra with theoretical spectra can be used to check the accuracy of the calculated spin-dependent potentials, and allow for the refinement of the potential parameters. Combined with the standard EXAFS analysis to determine structural parameters, it is possible to extract meaningful magnetic material properties from the spin-dependent atomic potentials determined from the MEXAFS spectra.

Interestingly, we have found[9] that in extracting the orbital and spin magnetic moments from the near edge MCD spectra of Fe and Co, the best agreement between theory and experiment occurred for *ab initio* calculations which incorporated orbital polarization corrections.[19] This suggests that, to accurately reproduce the MEXAFS oscillations, the inclusion of orbital polarization effects in the spin-dependent atomic potentials may be important.

In summary, we have shown that the L-edge soft x-ray absorption spectra of polycrystalline films of bcc Fe, hcp Co, and fcc Ni have a very large helicity dependence, far larger than for their K edges. The relative amplitude of the L-edge MEXAFS spectra does not scale linearly with the magnetic moment of the scattering atom and the oscillations are at a higher frequency than the EXAFS oscillations, identifying the dominant scattering paths to be longer than those for the nearest neighbors.

[11] The use of the transmission method offers a significant improvement of signal-to-noise ratio as compared to other methods, e.g., total electron yield, since with the former the entire sample is probed (and hence, samples as thick as 300–500 Å can be used) while with the latter only the top 25–50 Å are probed. The signal-to-noise ratio for partial fluorescence yield measurements, another method for measuring XAS, is always worse than the other methods and hence not suitable for the kind of measurements described in this work.

[16] The Fourier transforms of the data, as is usually done within the standard framework of EXAFS formalism, are not shown. While such conversions are necessary for the subsequent analysis of the data, their interpretation is complicated in this case due to the overlap of the L_3 and L_2 edges, requiring nontrivial deconvolution of the spectra which is beyond the scope of this manuscript and will be the subject of an upcoming manuscript (Ref. 14). The intention of the present manuscript is to illustrate the nature of the MEXAFS signal rather than presenting a detailed analysis of the (M)EXAFS data to extract bond lengths or Debye–Waller factors.

Magnetic circular dichroism in EELS (abstract)

G. R. Harp

We evaluate the possibility of using dichroic electron energy loss spectroscopy (DEELS) as an alternative to x-ray magnetic circular dichroism (XMCD). It is well known that electron energy loss spectroscopy and x-ray absorption spectroscopy are highly analogous, providing similar information. A simple semiclassical model suggests that DEELS might have a magnetic sensitivity similar to that of XMCD. This sensitivity will be reduced, however, by multiple scattering of the probe electron before and after the energy loss event. Thus it is difficult to predict the magnitude of the DEELS effect. Experiments were performed at the *L*-edge of polycrystalline Fe, Co, and Ni thin film samples with uniaxial in-plane magnetic anisotropy, prepared *in situ* with a magnetic bias field. Even in those most favorable cases, the DEELS effect is seen to be at least 10 times smaller than similar effects in XMCD. [S0021-8979(96)70408-3]

Magnetic properties of amorphous $Er_{1-x}Fe_x$ alloys with $x \approx 0.7$ have been studied. Macroscopic characterization has been performed by measuring temperature- and field-dependent magnetization. Applying a magnetic field the compensation temperature first decreases, but increases again at larger fields. This "exotic" behavior has been interpreted in terms of the sperimagnetic character of both subnetworks. The suggested scheme has been checked by measuring x-ray circular magnetic dichroism at the Er M_5-edge. Using this atom-sensitive technique we have been able to detect temperature-induced as well as field-induced flips of the Er-subnetwork with respect to the direction of the applied field. [S0021-8979(96)78608-1]

I. INTRODUCTION

Amorphous alloys have received much attention in the last years due to their interesting properties and their applicability for new devices.[1,2] Their magnetic properties are strongly affected by bond and chemical disorder causing a distribution of magnetic moments and exchange interactions. Also, the randomly varying electrostatic fields create, via spin–orbit coupling, locally varying single-site anisotropies giving rise to noncollinear arrangements of the magnetic moments. These sperimagnetic structures have been widely observed in amorphous rare-earth-transition-metals alloys $R_{1-x}T_x (0<x<1)$.[1] The large spin–orbit coupling of non-S-state rare earths gives rise to large local anisotropies and therefore to a fan structure in the R subnetwork moment. In the case of T=Fe noncollinear structures produced by the $R-T$ exchange have been observed also in the Fe subnetwork.[1]

In the case of heavy R, where R and T moments are coupled antiparallel,[3] the different temperature dependence of each subnetwork moment can lead to a vanishing global magnetization at a temperature T_{comp} called "compensation temperature." The fan magnetic structure in amorphous sperimagnets is responsible for a strong dependence of the magnetization of each subnetwork on the applied magnetic field. T_{comp} are therefore strongly dependent on the applied magnetic field.

The objective of the present paper is to characterize the magnetic behavior of an amorphous $Er_{1-n}Fe_n$ ($n \approx 0.70$) compound from a macroscopic point of view and to study independently the magnetic behavior of the Er subnetwork taking advantage of the element selectivity of x-ray absorption spectroscopy. X-ray magnetic circular dichroism (XMCD) measurements were performed at the Er M-edge as a function of temperature and applied magnetic field.

II. MACROSCOPIC STUDY

Crystalline alloys of $Er_{1-x}Fe_x$ with nominal composition $x=0.60$ were prepared by melting the starting elements in a cold crucible furnace. These alloys were used as targets in a sputtering chamber, using ionized Ar gas as sputter gas. Amorphous films were simultaneously grown on monocrystalline-Si and kapton foils, cooled at 77 K. A Si-deposited sample was used in the XMCD measurements to optimize the thermal contact with the cryostat head, while the kapton-deposited samples were used for macroscopic measurements in order to reduce the diamagnetic contribution of the substrate. The magnetic properties of the samples were shown to be independent of the nature of the substrate. Amorphization was checked by x-ray diffraction. Rutherford backscattering (RBS) with α particles performed on the amorphous films gave us a composition of $x=0.73\pm0.01$ and allowed us to determine the sample thickness. The work presented in this paper is focused on two samples: sample "a," 400 Å thick, and sample "b," 80 Å thick. All the samples were protected against oxidation by Cr 50 Å thick films.

Alternative magnetic susceptibility (χ) was measured in sample "a" with a superconducting quantum interference device from 4.2 to 300 K. The ordering temperature detected by measuring the thermal dependence of susceptibility, $\chi(T)$, is $T_c=190$ K. The macroscopic magnetic behavior of this compound was characterized by isofield-$M(T)$ and isotherms-$M(H)$ measurements from 4.2 K$<T<$300 K and $0<H<6T$ performed in a vibrating sample magnetometer. The Arrott-plots, $M^2(H/M)$, obtained from $M(H)$ measurements show a change of the slope around T_c, which is typical for random anisotropy systems.[4] $M(H)$ measurements show, up to $6T$, the characteristic lack of saturation associated with noncollinear magnetic structures. We can therefore assume that our compounds present sperimagnetic structures.

$M(T)$ measurements were performed on the sample "a" for different values of applied magnetic field. At low fields

 0021-8979/96/79(8)/6497/3/$10.00

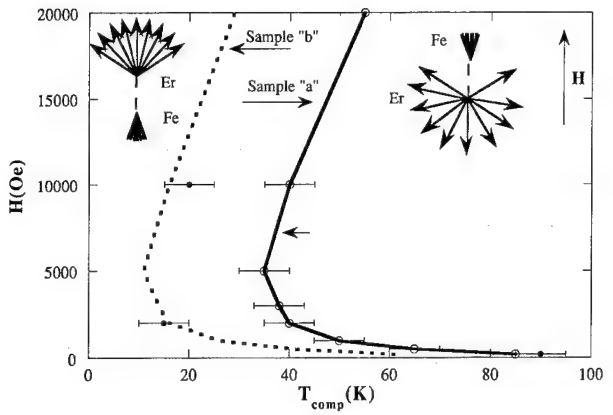

FIG. 1. Configuration phase diagram with respect to the applied field for two samples of $Er_{1-x}Fe_x$ ($x=0.73$): sample "a" (400 Å thick) and sample "b" (80 Å thick).

(around $0.05T$) $M(T)$ shows a compensation temperature at $T_{comp}=65$ K. By increasing H, the minimum of the magnetization shifts to lower temperatures and to nonzero magnetization values ($T_{comp}=35$ K at $H=0.5T$). For larger fields this tendency is reversed and the minimum is shifted to higher temperatures. In Fig. 1 we present the evolution of T_{comp} with the applied field.

For each magnetic field, we can identify the minimum in magnetization as a *pseudo*-compensation temperature, although no vanishing of magnetization occurs. As in the case of crystalline compounds, for $T<T_{comp}$ the R subnetwork is parallel to the external applied field. For $T>T_{comp}$ the T subnetwork magnetization dominates and the R moments flip to antiparallel to H. The strong evolution of T_{comp} as a function of H is quite unusual for $R-T$ alloys and has to be explained in terms of the sperimagnetic (fan) structure of the amorphous films. As the magnetic anisotropy of Fe is weaker than the Er one, a low magnetic field orients the Fe moments more easily than the Er moments. The reinforcement of the net Fe moment projected along the field gives rise to a decrease of T_{comp}. For higher fields this effect saturates, Fe moments are collinear with the applied field and the increase of the field reinforces the collinearity of the Er subnetwork, causing an increase of T_{comp}.

The minima detected in the $M(T)$ measurements of sample "b" (T_{comp}) show the same tendency of sample "a", but the minimum in the $T_{comp}(H)$ is shifted to lower temperatures. This change in compensation temperature is very likely due to a slight difference in the composition of samples "a" and "b." It has been reported that for $Tb_{1-x}Fe_x$ amorphous alloys a variation of composition of 1 at. % can cause a change of T_{comp} up to 40 K.[1]

The evolution of $T_{comp}(H)$ reported for these samples and the interpretation that we give to this phenomenon suggest that a flipping of Er and Fe subnetworks might be induced by the applied field, if a fixed-temperature slightly higher than the minimum of $T_{comp}(H)$ is chosen (Fig. 1). Macroscopic isothermal measurements performed at these temperatures, $M(H)$ or $\chi(H)$ do not allow us to probe the change of the direction of the two subnetworks. To test the validity of the proposed scheme, we need a technique able to separate the magnetic contribution of each subnetwork and their direction, and suited to amorphous systems.

III. XMCD STUDY

X-ray magnetic dichroism is the measure of the dependence of the x-ray absorption (XAS) spectra on the helicity of x-ray photons.[5–7] This technique is particularly valuable for our problem since: (a) it is atom selective. By tuning the photon energy to an absorption edge, it allows us to separate the magnetic contributions of the Er and Fe subnetworks; (b) it is sensitive to the direction of the magnetic moments with respect to the applied field and can therefore detect the flipping of the Er or Fe subnetwork upon application of temperature or field; (c) it does not need long-range order and can be applied to any kind of material, crystalline or amorphous, as long as a net magnetic moment exists on each subnetwork.

The XMCD measurements were carried out at SuperACO (LURE) on the SU22 beamline.[8] The calculated circular polarization rate is 12% in the studied energy range.[9] Due to the low XMCD signals at the Er M_4 edge[10] only M_5-edge absorption spectra ($3d\rightarrow 4f$ transitions) were carried out. Experiments were performed on sample "b" in total electron yield detection for temperatures from 4.2 to 300 K and in magnetic fields up to $5T$. The magnetic field was

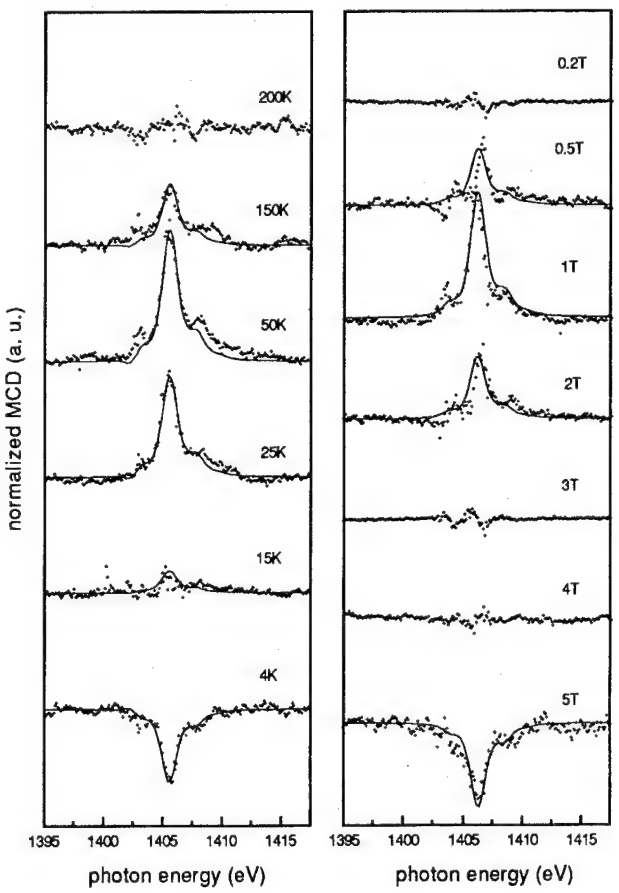

FIG. 2. (a) Temperature evolution of the Er M_5-XMCD signal of amorphous $Er_{1-x}Fe_x$ ($x=0.73$) in a magnetic field $H=1T$. (b) Evolution of the Er M_5-XMCD signal of the same compound as a function of the applied magnetic field and at a constant temperature of 25 K. The full lines are the theoretical fits to the data.

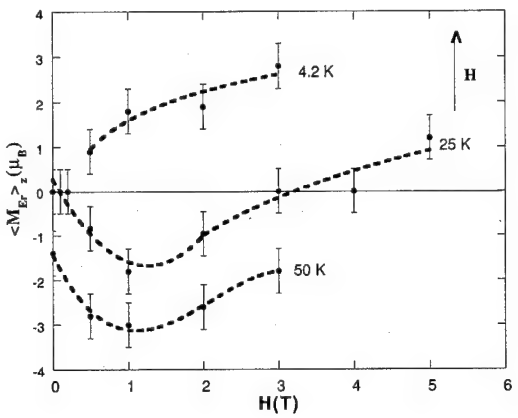

FIG. 3. Field dependence of the Er moment projected along the direction of an applied field at $T=4.2$, 25 and 50 K. Dashed lines are a guide to eye.

applied perpendicular to the sample surface and along the photon propagation direction. XMCD signals are normalized difference of two absorption spectra measured with a fixed helicity and opposite directions of the applied magnetic fields, $\sigma^+(E)$ and $\sigma^-(E)$.

In order to extract an approximate value of $\langle M_J\rangle_{4f}$ of Er from the experimental spectra, the $\sigma^+(E)$ and $\sigma^-(E)$ absorption spectra were calculated using an atomic approach. A combination of a magnetic field[5,11] and an axial crystal field[11] was used to calculate a perturbed level scheme of the Er^{3+} ion which fitted the experimental spectra.

The evolution of the Er M_5-XMCD signal as a function of temperature in an applied field of $1T$ is shown in Fig. 2(a). At low temperatures (4.2 K) the signal is negative as expected for Er magnetization parallel to the applied field.[10] At $T=15$ K, we are close to the compensation temperature for this field and the XMCD signal is zero. Above this temperature the signal changes sign, indicating that the Er-subnetwork magnetization is now antiparallel to the external field (flipping). Finally, the decrease of the signal for higher temperature is associated with the approach of the ordering temperature. The Er-$4f$ moments were calculated from a theoretical fit of the experimental data. The largest moment, detected at 50 K, is of the order of $3\mu_B$ which is by far smaller than the saturated $9\mu_B$ Er-moment. Reminding that XCMD gives the average Er-moment projected along the magnetic field, this result suggests a strongly asperomagnetic structure of Er-subnetwork, as proposed in Fig. 1. This result is consistent with the low values of the net projection of the R moment which were extrapolated from macroscopic measurements on other sperimagnetic $R_{1-x}Fe_x$ alloys.[1]

XMCD experiments as a function of the applied field were performed at different temperatures corresponding, in the diagram of Fig. 1, with thermal ranges in which the net moment of the R subnetwork is parallel to the field (4.2 K), antiparallel (50 K) and at a temperature (25 K) in which the isotherm crosses the dashed line of sample "b." In Fig. 3, we show the evolution of the Er-$4f$ moments calculated from the theoretical fit of XMCD for the three isotherms. At 4.2 K, the projection of the Er $4f$-moment along the field is always positive and increases with the field, which agrees with the fan structure proposed in Fig. 1. At $T=50$ K, this projection is always negative and a minimum in its dependence with the field is observed. The net Er $4f$ moment along the field is always antiparallel to the applied field as proposed in Fig. 1, increasing at low H values and decreasing at higher ones. The decrease at high fields is expected, since the field is applied in the opposite direction to the net magnetic moment direction. The increase at low fields can be explained considering the orientation of the Fe subnetwork along the field. Due to antiferromagnetic coupling between Er and Fe subnetworks, the antiparallel projection of the Er subnetwork has to follow the close-up of the angular distribution of the Fe moments.

Figure 2(b) shows selected experimental XMCD spectra measured at $T=25$ K, together with the corresponding theoretical fits. The H dependence of the fitted magnetic moments at 5, 25, and 50 K is shown in Fig. 3. At 25 K the signal is close to zero for low fields ($<0.2T$) since we are very close to the compensation temperature for these fields. For $0.5T$ and $1T$ the signal is positive, i.e., the Er moment is antiparallel to the applied field. For $3T$ and $4T$ the signal is again zero, indicating the approach of a compensation temperature. Increasing the field up to $5T$ induces a further flip of the Er magnetization, as expected on crossing the dashed line of Fig. 1.

In conclusion, the minima detected in the $M(T)$ curves, the Er subnetwork flips with respect to the H direction. This must be correlated with a flip in the Fe subnetwork. The different anisotropy of Fe and Er subnetworks explains the reported $T_{comp}(H)$ behavior in this sperimagnetic compound. This "exotic" behavior gives rise not only to temperature-induced but also field-induced flips of the Er.

Magnetic circular dichroism at the *K* and *L* edges of Co and Cu in Co/Cu(001)

Ruqian Wu

A. J. Freeman
Department of Physics and Astronomy, Northwestern University, Evanston, Illinois 60208-3112

The fcc Co/Cu(001) system is investigated using the full potential linearized augmented plane wave method. Through the atomic force approach, large multilayer relaxations (6.5%, 5.3%, and 2.8%) are found between the adjacent Cu layers, which reduces the total energy by 128 meV. The spin and orbital magnetic moments for Co atoms are 1.79 and 0.12 μ_B, respectively. At the interfacial Cu site, we found a sizable induced magnetic moment, 0.05 μ_B, which can be split into d (0.074 μ_B) and s,p(0.024 μ_B) contributions. Interestingly, the spin polarization of d and s,p states can be detected separately through the magnetic circular dichroism at the L and K edges, for which the calculated results agree very well with experiments. © *1996 American Institute of Physics.*
[S0021-8979(96)78708-9]

Magnetism in Co/Cu has attracted extensive attention because of its importance in both technical and fundamental aspects, such as the mechanism of magnetic ordering through a Cu spacer and the giant magnetoresistance.[1,2] As a prototype example of layer-by-layer growth, the Co/Cu interface was found to be very sharp with negligible interdiffusion [less than 0.1 monolayer (ML)].[3,4] Recent experimental work has focused on identifying the quantum-well states[5] in the Cu layers and their role in magnetic ordering. However, being overwhelmed by the magnetism of Co, it is very hard to detect the spin polarization of these quantum-well states with usual photoemission techniques.[6] Fortunately, we can solve this problem by using the newly developed magnetic circular dichroism (MCD) technique.[7] Since MCD involves photon-induced excitation from the core levels to the valence states, it has element selectivity. Very recently, strong magnetic signals (from s, p, and d bands) were detected for Cu in Co/Cu(001) and Fe/Cu(001),[8,9] which challenges theoretical explanation.

In our previous first-principles calculations using the full potential linearized augmented plane wave (FLAPW) method, we found strong proximity effects from the Cu substrate to the magnetic overlayers.[10] For example, the large magnetic moment (2.07 μ_B) of the Co free monolayer is reduced substantially to 1.78 μ_B when in contact with Cu(001), which is even 5% smaller than that (1.87 μ_B) at the clean fcc Co(001) surface.[11] In this article, the magnetic properties of Co/Cu(001) are scrutinized further by means of discussing the spin and orbital magnetic moments, their angular decompositions, and the calculated K-edge and L-edge MCD spectra for both the Co and the interfacial Cu atoms. In addition, using the force approach, we reoptimized the atomic structure of the Co/Cu(001) overlayer system and found some significant multilayer relaxations.

Here, the Cu(001) substrate is simulated by a seven-layer slab covered on each side by a pseudomorphic Co layer. The lattice constant in the lateral plane adopts the experimental value of the fcc Cu bulk (a=3.615 Å) while the vertical positions of all the atoms are optimized according to their atomic forces. In the FLAPW approach, there is no shape approximation for the charge, potential, and wave functions. The Kohn–Sham equations are solved self-consistently with an energy cutoff of 13 Ry for the variational plane wave basis set. Within the muffin–tin (MT) spheres (r_{Co}=r_{Cu}=2.20 a.u.), lattice harmonics with an angular-momentum l up to 8 are employed to expand the charge density, potential, and wave functions. Summations over 36 k points in the 1/8 irreducible two-dimensional Brillouin zone are employed for k-space integrations. After the mean-root-square differences between the input and output charge and spin densities in the semirelativistic iterations become less than 1.0×10^{-4} e/(a.u.)^3, the spin–orbit coupling is invoked in a second variational way.

Surprisingly, as listed in Table I, a large multilayer relaxation is found in Co/Cu(001), which lowers the total energy by as much as 128 meV/cell compared to the unrelaxed geometry. The distance between interior Cu layers (e.g., $d_{Cu(C)-Cu(I-2)}$) shrinks 2.8% from that in the ideal fcc Cu lattice, 3.41 a.u. Even larger relaxations are found in the surface and subsurface regions where the $d_{Cu(I)-Cu(I-1)}$ and $d_{Cu(I-1)-Cu(I-2)}$ shrink by 6.5% and 5.3%, respectively. These large multilayer relaxations, however, are mainly due to the fact that the experimental lattice constant used in the lateral plane is too large. Our total energy calculations for the fcc bulk Cu indicate that the equilibrium lattice constant is 6.647 a.u.—a value of 2.7% smaller than the experimental one, 6.831 a.u. Nevertheless, since $d_{Cu(I)-Cu(I-1)}$ is clearly shorter than the interlayer distances between interior Cu layers, the presence of a Co overlayer does not fully restore the relaxation on the Cu(001) surface. The calculated equilibrium dis-

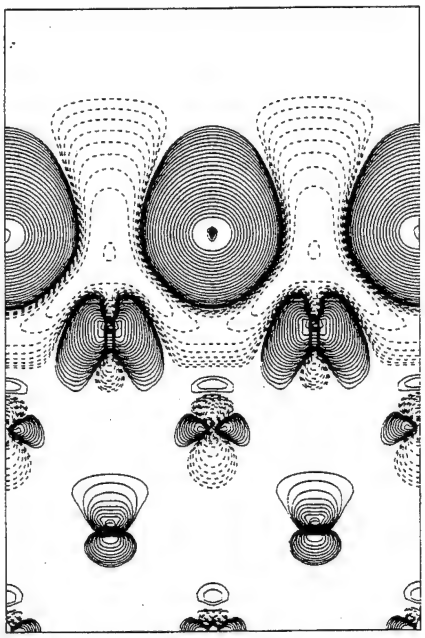

FIG. 1. Calculated spin density for Co/Cu(001). Contours in start from $\pm 1\times10^{-4}$ e/a.u.^{3} and increase successively by a factor of $\sqrt{2}$.

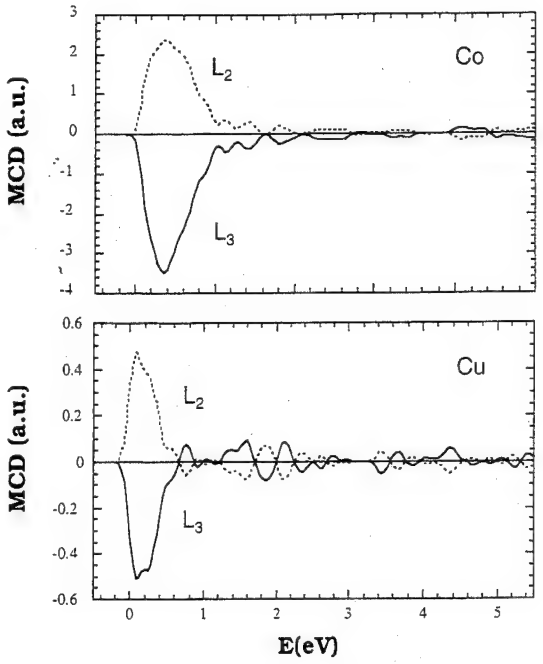

FIG. 2. Calculated L-edge MCD spectra for the Co and Cu atoms in Co/Cu(001). Solid and dotted lines stand for the L_3 and L_2 edges, respectively.

tance between the Co and Cu(I) is 3.06 a.u., which is about 3% smaller than that obtained previously[11] when the relaxations in the Cu substrate were excluded.

In the equilibrium geometry, the spin density shown in Fig. 1 suggests the detrimental effects of the Cu(001) substrate on the spin polarization in the Co overlayer. The area with positive spin density around the Co atom is obviously suppressed in the interfacial direction. As found in most of the magnetic systems,[10] the spin density in the interstitial region (mostly from the s, p states) differs in sign from that in the near nuclear region (mainly from the d states). Clearly, the induced magnetization around the interfacial Cu site is parallel to that of Co. Due to the screening effects, the magnetic interference decays very quickly upon going into the interior Cu region. Quantitatively, as listed in Table I, the magnetic moment in the Co MT sphere in Co/Cu(001) is 1.785 μ_B, which can be further decomposed into contributions from the s (0.013 μ_B), p (-0.002 μ_B), and d (1.774 μ_B) states. The orbital magnetic moment is also very large, 0.116 μ_B. Both results agree very well with the measured spin and orbital magnetic moments, 1.71 and 0.126 μ_B, respectively.[8]

On the other side, small spin and orbital magnetic moments, 0.050 and 0.004 μ_B, are induced at the interfacial Cu site. The angular decompositions of the spin moment are -0.006, -0.017, and 0.073 μ_B for the s, p, and d states. Corresponding to the weakly spin density, the magnetic moment decreases to almost zero for the interior Cu atoms. However, one should note that both the spin density and the magnetic moment show an oscillative behavior going into the interior Cu layers. This may be somewhat important for the magnetic ordering and transport properties through the Cu spacer layers.

To compare with experimental results,[8] the calculated L-edge MCD cross sections for the Co and Cu are presented in Fig. 2. As expected, strong MCD signals can be detected from the Co site. Since the Co atom also possesses a large orbital magnetic moment, 0.116 μ_B, the area of the L_2 edge (results from $2p_{1/2}$–$3d$ dipole transition) is obviously smaller than that of the L_3 edge (results from the $2p_{3/2}$–$3d$ dipole transition). Interestingly, the Cu-MCD signal is quite strong (1/5–1/8 in amplitude of that for Co) despite the fact that the induced magnetic moment at the Cu site is relatively

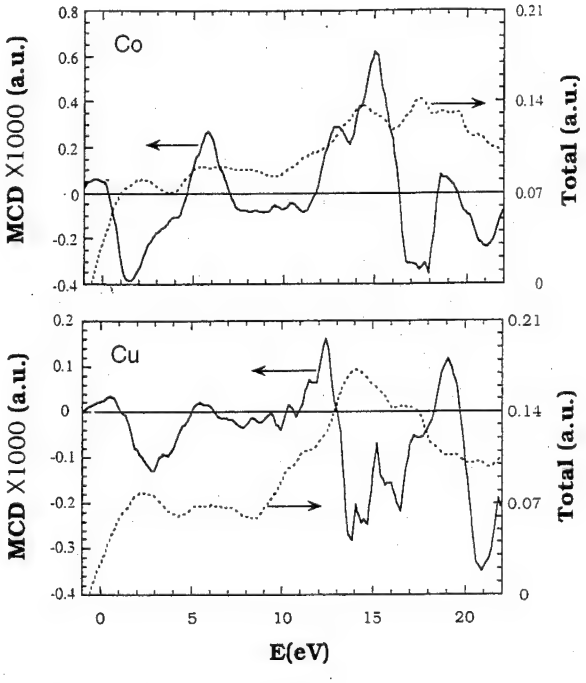

FIG. 3. Calculated K-edge MCD (solid lines) and total absorption (dotted lines) spectra for the Co and Cu atoms in Co/Cu(001).

very small. This is partially due to the smaller spatial extension of the Cu-3*d* orbit, which enhances the radial part of the momentum matrix and thus the cross section. We found that the Cu L_2 and L_3 edges (located at 908 and 928.5 eV) split by 20.5 eV, which agrees well with the measured splitting, 20 eV.[8]

The *K*-edge spectra for both Co and Cu atoms are given in Fig. 3. Strikingly, the profile of the Cu-MCD curve follows very closely that for Co in the lower energy range, which indicates that the spin polarization of the Cu-4*p* states is mainly induced by the Co-4*p* states. As also found experimentally,[9] the MCD signals for both Co and Cu consist essentially of a negative peak in the vicinity of the inflection point of the absorption edge with a small blip at the beginning. Surprisingly, the Co *K*-edge MCD signal is not much stronger than that of Cu. This may be attributed to the weakness of the *p* magnetic moment at the Co site (cf. Table I). Different from the *L* edge, the *K*-edge MCD and even the total absorption spectra show plenty of structures and deserve further investigation since the energy resolution of the currently measured spectra is not high enough to permit detailed comparison. Nevertheless, most of the main features of the Co and Cu *K*-edge MCD and total absorption curves appear to agree fairly well between theory and experiment.[12]

[12] (i) The calculated spectra have more structures since we used a narrower Gaussian broadening (0.2 eV); (ii) LDA wave functions become less reliable 10 eV above the Fermi level and thus a comparison between theory and experiment does not make too much sense in the high energy region.

Determination of the energy dependence of the off-diagonal terms of the dielectric tensor by means of $M_{2,3}$ reflection MCD measurements (abstract)

Hartmut Höchst, Dai Zhao, and David Huber
Synchrotron Radiation Center, University of Wisconsin-Madison, Stoughton, Wisconsin 53589

We present the first magnetic circular dichroism (MCD) measurements around the M edges of 3d metals utilizing SRCs recently developed quadruple reflection polarizer system.[1] The reflection polarizer converts linearly polarized light by means of the phase shift between s- and p-reflections into either left or right circular polarized radiation.[2] The concept of the phase shifter has been tested at a bending magnet beam line at the Aladdin storage ring using the $M_{2,3}$ absorptions of magnetically ordered thin films of Fe, Co and Ni. The normalized MCD signal e.g., $(I_R - I_L)/0.5*(I_R + I_L)$ is on the order of several % from peak to peak and scales linearly with the magnetic moments. The shape of the reflection MCD signals has a very pronounced angular dependence with a maximum around a reflection angle of θ=60°–65°. The main trends in the angular dependence of the reflection MCD signal can be verified by model calculations. The model also allows us to extract the energy dependence of the off-diagonal terms in the dielectric tensor from the experimental data. The potential use and high sensitivity to variations in the local magnetic environment will be demonstrated with high resolution measurements of several ferrimagnetic compounds. Magnetic dichroism measurements of the valence bands of films of fcc Co/Cu (001) have been performed using angle-resolved UV photoemission in low-symmetry, off-normal emission geometries, and linearly polarized light. Asymmetries of magnitude 4% are observed upon magnetization reversal. Evidence of both spin-dependent surface transmission and magnetic dichroism in the angular distribution of photoelectrons is seen. The asymmetry spectra indicate sensitivity to both magnetic exchange splitting and to spin–orbit splitting. © *1996 American Institute of Physics.* [S0021-8979(96)78808-3]

Magnetic dichroism in the angular distribution of photoelectrons (MDAD) makes it possible to study the interplay between the magnetic exchange and spin–orbit interactions in solids. To date, it is primarily the deep[1,2] and shallow core[3,4] levels of magnetic materials which have been investigated in this way. Over the course of these studies, a series of findings have overturned expectations, and lead to a better understanding of the technique and its potential. It turns out that the dichroism is sizable not only in the deepest core levels, that circularly polarized light is not required, and a larger dichroism may often be obtained using linearly polarized light;[3,5] and that the dichroism from core levels is not independent of emission angle, but contains significant crystallographic information.[1,6] These findings all suggest the application of MDAD to valence band studies, to see what can be learned about the magnetically important states near the Fermi level without recourse to more complicated spin-resolved experiments, or to monochromators specialized for the production of circularly polarized light. All that is required is a conventional angle-resolved photoemission apparatus, a source of linearly or unpolarized monochromatic light, and a means to reverse the remanent magnetization of the sample.

A few experimental studies which confirm the existence of MDAD in the valence bands have been reported, but most have used circularly polarized light,[7] and all have used normal emission geometries which restrict access to a few regions of the Brillouin zone.[8] Furthermore, a straightforward qualitative model giving an overview of the mechanism by which the dichroism arises in valence band emission is still missing. It is therefore difficult to interpret the measurements without recourse to specialized one-step photoemission calculations with nonperturbative treatments of the exchange and spin–orbit coupling in the surface electronic band structure.[9] These calculations are not yet available for general, low symmetry experimental geometries. The purpose of the present experiments is, in the first place, to observe the magnetic dichroism in the valence bands in off-normal emission geometries, using linearly polarized light. With measurements in hand, it may be possible to better assess how the dichroism can be used in a practical sense to learn about the electronic structure at magnetic surfaces.

An example of the ambiguities which arise in magnetic dichroism experiments in the valence bands, is the question of the conceptual origin of the observed dichroism. For concreteness, consider the experimental geometry in Fig. 1. The remanent magnetization, **M**, is in the surface of the sample crystal, and both the incident light wave vector, **q**, and the photoelectron wave vector, **k**, lie in the *xy* plane normal to **M**. The light is linearly polarized in this plane. In Fig. 1, **q** and **k** are collinear, but this need not be the case. It is further assumed that the *xz* plane containing **M** is a mirror symmetry plane of the crystal—a common situation among itinerent ferromagnets.

The experiment involves collecting two angle-resolved photoelectron energy distributions—one for each of the two reversed remanently magnetized states of the sample. The difference in these two energy distributions is the energy- and angle-resolved dichroism. There are two mechanisms which may contribute to the dichroism. The first is spin-dependent transmission.[10] It is most apparent as a "final state effect" in a three-step model of photoemission, where photoexcitation occurs between bulklike electronic states and the photoelectrons are subsequently transmitted to the vacuum. At the surface, the photoelectron states in the crystal (which are not pure spin states, because of spin–orbit coupling) must be matched to those in the vacuum (which are pure

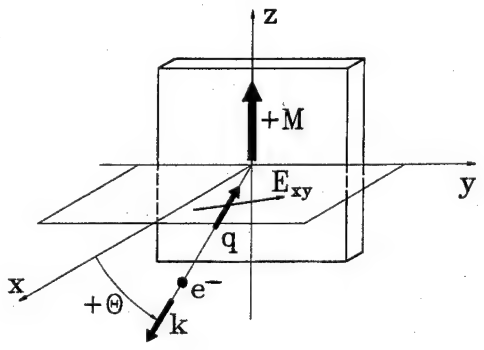

FIG. 1. The Co(001) film has remanent magnetization along $\pm z$, and lies in the *xz* mirror plane. The incoming light with wave vector **q** (with linear polarization $\mathbf{E}_{xy}$) and the photoelectron wave vector **k** all lie in the *xy* mirror plane, making an angle θ with the *x* axis.

 0021-8979/96/79(8)/6504/3/$10.00

spin states). This leads to spin-dependent transmission coefficients. In the above experiment, reversing the magnetization reverses the spin character of the photoelectrons, and the altered transmission coefficient may cause the dichroism. Recent results for Cu show that this mechanism can cause an asymmetry of $\pm 3\%$ in $3d$ metals.[11]

MDAD is typically considered to arise from the photoexcitation step itself.[12,13] The spectra taken with reversed magnetization compare two inequivalent experimental geometries which are related by a mirror reflection—a traditional statement of dichroism. This can be understood with reference to Fig. 1, where reversal of the magnetization is equivalent to reflection in the xz mirror plane of the crystal. However, this operation also alters the experimental quantities $\mathbf{k}$, $\mathbf{q}$, and $\mathbf{E}_{xy}$. In particular, the even and odd parts of $\mathbf{E}_{xy}$ and the photoelectron wave function undergo a relative change in phase, and the resulting photoexcitation matrix element will have both even and odd parts. Upon squaring and subtracting to form the dichroism, only the interference terms between the even and odd parts of the matrix element survive, giving the dichroism.[13] Because of its origin in the transition matrix elements, MDAD is usually classified as an "initial state effect."

The view that magnetic dichroism arises from MDAD when it is an initial state effect and from spin-dependent transmission when it is a final state effect cannot be considered as a rigid classification. However, alternative classifications are worse: In the three-step model of photoemission, spin-dependent transmission exists, but MDAD (with linearly polarized light) does not. In a one-step model, all the dichroism must be assigned to the matrix elements—that is MDAD. These classifications are not as useful for qualitative arguments, and ultimately for the understanding of experiments.

The photoemission experiments were carried out at the BESSY synchrotron storage ring, using a 6.5 normal incidence monochromator, and an angle-resolved photoemission apparatus which is described elsewhere.[14] The samples were 5 or 6 monolayer fcc Co films grown on a Cu(001) substrate. The film growth was monitored using medium energy electron diffraction.[15] Hysteresis loops measured by the magneto-optic Kerr effect confirmed that the films were remanently magnetized in the plane of the surface. The electron energy analyzer had a hole in the back, which allowed the light beam to pass through the entrance lenses, and permitted the experimental geometry with $\mathbf{k}=-\mathbf{q}$, as shown in Fig. 1. This geometry has three important attributes: (a) A wide range of off-normal emission conditions can be reached by a single rotation of the sample about the $\mathbf{z}$ axis. (b) Since $\mathbf{k}$, $\mathbf{q}$, and $\mathbf{M}$ are coplanar, oriented atom models of MDAD predict no dichroism[12]—any observed effects will be related to crystallographic information. (c) The xy plane is a true mirror plane for the magnetic system plus the experiment. This latter point implies that MDAD using either linearly or circularly polarized light measures the same matrix elements, as has been confirmed theoretically[13] and experimentally.[16] A disadvantage of this geometry is that the light passing through the spectrometer creates more secondary electrons

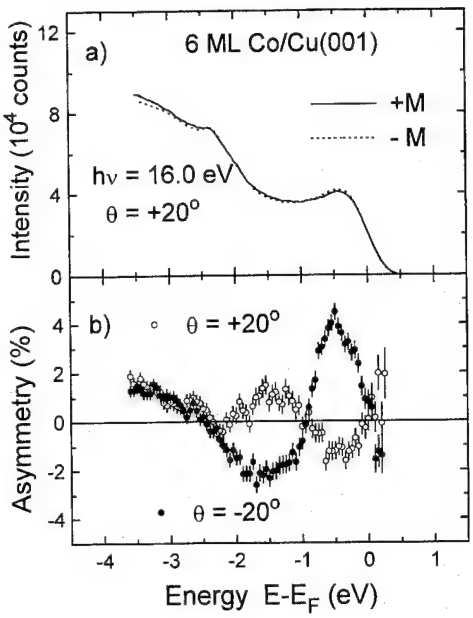

FIG. 2. (a) Photoelectron intensity spectra for two senses of magnetization, with a photon energy of 16.0 eV and emission angle +20°. (b) The resulting intensity asymmetry for the data in part (a) (open symbols), and for data measured at an emission angle of −20° (closed symbol).

than is usual, and this limits the useful energy range of the spectra, particularly at lower photon energies.

Experimental results for a photon energy of 16.0 eV, with $\theta=+20°$ are shown in Fig. 2. Part (a) presents the separate intensity spectra for positive and negative magnetization. The spectra have had a linear background (determined before the Fermi energy) removed, and have been normalized to compensate for changes in the photon flux during the course of the measurements. The open symbols in part (b) show the intensity asymmetry, defined as the difference of the two spectra divided by their sum. It shows clear positive and negative peaks in the energy range down to about −2.5 eV where the Co d bands lie, and a gradual upward slope at lower energy. The asymmetry of a similar pair of data sets collected at $\theta=-20°$ are also plotted in Fig. 2(b). The asymmetry peaks for this angle are reversed in the energy region of the Co bands, as they must be if they are due to either MDAD or spin-dependent transmission. The slope in the region of secondary electrons depends instead on the absolute sign of the magnetization, and probably represents a perturbation of the secondary electrons generated by the light passing through the spectrometer.

It can be seen immediately that the magnitude of the dichroism in off-normal emission is in the range of 2%–4% when secondary electrons are not removed. This is the same approximate size as that seen in previous experiments in normal emission, and is also the same as typical (rather than maximum) values seen in MDAD from core levels when the secondary electrons are not removed. MDAD experiments in the valence bands are not significantly more difficult than those in the core levels. This example also demonstrates the advantage of using a differential spectroscopy such as MDAD—it is possible to display clearly the presence of Co states near −1.5 eV despite the fact that they do not appear

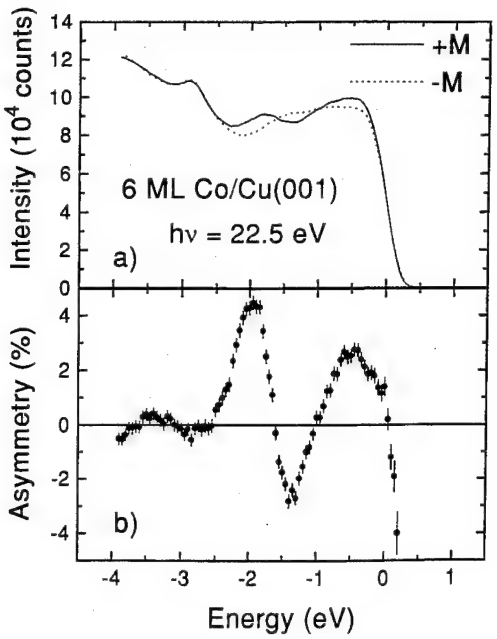

FIG. 3. (a) Photoelectron intensity spectra for two senses of magnetization, with a photon energy of 22.5 eV and emission angle −16°. (b) The resulting intensity asymmetry for the data in part (a).

as peaks in the intensity spectra. The form of the dichroism spectra suggests that, in this instance, the dichroism arises primarily due to spin-dependent transmission at the surface. The first-order perturbation observed in the intensity spectra is a change in the size of the peak—there is no indication that the intensity peak near −0.5 eV is shifted when the magnetization is reversed. This behavior is expected for the final state effect of spin-dependent transmission upon spin reversal. The positive and negative peaks in the asymmetry are then interpreted as being due to separate transitions from states of opposite spin, which are separated by approximately 1.2 eV, in agreement with the exchange splitting found in calculations and spin-resolved photoemission experiments[17] for fcc Co. Note that the absolute sign of the asymmetry is not easily related to the spin of the photoelectrons, since it depends on the surface transmission coefficients.

The data presented in Fig. 3 for a photon energy of 22.5 eV and $\theta = -16°$ show a different behavior. The peak below about −2.5 eV is due to the Cu substrate, and shows no asymmetry. However, a well-resolved peak at −1.8 eV seen with $+\mathbf{M}$ shifts to −1.6 eV when the magnetization is reversed, but the peak intensity is not greatly affected. This is the behavior expected for MDAD. The first-order effect of weak spin–orbit coupling on the initial states is to introduce hybridization between nearly degenerate bands of opposite spin. While the energy of the hybridized states depends on the relative orientation[18] of the spin σ and $\mathbf{M}$, as $\sigma+\mathbf{M}$, the transition matrix elements depend as well on the absolute spin direction through the spin–orbit coupling $\sigma \cdot l$. Thus the transition with a given orientation of $\sigma \cdot l$ occurs at a different energy when $\mathbf{M}$ is reversed, leading to the apparent shift in the peak energy in the intensity spectra. A rapid minus/plus variation in the asymmetry results. The experimentally observed energy shift is of the magnitude expected for the spin–orbit interaction for $3d$ metals. These spectra coincidentally demonstrate that MDAD persists in this low-symmetry geometry, where $\mathbf{q}$, $\mathbf{k}$, and $\mathbf{M}$ are coplanar, even though models based on photoemission from oriented atoms predict a null effect. This is a consequence of the crystalline symmetry, rather than atomic symmetry, of the system, and is not surprising for such low photon energies.

The asymmetry close to the Fermi level in Fig. 3 is not as clear cut as the previous two examples, and more a detailed analysis is called for. It is not yet clear whether or not a simple criterion can be found to distinguish MDAD from surface transmission effects. Analysis of the systematics of a more comprehensive data set in underway to determine how widely the present classification of asymmetry features is applicable.

Spin polarized photoemission studies of the 3*s* core level in ferromagnetic systems[a] (abstract)

Y. Liu, J. Xu, D-J. Huang, and P. D. Johnson
Physics Department, Brookhaven National Laboratory, Upton, New York 11973

Spin polarized core level photoemision studies are capable of providing local site specific magnetic information. 3*s* core level photoemission spectra are characterized by a main peak and satellite whose separation reflects the exchange interaction between the core level and the net spin in the valence bands. However, there is currently considerable disagreement as to whether the splitting between these two peaks may be taken as a measure of the local moment. An alternative approach is to examine the intensities of the different peaks in the spectra. Indeed analysis of the multiplet intensities in the final state suggests that it should be possible to obtain a reasonable measure of the local magnetic moment through measurement of the spin dependent intensities in the multiplet structure. In detailed spin polarized photoemission studies of the 3*s* core level of Fe and Co films grown on Ag(001) and Cu(001) substrates, respectively, we find that this is indeed the case. This suggests that studies of the spin polarization of the 3*s* core level photoemission may provide an important new technique for the measurement of magnetic moments in thin films. Lineshape fitting reveals new information about the lifetime of the core holes. Previous studies have suggested that a majority spin core hole will be shorter lived than a minority spin core hole because of the higher density of majority spin electrons in the valence bands. However, our studies indicate that the lifetime is more complicated and that it shows a strong dependence on the LS in the final state. [S0021-8979(90)70668-5]

Magnetic dichroism in the soft x-ray regime for magnetic domain imaging by total yield microscopy (abstract)

F. U. Hillebrecht, T. Kinoshita,[a] Ch. Roth, H. B. Rose, D. Spanke, J. Dresselhaus, and E. Kisker
Institut für Angewandte Physik der Heinrich-Heine-Universität Düsseldorf, Germany

Among the techniques for studying magnetic materials, methods utilizing magnetic dichroism in the soft x-ray region are receiving particular attention because of the unique feature of chemical specificity introduced by probing core levels. In soft x-ray absorption of linearly polarized light, the dichroism is proportional to the square of the magnetization M.[1] The transverse magneto-optic Kerr effect is characterized by a change of the specular reflectivity when M is reversed, thus it is linear in M.[2] Due to the relationship between reflected and transmitted radiation, a dichroism may also be expected in the absorption. We confirmed this by quasi-simultaneous measurement of the reflectivity and total yield around the Fe and Co $3p$ thresholds, using p-polarized light at oblique incidence:[3] Switching the magnetization between the two directions normal on the plane of incidence indeed shows a magnetic dichroism. The relationship between the dichroisms in total yield and specular reflectivity was investigated as function of incidence angle. In addition to this new form of magnetic dichroism, other forms have been explored for imaging near-surface magnetic domains of elemental and compound materials in a total yield microscope. By using different light polarizations different components of the magnetization are detected. p- and circular polarization yield magnetization components parallel to the surface, normal to and in the plane of light incidence, respectively. With linearly s-polarized light, images similar to those with circularly polarized light were obtained. This is evidence for a sizeable Faraday rotation, leading to a significant degree of circular polarization before the optical transition takes place. The helicity of the Faraday-induced ellipitical polarization depends on the local sample magnetization, thereby generating the magnetic contrast in an analogous fashion as does circularly polarized light. This mechanism is expected and found to be effective also for p-polarized light, however, with contrast smaller than that related to the transverse MOKE. Finally, we report first results for an antiferromagnet, where domains were observed via the M-quadratic Voigt effect in the soft x-ray region. [S0021-8979(96)70708-0]

Spin resolved resonant Raman scattering measurements in Gd metal made by exciting x-ray resonant Raman scattering with circularly polarized x rays near the L_{III} edge of Gd are presented. The incident photon energy was fixed at the peak of the $2p \rightarrow 4f$ quadrupolar transition, and the scattered photon was energy analyzed around the $3d \rightarrow 2p$ fluorescent energy. Asymmetry ratios in the scattered intensity much larger than that of the L_{III} XMCD effect (x-ray magnetic circular dichroism) were observed upon reversal of the magnetization of the sample or the helicity of the photon. A detailed comparison of these results with XMCD results from both the $M_{IV,V}$ edges and L_{III} edge of Gd metal will be discussed. © *1996 American Institute of Physics.*
[S0021-8979(96)78908-2]

In the last two decades several new techniques to study magnetic phenomena and the fine structure of absorption edges using synchrotron radiation (SR) have been developed.

One of them x-ray magnetic circular dichroism (XMCD), first observed at the Fe K edge,[1] measures the difference in absorption for left and right circularly polarized photons in magnetic materials. In the near edge region the dichroism directly yields information on the magnetic aspects of the electronic structure.

Resonant Raman scattering (RRS), first observed in 1974,[2] is the absorption of a photon with an energy just below the absorption edge and the detection of a photon that is emitted by the electron from an atomic state filling the lower lying core hole.

This technique was used extensively in gas phase studies in the soft x-ray region (<5 keV) by Cowan *et al.* They investigated both atomic systems and small molecules where information about bond orientation was obtained using linear polarized SR.[3]

Later Hämäläinen *et al.* used RRS in dysprosium nitrate in order to overcome the lifetime broadening in absorption and to separate a quadrupolar transition from the dominating dipolar one. The energy of the fluorescence and the available crystal analyzers however prevented a complete study.[4] The simulations[5] where it is possible to calculate the fluorescence signal for different incident energies show a relatively complicated structure. By taking a cut in the right direction of the $E_i - E_i - E_f$ plane, these simulations agree very well with the measured data. Recently, Krisch *et al.* measured, with high resolution, the RRS signal from gadolinium gallium garnet (GGG) near the L_{III} edge.[6] They clearly separated the quadrupolar transition from the dipolar one by measuring, for different incident energies, the $L\alpha_2$ fluorescence. The results for Gd metal, which are shown in Figs. 1 and 2, are very similar to those obtained from GGG. The success of this experiment motivated us to combine RRS and MCD as a means to measure the RRS signal using circularly polarized photons in the incident beam.

The experiment was done at the wiggler-beamline X25 at the National Synchrotron Light Source.[7] The x rays were focused onto the sample using a toroidal mirror and monochromatized with a Si(220) double-crystal monochromator. The energy resolution of the incident beam is about 1 eV and the focal spot size on the sample is about 0.5×0.5 mm^2. The incident beam, which is usually linearly polarized in the plane of the ring, is partially circularly polarized with a diamond (111) quarter-wave plate.[8,9] The degree of polarization is about 50% and was measured using the MCD effect in iron. Due to absorption the efficiency of the quarter-wave plate is only 10%.

In this experiment the sample was a 250-μm-thick gadolinium foil, mounted on the cold finger of a liquid nitrogen cryostat inside an evacuated beryllium can. The sample temperature was about 200 K so that a magnetization of 80% could be achieved. The sample was magnetized with an external electromagnet. The scattered photons were energy analyzed with a spherically bent Si(333)-analyzer (R=890 mm)

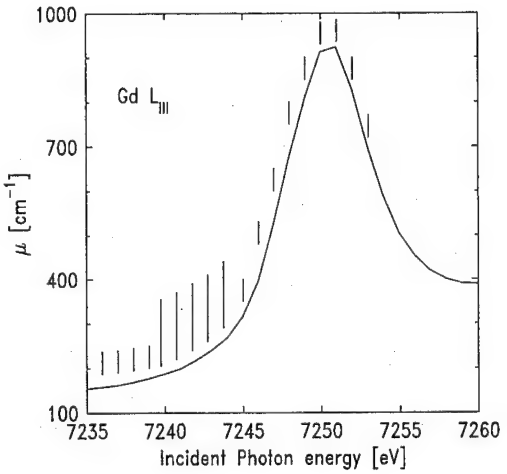

FIG. 1. Absorption coefficient of gadolinium metal around the L_{III} edge. The vertical lines correspond to the incident photon energies at which the high resolution spectra of the inelastically scattered photons were measured. The longer lines indicate the spectra which are shown in Fig. 2.

with the sample and the detector on the Rowland circle. The energy resolution of the analyzer was better than 1 eV (see also Fig. 3).

The data were collected in the following mode. The incident and the final energies were fixed and the quarter-wave plate produced one handedness of circularly polarized x rays. After that, the orientation of the magnetic field was flipped with a frequency of 0.1 Hz while the intensity of the scattered photons was measured until about 2000–100 000 counts per orientation of the magnetic field were collected depending on the intensity of the signal. After that the handedness of the circularly polarized x rays was changed by rotating the quarter-wave plate and the same procedure was repeated in order to minimize systematic errors. This was done at several final energies for the incident energy, where the quadrupolar effect is relatively large.

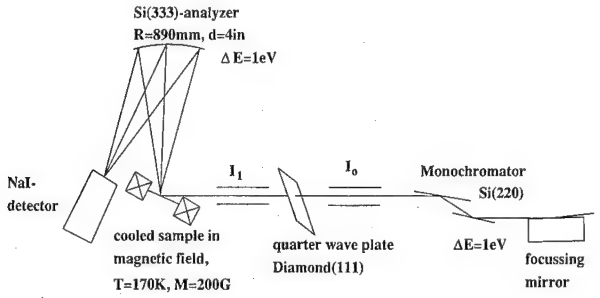

FIG. 3. Experimental setup: The radiation from the X25-wiggler is focused on the sample by a toroidal mirror and monochromatized by a pair of Si(220) crystals. The linearly polarized x rays are partially converted into circularly polarized x rays with the diamond quarter-wave plate. The scattered photons are energy analyzed with a spherically bent Si(333) analyzer and a scintillation counter. The detector and the sample are on the Rowland circle.

In order to process the data we calculate for each energy the ratio $(\uparrow\uparrow-\uparrow\downarrow)/(\uparrow\uparrow+\uparrow\downarrow)$, where $\uparrow\uparrow$ stands for the parallel electron and photon spin and $\uparrow\downarrow$ for the antiparallel orientation (Fig. 4). As we reverse both the magnetic field and the photon spin we obtain two curves which are almost symmetric around 0. The small difference can be explained by the difference in the absorption of the incident photons.

The data show three distinct features: a relatively strong peak (5%–6% effect) at the quadrupolar transition at 1191 eV, a second peak at 1195 eV, which is on the low energy shoulder of the dipolar transition, and then a change of the sign at the peak of the dipolar transition and a positive feature on the high energy shoulder. In the observed region this feature seems not to go back to 0, but the low count rate did not allow us to continue the measurement beyond this region.

The first step is to compare these data with XMCD data in the L_{III} edge obtained by Schütz *et al.*[10] where theoretical calculations[11] agree reasonably well with the measurements. As expected the structure at the quadrupolar transition in our measurement is of opposite sign compared to the XMCD. An unexpected difference is that the sign of the feature on the low energy side of the dipolar transition is the same as the quadrupolar peak. In the one-electron approximation one would expect a different sign in the quadrupolar transition and the lower lying dipolar transition but the interaction of the core hole, in this case now a $3d$ hole in the final state, with the $4f$ electrons might change the states of the $3d$ electrons, so that the exchange splitting of the $5f$ electrons gets canceled by a larger splitting of the $3d$ electrons.

The final state in the quadrupolar peak is $3d^9 4f^{n+1} 5d^0$ and the whole absorption–emission process corresponds to

an $M_{IV,V}$-edge absorption. The final state of the dipolar feature, $3d^9 4f^n 5d^1$, is forbidden in direct absorption and therefore not visible in M edges.

In direct $M_{IV,V}$ MCD the calculations[12] first show a small positive peak and then a very strong negative peak at the maximum of the absorption. The problem in our measurement is that the intensity of the quadrupolar transition itself is already very low so that we cannot see the positive feature. The strong negative feature in direct MCD changes sign in our measurement as expected and is equal in strength to the dipolar transition.

These measurements in general show that an effect can be observed by exciting RRS with circularly polarized x rays and that the results agree to a certain extent with the ones from L- and M-edge MCD.

However the differences compared to the L-edge MCD data show that even simple models do not qualitatively describe the data. This work is one further step toward the so-called complete experiment, where the spin and energy of the incoming photon is fixed and the energy and spin of the scattered photon are determined. We hope that this work will stimulate some theoretical effort in the calculation of spin resolved resonant Raman spectra.

It should be noted that similar experiments on the same system were done at about the same time by Schülke *et al.*[13] and Krisch *et al.*[14] with similar results.

We would like to thank the CMC-CAT, especially R. Hewitt and A. Bommannavar, for loan of the diamond crystal. The National Synchrotron Light Source is supported by the U.S. Department of Energy under Contract No. DE-ACO2-76-CH00016.

Raman heterodyne detection of magnetic resonance in a phosphate glass

G. K. Liu, C.-K. Loong, James V. Beitz, Ruoxin Cao,[a] Y. H. Chen, and K. Suzuya[b]
Argonne National Laboratory, Argonne, Illinois 60439-4814

A Raman heterodyne detection of magnetic resonance has been performed for probing the local structure of a sodium phosphate glass doped with trivalent europium. High resolution rf modulation spectra between 0.5 and 10 MHz were observed without the laser field in resonance with electronic transitions of the glass. The intensity of the observed Raman heterodyne signal depends on the external static magnetic field and sample temperature as well as the intensity of the laser and rf fields. The ability of monitoring the rf resonance spectra with micrometer spatial resolution may offer a potentially important means to probe the variation of local structure in disordered solid state materials. © *1996 American Institute of Physics.* [S0021-8979(96)79008-X]

INTRODUCTION

The structure of vitreous P_2O_5 is thought to consist of a three-dimensional network of corner-sharing PO_4 tetrahedra each of which is decorated with a nonbridging P═O bond.[1] A complex structural modification of the parent PO_4 network occurs as metal oxides are added into the system. In the glassy $xM_2O\cdot(1-x)P_2O_5$ system where M^+ is the network-modifying cation such as Na^+, it is expected that the population of the branching configuration (where three O atoms of a PO_4 unit are shared with three neighboring PO_4) decreases and is replaced by the middle configuration (two bridging O per PO_4) as $R=x/(1-x)$ changes from 0 to 1. At the metaphosphate composition ($R=1$), the dominant structural units are believed to be corner-sharing PO_4 chains. Details of such intermediate-range (e.g., chain-length distribution, interchain correlations, etc.) are difficult to determine experimentally. Data from conventional diffraction methods provide a reasonable description of the short-range atomic correlations, but interpretation of intermediate-range ordering usually resorts to a comparison with theoretical models. Perhaps the technique of high performance liquid chromatography[2] provides the most substantial information.

Nuclear magnetic resonance spectroscopy, on the other hand, is capable of yielding accurate information regarding the local environments of selective atomic nuclei (e.g., ^{31}P) in a glass.[3,4] Electronic bonding and interactions among the nuclear spins and electrons give rise to different shielding conditions at nuclear sites which can be detected and analyzed in terms of chemical shifts against a reference compound of known structure. Optically detected nuclear magnetic resonance (ODNMR) is another method for measuring transitions between nuclear sublevels through rf optical double resonance between optically pumped electronic and magnetically split nuclear states. The added advantage of this method is the availability of coherent laser light and noise-reduction techniques of rf wave mixing so that high resolution and high sensitivity can be achieved. In this article we describe a Raman heterodyne detection of nuclear magnetic resonance in a europium-doped sodium metaphosphate glass.

EXPERIMENTAL DETAILS

A sodium metaphosphate glass, $(Na_2O)_{50}\cdot(P_2O_5)_{50}=NaPO_3$, was prepared from melting and quenching of the appropriate amounts of reagent grade Na_2CO_3 and H_3PO_4. The glass was then ground into a powder and mixed Eu_2O_3 powder in a weight ratio of $NaPO_3$ to Eu_2O_3 of 9 to 1. The mixed powder was heated to 1270±5 K in a Pt crucible in air for 30 min and the melt was subsequently quenched on a copper plate. A small amount of undissolved Eu_2O_3 powder was found in the Pt crucible, so the dopant concentration of Eu_2O_3 is expected to be less than 3 mol %, but the Na_2O/P_2O_5 ratio of 1 is unchanged. A piece of the Eu-doped $NaPO_3$ glass was cut with a diamond disk to a rectangular parallelpiped of edges 5–7 mm with two opposite faces polished for the experiment. The sample was kept in a nitrogen purged dry box to minimum exposure of the glass to moist air. No solvent was used during the cutting and polishing.

The schematic layout of the Raman heterodyne detected nuclear magnetic resonance (RHDNMR) apparatus is shown in Fig. 1. A continuous-wave single wavelength laser tunable from 570 to 620 nm was employed. The sample was mounted inside a rf coil with its two polished faces normal to the horizontal laser beam. The sample assembly was placed inside a liquid helium cryostat equipped with a superconducting magnet producing a static magnetic field up to 5 T at

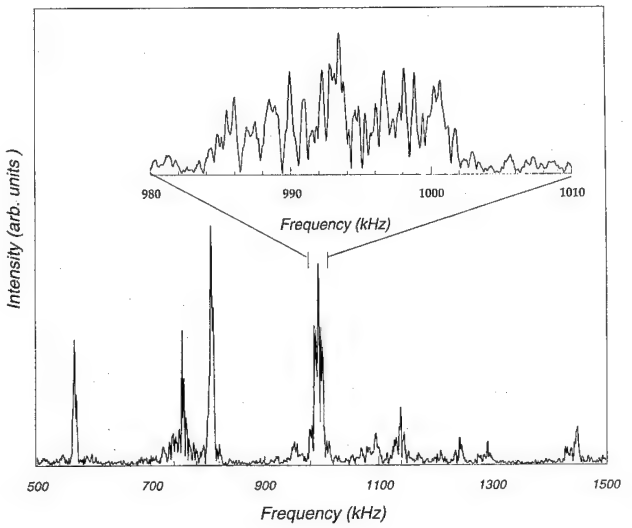

FIG. 2. Observed spectrum of rf resonance in phosphate glass detected via Raman heterodyne method at 3 K and a static magnetic field of 2.26 T. The inset segment from 980 to 1010 kHz is a separate scan. All major features in the spectrum are repeatable and minor variations in the relative intensity are due to laser power fluctuations.

the sample position while the sample was held at temperatures between 2 and 300 K. Two rf generators produced sweeping rf waves, f_1 and f_2, at a fixed difference ($f_1 - f_2 = 50$ kHz). The output of one rf generator was amplified and sent to the coil inside the cryostat. The other rf generator served as the local oscillator for the frequency mixer. The photocurrent signal from a photodiode intercepting the transmitted laser beam was amplified and mixed with local oscillator signal. The output signal of the mixer was analyzed by a lock-in amplifier using a 50 kHz reference frequency.

The technique of RHDNMR was first introduced by Mlynek and co-workers.[5] It relies on a coherent Raman process being stimulated by resonant rf and laser fields. The method has been applied to investigate the level structure and spin transient properties of an atomic vapor as well as solids doped with impurity ions.[6–8] In the present work, rf resonance in a glassy system was observed *without* optical resonance but requiring the presence of an external magnetic field. This type of modulation was first observed in a lanthanide fluoride crystal,[9] and the mechanism of this novel rf-optical coupling in a solid is not yet understood.

RESULTS AND DISCUSSION

Sharp modulation of the rf field from 0.5 to 10 MHz in the transmitted laser beam was observed at low temperatures in an applied static magnetic field. Figure 2 shows the spectra of the $NaPO_3$ glass at 3 K in a field of 2.26 T obtained using a rf sweep from 0.5 to 1.5 MHz. It consists of many resonance groups each of which exhibits numerous lines with widths as narrow as 200 Hz. Care has been given to verifying the observed rf resonance. In a series of tests, rf field, laser intensity, sample temperature, and external static magnetic field were varied to confirm our observation and to eliminate possible rf noise from the electronics and the laser. The resonance lines diminished as the magnetic field was reduced. At zero field no resonance was observed. Moreover, the resonance frequencies were independent of the magnetic field strength which was varied from 0.4 to 3 T. Given the energy scale of the rf resonance in MHz and the linewidth in kHz, the observed rf modulation is unlikely to be associated with coupling of the hyperfine split states to phonons such as in coherent Raman or Brillouin scattering. The magnetic-field independence of the resonance frequencies, on the other hand, rules out the possibility of response from noninteracting nuclear spins of ^{31}P and ^{23}Na in the sample. We believe that magnetic resonance among *spin-coupled* nuclear states of ^{31}P ($I=1/2$) and/or ^{23}Na ($I=3/2$) under the influence of a magnetic field gives rise to the observed rf spectra. Presumably, the ligand nuclear spin–spin interaction is considerably stronger than the applied field strength. Resonant transitions between the polarized states of the correlated spin moments in an external magnetic field evidently are induced by the rf frequency sweep.

Our initial intent was to observe optical-rf double resonance that involved the electronic and nuclear transitions of the Eu^{3+} ions in the glass. However, rf resonance was observed over the 570–620 nm range of laser wavelengths investigated. Additionally, the observed rf resonance frequencies are lower than those expected for the nuclear quadrupole splitting of Eu^{3+}.[10,11] Therefore, we conclude that the optical transition from the Eu^{3+} $^7F_0$ ground state to the $^5D_0$ excited state at 588 nm does not contribute to the rf resonance observed by the Raman heterodyne method. Similar rf resonance spectra were observed also in other phosphate glasses which contain no Eu.

An important feature in our experiment was the spatial distribution of the rf modulation within the transmitted laser beam. In general, variation of the rf resonance pattern as the laser beam traverses the sample suggests structural inhomogeneity in the material. What appears to be a unique capability in our measurements was the fine spatial resolution of the order of 1 μm. This is achieved by expanding the transmitted laser beam through a lens and monitoring the line intensities as the photodiode (0.5 mm diam) is translated across the expanded beam. The intensity variation presumably reflects the changes in the local structure which contributes to the rf resonance. The combination of high sensitivity and good spatial resolution might be potentially useful for probing the structural variation in a disorder solid.

The rf resonance was observed only at low temperatures. Intensity of the spectrum diminished as the sample was warmed up. At 100 K the resonance was no longer observable. This temperature dependence is consistent with the hypothesis that the observed rf resonance arises from a correlated nuclear spin ensemble. At high temperatures the spin coherency apparently is destroyed by interactions with the surrounding medium (e.g., thermally populated electronic and phonon states).

In summary, the present RHDNMR is highly sensitive to the local structure of the spin–spin coupled nuclear states. Since electronic bonding and ligand field effects affect directly the nuclear spin level structure, this method is useful to probe the local electronic structure, particularly for disorder systems. The observed effect does not require optical resonance with electronic transitions yet the rf resonance exhibits sharp modulations that are immune to inhomogeneous broadening. In the case of a sodium ultraphosphate glass, $NaPO_3$, a richly detailed rf resonance spectrum was observed at low temperatures. Although the spectra are not understood quantitatively, the structure of the resonance patterns seems likely to reflect the complex cross linking of the Na^+ cations between different PO_4 chains. Such intermediate-range order structure is known to depend on the cation size. Thus it will be instructive to study the systematic of the rf resonance spectra of phosphate glasses with different metal cations. RHDNMR measurements of Ca and Pb phosphate glasses as well as phosphate crystals are currently underway.

Magnetic and Mössbauer studies of hot-pressed MnZnNi ferrites (abstract)

V. K. Babbar
Applied Physics Department, GND University, Amritsar, India

R. K. Puri
Physics Department, Indian Institute of Technology, Delhi, India

Hot-pressed MnZn ferrites are extensively used for magnetic recording applications. The present work investigates the magnetic properties of MnZnNi ferrites by using the Mössbauer spectroscopy and taking bulk magnetic measurements. Ferrites of the composition $Mn_{0.6}Zn_{0.4-x}Ni_xFe_2O_4$ ($0 \leqslant x \leqslant 0.4$) have been prepared by uniaxial hot pressing technique. The final sintering was performed at 1250 °C for 3 h under a pressure of 35 MPa. The samples exhibit high density (porosity <0.1%) nearly uniform grain size (average grain size=0.01 mm approx.), and large Vickers' hardness (650 approx.). The variations of initial permeability, saturation magnetization, Curie temperature, and coercive field are studied by changing Ni^{2+} content. The initial permeability increases slightly for $x \leqslant 0.05$, attains a maximum value of 5660, and decreases continuously for $x > 0.05$. The saturation magnetization increases for $x \leqslant 0.25$ and decreases for $x > 0.25$. The maximum saturation magnetization obtained for $x=0.25$ is 4825 G. The Curie temperature increases markedly from 431 to 682 K with increasing Ni^{2+} content. The coercive field decreases slightly for $x \leqslant 0.05$, becomes as low as 0.09 Oe, and increases almost linearly thereafter. The results are explained on the basis of sublattice magnetizations, strength of *AB* exchange interactions and change in magnetocrystalline anisotropy constant. The Mössbauer studies reveal the well-defined hyperfine spectra for Ni^{2+}-substituted samples. The isomer shift remains almost unaffected by Ni^{2+} substitution, while the quadrupole splitting is observed to be negligible for all the samples. The hyperfine field decreases continuously as x increases from 0 to 0.4. The occupancy ratio of Fe^{3+} ions on octahedral to tetrahedral sites yields a cation distribution which conforms with the bulk magnetic measurements. The MnZnNi ferrite compositions with x ranging from 0.05 to 0.10 exhibit properties which make them suitable materials for recording head applications. [S0021-8979(96)81208-8]

Quantum vortex motion in high-T_c superconductors

A. García, X. X. Zhang, and J. Tejada
Departament de Física Fonamental, Universitat de Barcelona, Diagonal 647, E-08028 Barcelona, Spain

Magnetic relaxation experiments at low temperatures were performed in different zero-field-cooled (ZFC) and field-cooled (FC) high-T_c superconductors (HTSCs): TlBaCaCuO (2212 and 2223 phases, polycrystalline and thin-film samples), (Hg,Tl)BaCaCuO (1223 phase, polycrystalline material), and (Bi,Pb)SrCaCuO (2212 phase, single crystal). For each system and in the whole temperature range investigated, the relaxation curves obtained after both cooling processes are linear with the logarithm of time. The temperature dependence of the relaxation rate normalized to the first magnetization value, $R=|d(M/M_0)/d\ln(t)|$, follows a trend which is common to all systems: R decreases linearly with decreasing temperature down to a value, which is called the crossover temperature, below which it levels off to a T-independent plateau. This behavior gives evidence of a transition in the mechanism responsible for the relaxation process at low temperatures, from thermally activated (linear dependence on T) to quantum vortex motion (T-independent regime). The experimental values for the crossover temperatures and normalized relaxation rates compare fairly well to numerical estimates in the framework of the theories of quantum vortex motion in layered HTSCs. Finally, the transition from one regime into another was studied in two samples of the TlBaCaCuO, 2223 phase, system in order to investigate the influence of dissipation on the quantum process. A clear conclusion on this point could not be drawn from these kinds of measurements. © *1996 American Institute of Physics.* [S0021-8979(96)57408-0]

During recent years, quantum motion of vortices at low temperatures in high-T_c superconductors (HTSCs) has been extensively investigated in a great variety of systems, mainly by means of the detection of the time evolution of the magnetization.[1,2] At low temperatures this decay with time, which is known as magnetic relaxation, is usually well fitted to a logarithmic law, $M(t)=M_0[1-R(T)\ln(t/t_0)]$, where M_0 is the first magnetization point recorded at t_0 and $R(T)$ is called the normalized relaxation rate, $R\equiv|d\ln(M/M_0)/d\ln(t)|$. The time-logarithmic law is the natural dependence found in the Anderson–Kim model[3] for thermally activated flux creep and is restricted to the low-temperature regime. As far as a linear dependence is predicted by this model, R should vanish as temperature goes to zero; however, in all reports mentioned above, as the temperature tends to zero, R presents a large, temperature-independent plateau, rather than extrapolating to zero, suggesting a decay of magnetization by quantum motion of vortices through the energy barriers.

Quantum vortex motion in HTSC was first described by Blatter and Geshkenbein in the context of the quantum collective creep (QCC) theory.[4] In this theory, the normalized relaxation rate at $T=0$ in the regime of single vortex pinning is given by $R\simeq -\hbar/S_E^{\rm eff}$, where $S_E^{\rm eff}$ is the saddle-point solution for the effective Euclidean action of the tunneling process in the limit of strong ohmic dissipation, and is given by the following expressions:[5]

$$S_E^{\rm eff}/\hbar\simeq(\hbar/e^2)(L_c/\rho_n) \quad \text{(3D case)}, \tag{1a}$$

$$S_E^{\rm eff}/\hbar\simeq(\hbar/e^2)(d/\rho_n) \quad \text{(2D case)}. \tag{1b}$$

In these equations $\hbar/e^2\simeq 4.1\ \text{k}\Omega$ is the quantum of resistance, ρ_n is the normal state resistivity extrapolated at $T=0$, d is the interlayer spacing, $L_c\simeq(\xi/\gamma)(J_0/J_c)^{1/2}$ is the longitudinal dimension of the tunneling object, ξ is the superconducting coherence length at $T=0$, and J_0 and J_c are the depairing and critical current density. All values are taken in the $a-b$ plane.

Because of the layered nature of HTSCs, a flux line in these materials can be pictured as a stack of two-dimensional (2D) pancake vortices lying in adjacent copper oxide layers, connected by Josephson vortices.[6] The dimensionality of the object involved in the tunneling process, however, depends on the strength of the magnetic field applied before or during the measurements relative to a certain dimensional crossover field, $H_{\rm 3D\text{-}2D}\simeq\Phi_0/(\gamma d)^2$, where Φ_0 is the flux quantum, and γ is the anisotropy parameter of the material. Below $H_{\rm 3D\text{-}2D}$, 2D pancake vortices are coupled along the c axis and form a three-dimensional (3D) flux line. In this case, the Euclidean action is given by Eq. (1a) and the normalized relaxation rate is represented as $R_{d,\rm 3D}$, where the subscript d stands for the dissipative limit. On the other hand, for fields larger than $H_{\rm 3D\text{-}2D}$, the interaction within one layer is stronger than the interaction between adjacent layers, and 2D pancake vortices become decoupled. In this case, the Euclidean action is given by Eq. (1b) and the normalized relaxation rate is represented as $R_{d,\rm 2D}$.

Very recently, Feigel'man *et al.*[7] suggested that, because of the special values of their superconducting parameters, HTSCs at low temperatures should enter a nondissipative regime in which vortex motion is dominated by the Magnus instead of the friction force acting on it. In this limit, the

 0021-8979/96/79(8)/6516/3/$10.00

TABLE I. Superconducting transition temperature T_c, lower critical field H_{c1} at 5 K, dimensional crossover field $H_{3D\text{-}2D}$ and applied magnetic field H_a for the different samples. For each T_c the magnetic field at which it has been measured is reported. In sintered samples, only intragranular H_{c1} are listed.

	Tl-pd	Tl-ps	Tl-f	Hg-ps	Bi-sc
T_c (K)	108 (100 Oe)	116 (50 Oe)	112 (1 Oe)	133 (50 Oe)	85 (10 Oe)
H_{c1} (kOe)	0.3	0.7	0.03	0.14	0.08
$H_{3D\text{-}2D}$ (kOe)	0.007	16	16	10	0.2
H_a (kOe) for M_{ZFC}	1.5	···	0.5	···	0.1
H_a (kOe) for M_r	0.1	3, 6	0.5	3, 10	···

expressions for the Euclidean action are the following:[7]

$$S_E^H/\hbar \simeq n_s \xi^2 L_c \quad \text{(3D case)}, \tag{2a}$$

$$S_E^H/\hbar \simeq n_s \xi^2 d \quad \text{(2D case)}, \tag{2b}$$

where n_s is the density of superelectrons. The corresponding normalized relaxation rates will be represented as $R_{H,3D}$ and $R_{H,2D}$ for the 3D and 2D cases, respectively, where the subscript H stands for the Hall limit.

The calculations so far reported correspond to the limit of zero temperature. At finite temperatures, however, quantum tunneling is thermally assisted and a gradual transition, instead of the sharp one which characterizes the $T=0$ limit, from thermal to quantum vortex motion occurs,[4]

$$R(T)=R(0)[1+(T/T_0)^2], \tag{3a}$$

$$R(T)=R(0)[1+\exp(-T_0/T)], \tag{3b}$$

corresponding respectively to the strong-ohmic-dissipative and nondissipative limit, which includes the Hall limit. In these equations, T_0 is a characteristic temperature. In any case, the quantum rate will be thermally assisted up to a crossover temperature T_{cr} which is given by[4]

$$\hbar/S_E^{(\text{eff})}(0) \simeq k_B T_{cr}/U_c, \tag{4}$$

where $\hbar/S_E^{(\text{eff})}(0)$ is the normalized relaxation rate at $T=0$ and U_c is the energy barrier for thermal activation.

In this article we present experimental evidence of quantum vortex motion at low temperatures in different samples: polycrystalline sintered and epitaxial thin-film $Tl_2Ba_2Ca_2Cu_3O_{10}$ (Tl-ps and Tl-f respectively), polycrystalline sintered $(Hg,Tl)Ba_2Ca_2Cu_3O_8$ (Hg-ps), polycrystalline powder $Tl_2Ba_2CaCu_2O_8$ (Tl-pd), and single-crystal $(Bi,Pb)_2Sr_2CaCu_2O_8$ (Bi-sc). Details on each sample preparation are described elsewhere.[8,9] The magnetic relaxation measurements were performed in a commercial ac superconducting quantum interference device (SQUID) (Quantum Design) magnetometer ($1.8<T<400$ K; $H_{max}=5.5$ T), following two different procedures. In the first one, the sample was cooled from $T>T_c$ in a zero applied field [zero-field-cooling (ZFC) process] down to the working temperature and, after attaining a stable temperature (temperature stability was 0.01 K in the low-temperature range), a magnetic field was switched on and kept constant during the measurement of the time decay of the ZFC magnetization: M_{ZFC} vs t. In the second procedure, the sample was cooled with a magnetic field applied on [field-cooling (FC) process] and, after attaining a stable temperature, the field was switched off and the remanent magnetization was recorded as a function of time: M_r vs t. After each run was complete the sample temperature was raised well above T_c in order to remove completely the trapped flux lines. Table I summarizes the superconducting transition temperature T_c, lower critical field H_{c1}, dimensional crossover field $H_{3D\text{-}2D}$, and magnetic procedures performed for each sample.

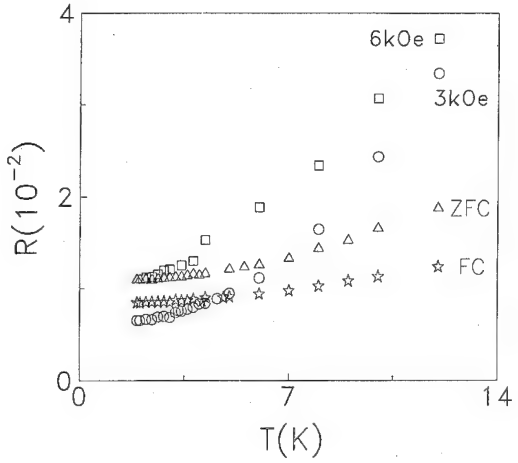

FIG. 1. Temperature dependence of the normalized relaxation rate for the Tl-ps and Tl-f samples. Circles and squares correspond to M_r of Tl-ps obtained with $H_a=3$ and 6 kOe, respectively; triangles and stars represent, respectively, M_{ZFC} and M_r of Tl-f obtained with $H_a=0.5$ kOe.

In the whole low-temperature range investigated ($1.8<T<20$ K), the evolution with time of the remanent and ZFC magnetization of all samples is very well fitted to a time-logarithmic law in the studied time window (the total duration of each measurement was about 1 h). Figure 1 presents the temperature dependence of the normalized relaxation rates corresponding to Tl-f (M_{ZFC} and M_r obtained with 0.5 kOe) and Tl-ps (M_r obtained with $H_a=3$ and 6 kOe). As

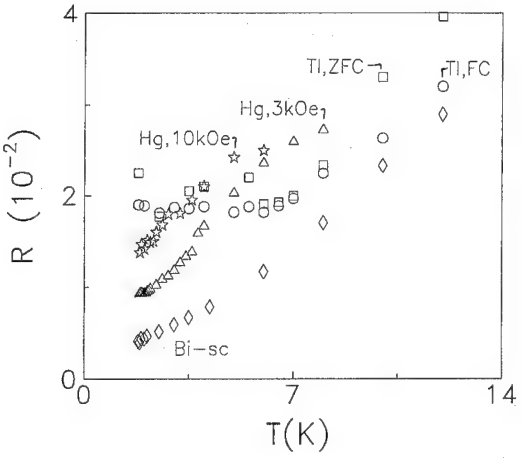

FIG. 2. Normalized relaxation rate vs temperature for Tl-pd, Hg-ps, and Bi-sc. Circles and squares stand, respectively, for Tl-pd M_r obtained with $H_a=0.1$ kOe and M_{ZFC} with $H_a=1.5$ kOe, triangles and stars represent M_r of Hg-ps obtained with $H_a=3$ and 10 kOe, respectively; diamonds are used for Bi-sc.

TABLE II. Experimental and estimated parameters for the samples where quantum tunneling is observed. From top to bottom: experimental value ($R_{0,e}$), dissipative (R_d), and Hall (R_H) estimate for the plateau; experimental plateau temperature (T_p), and estimated crossover temperature (T_{cr}). When appropriate, the applied magnetic field or the type of magnetization is reported.

	Tl-ps	Tl-f	Tl-pd	Hg-ps
$R_{0,e}$ (%)	0.7 (3 kOe), 1.1 (6 kOe)	0.85 (M_r), 1.1 (M_{ZFC})	2	1 (3 kOe)
R_d (%)	1.6	1.6	2.4	2.3
R_H(%)	5	5	7	7
T_p (K)	2.5–3	2.5–3	5–6	2.1
T_{cr} (K)	4	7–8	6–7	2.6

temperature decreases, all curves show a transition from a more or less linear dependence to a temperature-independent plateau which begins between $T_p \simeq 2.5$ and 3 K, suggesting a crossover from thermal to quantum vortex motion at low temperatures. The experimental plateau values $R_{0,e}$ are similar for both samples: For Tl-ps, $R_{0,e} \simeq 0.7\%$ for $H_a = 3$ kOe and $\simeq 1.1\%$ for $H_a = 6$ kOe; $R_{0,e} \simeq 0.85\%$ and $\simeq 1.1\%$ for the Tl-f FC and ZFC curves, respectively. In order to compare with theoretical values, we must first estimate the dimensional crossover field $H_{3D\text{-}2D}$. Using $\gamma \simeq 20$ (Ref. 10) and $d \simeq 18$ Å (Ref. 11), $H_{3D\text{-}2D} \simeq 16$ kOe is obtained, which is larger than the magnetic fields applied. Thus, quantum vortex motion is of 3D nature in both samples. Substitution of typical HTSC values [$(J_0/J_c)^{1/2} \simeq 15$, $\xi \simeq 30$ Å, $\rho_n \simeq 15$ $\mu\Omega$ cm, $n_s \simeq 10^{21}$ cm^{-3}] in Eqs. (1a) and (2a), gives $R_{d,3D} \simeq 1.6\%$ and $R_{H,3D} \simeq 5\%$, which agree qualitatively well with $R_{0,e}$ (an attempt to obtain a quantitative agreement requires the use of more accurate parameters). Finally, good fittings of each gradual transition to Eqs. (3a) and (3b) were obtained, with comparable accuracy in both cases. Therefore, no conclusion can be drawn about the dissipative nature of the quantum process. The temperature up to which each fitting rule varies from 6 to 9 K, depending on the sample and extent of the low-temperature range studied. The crossover temperatures calculated from Eq. (4) are $T_{cr} \simeq 4$ K for Tl-ps (with $U_c \simeq 400$ K, as estimated in the thermally activated regime), and $\simeq 7$–8 K for Tl-f (with $U_c \simeq 700$–1000 K). Both values are larger than, but comparable in order of magnitude to, T_p.

The temperature dependence of the normalized relaxation rates corresponding to Tl-pd (M_r obtained with 0.1 kOe and M_{ZFC} obtained with 1.5 kOe), Hg-ps (M_r obtained with 3 and 10 kOe), and Bi-sc (M_{ZFC} obtained with 0.1 kOe) are plotted in Fig. 2. The transition in the Hg-ps curve for $H_a = 3$ kOe and both two Tl-pd curves appear to be very sharp, with no evidence of thermally assisted quantum tunneling. The experimental plateau values are $R_{0,e} \simeq 1\%$ for Hg-ps and $\simeq 2\%$ for both two Tl-pd curves. Using $\gamma \simeq 30$ and $d \simeq 16$ Å for Hg-ps,[9] and $\gamma \simeq 350$ (Ref. 12) and $d \simeq 15$ Å (Ref. 11) for Tl-pd, $H_{3D\text{-}2D} \simeq 10$ and 0.07 kOe are, respectively, obtained. Therefore, Hg-ps is in the 3D quantum creep regime ($H_a < H_{3D\text{-}2D}$), and Tl-pd is in the 2D regime ($H_a > H_{3D\text{-}2D}$). Then, $R_{d,3D} \simeq 2.3\%$ and $R_{H,3D} \simeq 7\%$ are obtained for Hg-ps, while Eqs. (1b) and (2b) give $R_{d,2D} \simeq 2.4\%$ and $R_{H,2D} \simeq 7\%$ for Tl-pd, which are qualitatively comparable to $R_{0,e}$. The plateau temperatures are $T_p \simeq 2.1$ and $\simeq 6$ K for Hg-ps and Tl-pd, respectively, in good agreement with estimates of the crossover temperature from Eq. (4), $T_{cr} \simeq 2.6$ K for Hg-ps, and $\simeq 6$–7 K for Tl-pd. Finally, no plateau can be found in the Hg-ps curve with $H_a = 10$ kOe and Bi-sc curve, suggesting that one must go down to temperatures below 1.8 K to find quantum vortex motion with these magnetic fields. Actually, very low-temperature studies in 2212 Bi-based single crystals present plateaus which begin below 2 K and stretch down to the mK regime.[2] Table II summarizes the relevant parameters for the samples in which quantum motion has been detected.

In summary, we have reported on the detection of quantum relaxation at low temperatures in different HTSCs. In some samples (Tl-pd, Hg-ps) the transition from the thermal to the quantum regime appears to be very sharp, while in some others (Tl-ps, Tl-f) it is more gradual. In the second case, the transition was investigated in order to gain insight on the dissipative nature of the quantum process, but no conclusion could be drawn from the present study. Finally, quantum vortex motion was not detected in a couple of samples (Hg-ps and Bi-sc), suggesting the extension of magnetic relaxation measurements to the regime of ultralow temperatures.

An ultrasonic study of spin-density-wave effects in a Cr+0.2 at. % Ir alloy single crystal

J. Martynova, H. L. Alberts, and P. Smit
Department of Physics, Rand Afrikaans University, P. O. Box 524, Auckland Park, Johannesburg 2006, South Africa

Measurements of the temperature dependences of the second-order elastic constants and attenuation of ultrasonic waves through the magnetic phase transition temperatures of a Cr+0.2 at. % Ir alloy single crystal are reported. The incommensurate–commensurate spin-density-wave transition is marked by steplike decreases, accompanied by hysteresis of width about 16 K, in all the elastic constants on heating through the transition temperature. The attenuation coefficient shows a spikelike peak at this transition. A deep minimum in c_{11} and small peaks in c_{44} and $\frac{1}{2}(c_{11}-c_{12})$ are observed at the Néel transition. © *1996 American Institute of Physics.* [S0021-8979(96)57508-4]

I. INTRODUCTION

Magnetic interactions in Cr and its dilute alloys are relatively strong,[1] resulting in large anomalies of magnetic origin in the elastic constants at the magnetic phase transition temperatures of these materials. Cr alloys with group-8 nonmagnetic transition metals Ru, Os, Rh, Ir, and Pt are of particular interest[1] in this regard. The magnetic phase diagrams of this group of Cr alloys all contain a paramagnetic (P), an incommensurate (I), and a commensurate (C) spin-density-wave (SDW) phase.[1] Interesting behavior was observed for the polycrystalline elastic constants, Young modulus, the bulk modulus B, and shear modulus G of Cr–Ru,[2] Cr–Rh,[3] Cr–Pt,[4] and Cr–Ir (Ref. 5) alloys near the magnetic phase transition temperatures. Magnetoelastic studies on these polycrystalline alloys are, however, of limited value and measurements on single-crystalline alloys are needed for a better understanding of the magnetoelasticity of the above group of Cr alloy systems. Only one of these alloy systems, namely, the Cr–Ru system, was studied[6] up to now for SDW effects on the single-crystal second-order elastic constants c_{11}, c_{44}, and $c'=\frac{1}{2}(c_{11}-c_{12})$. Remarkable magnetoelastic effects were observed for Cr–Ru alloy single crystals. The longitudinal mode elastic constant c_{11} as well as the shear mode constants c_{44} and c' of Cr–Ru alloy single crystals show steplike decreases, which have the characteristics of a first-order transition, on heating through the ISDW–CSDW magnetic phase transition temperature, T_{IC}. The behavior at the CSDW–P transition at the Néel temperature T_N is, on the other hand, quite different. The longitudinal mode constant c_{11} shows a very deep minimum at T_N of Cr–Ru alloys while the shear constant c_{44} and c' show only weak effects in going through T_N.

We studied an alloy in another of the above group of alloy systems and report here an investigation of the elastic constants and attenuation of ultrasonic waves in a Cr+0.2 at. % Ir alloy single crystal. This alloy concentration was chosen for preparing a single crystal because it is above the triple-point concentration on the magnetic phase diagram,[1] resulting in the presence of both ISDW–CSDW and CSDW–P magnetic phase transitions on heating the crystal from low temperatures.

II. EXPERIMENTAL TECHNIQUES

The Cr–Ir single crystal with 0.2 at. % Ir was grown by a floating-zone technique using radio-frequency heating. The starting material was a polycrystalline rod prepared from 99.996% pure Cr and 99.9% pure Ir. The actual concentration was determined, using electron microprobe techniques, to be 0.20±0.05 at. % Ir. Velocity and attenuation of 10 MHz ultrasonic waves were measured by using a standard pulse-echo overlap technique. The distances between parallel sets of (100) and (110) planes on the sample were between 6 and 8 mm. Measurements were done during both cooling and heating runs.

III. RESULTS AND DISCUSSION

The temperature dependences of the elastic tensor components c_{11}, $c_L=\frac{1}{2}(c_{11}+c_{12}+2c_{44})$, c_{44}, and $c'=\frac{1}{2}(c_{11}-c_{12})$ are shown in Fig. 1 for heating runs. Figure 2(a) shows the temperature dependence of the bulk modulus $B=\frac{1}{3}(c_{11}+2c_{12})=c_{11}-\frac{4}{3}c'$ of the Cr+0.2 at. % Ir crystal as well as the expected nonmagnetic component taken[7] as $B(T)$ of a Cr+5 at. % V crystal.[7] The magnetic component ΔB of B for Cr+0.2 at. % Ir is shown as a function of temperature in Fig. 2(b). ΔB is obtained as $\Delta B=B(Cr_{95}V_5)-B(Cr_{99.8}Ir_{0.2})$, where $B(Cr_{99.8}Ir_{0.2})$ was calculated from the data in Fig. 1.

The data of Fig. 1 show two well-defined anomalies. One of these, in the form of a steplike decrease during heating for all the elastic constants, occurs at a temperature around 270 K. In accordance with the magnetic phase diagram of Cr–Ir alloys,[1] this anomaly is taken to occur at the ISDW–CSDW magnetic phase transition temperature T_{IC}. The other anomaly is in the form of a deep minimum around 370 K in both the $c_{11}-T$ and c_L-T curves and in the form of small peaks in the $c_{44}-T$ and $c'-T$ curves. These anomalies are associated with the Néel transition.

Figure 3 shows the temperature dependence of c_{11}, c_L, c_{44}, and c' near the ISDW–CSDW phase transition for measurements taken during both cooling and heating runs. This transition shows large hysteresis effects of width about 16 K for all modes. Above about 280 K the elastic constants in Fig. 3 show no thermal hysteresis between heating and cooling runs, showing that hysteresis effects disappear at

 0021-8979/96/79(8)/6519/3/$10.00

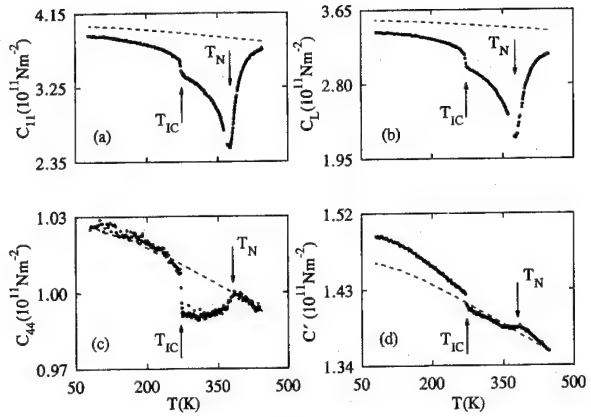

FIG. 1. Temperature dependence of (a) c_{11}, (b) $c_L = \frac{1}{2}(c_{11} + c_{12} + 2c_{44})$, (c) c_{44}, and (d) $c' = \frac{1}{2}(c_{11} - c_{12})$ obtained during heating runs for a Cr+0.2 at. % Ir single crystal. The broken lines represent the temperature dependence of the nonmagnetic component of the corresponding elastic constant of the Cr+0.2 at. % Ir crystal, and are obtained[7] from the corresponding elastic constant of a Cr+5 at. % V crystal that remains paramagnetic at all temperatures.

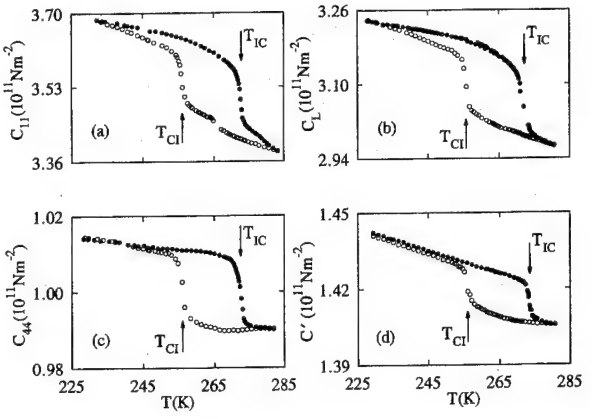

FIG. 3. Hysteresis effects in (a) c_{11}, (b) $c_L = \frac{1}{2}(c_{11} + c_{12} + 2c_{44})$, (c) c_{44}, and (d) $c' = \frac{1}{2}(c_{11} - c_{12})$ near the ISDW–CSDW magnetic phase transition of a Cr+0.2 at. % Ir single crystal for (●) heating runs and (○) cooling runs.

temperatures about 8 K higher than T_{IC} (on heating) for all elastic modes. On the other hand, hysteresis effects are present for the two longitudinal modes, c_{11} and c_L, of Fig. 3 down to 232 K, about 24 K below T_{CI} (on cooling), and only to 245 K, about 11 K below T_{CI}, for the two shear modes, c_{44} and c'. Below 245 K the hysteresis effects for the shear modes are negligible. The observation that hysteresis effects persist in the Cr+0.2 at. % Ir crystal in a much larger temperature range below T_{CI} than above T_{IC} was also noted[8] for a Cr+0.3 at. % Ru single crystal. The difference in behavior between the two crystals is that for the Cr+0.3 at. % Ru crystal[8] this phenomenon was observed for both longitudinal and shear mode elastic constants, while it is observed mainly for the longitudinal mode constants of the Cr+0.2 at. % Ir crystal. All the elastic constants of Fig. 3 show the same first-order character at the I–C or C–I transition as was observed for a Cr+0.3 at. % Ru crystals.[8] No hysteresis effects were observed within the experimental error during cooling and heating runs through the Néel transition.

Figure 4 shows the temperature dependence of the attenuation of 10 MHz ultrasonic waves for the different vibration modes in the Cr+0.2 at. % Ir crystal near the ISDW–CSDW phase transition for both heating and cooling runs. The C–I transition (on cooling) is characterized by a sharp spikelike attenuation peak at a temperature T_{CI}. This is also the case for the I–C transition (on heating) that shows a similar peak at T_{IC}. The width of the attenuation peak at half amplitude is about 1.5 K or less. An interesting behavior in Fig. 4 is the broad hump in attenuation at temperatures just above the sharp peak for the c_{11} mode of vibration and also the double peak for the c_L mode. At present we do not know the reason for this behavior but note that it is rather small for the two shear vibration modes. From the average temperatures of the peaks in Fig. 4 we obtain T_{IC}=272.2±0.8 K and T_{CI}=256±1 K. These temperatures correspond with the temperatures at the inflection points of Fig. 3, identifying the

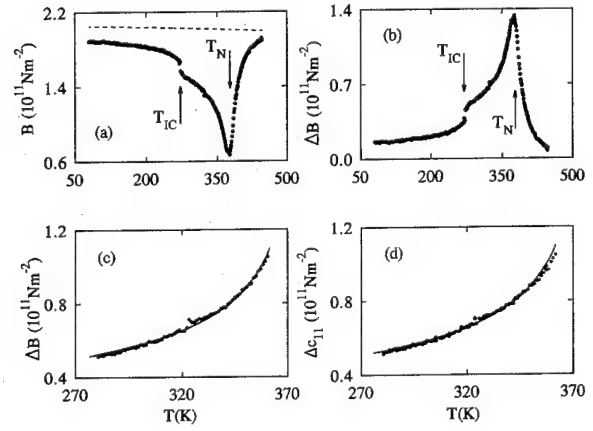

FIG. 2. Temperature dependence of (a) the bulk modulus B and (b) of the magnetic contribution ΔB to B of Cr+0.2 at. % Ir. (c) and (d) show the best fit (solid line) of Eq. (1) to the experimental data for ΔB and Δc_{11} in the CSDW phase. Results of heating runs are shown.

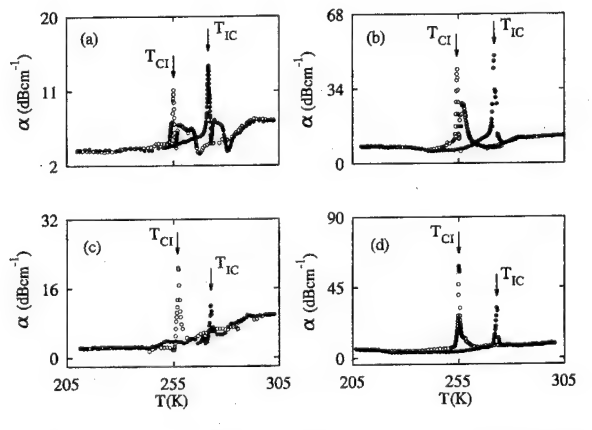

FIG. 4. Ultrasonic (10 MHz) attenuation coefficient α of Cr+0.2 at. % Ir for modes of propagation corresponding to (a) c_{11}, (b) $c_L = \frac{1}{2}(c_{11} + c_{12} + 2c_{44})$, (c) c_{44}, and (d) $c' = \frac{1}{2}(c_{11} - c_{12})$: (●) heating runs and (○) cooling runs.

inflection points as the I–C and C–I SDW transition points on the $c-T$ curves. The ultrasonic attenuation becomes extremely large in the vicinity of the Néel transition and we were unable to measure it reliably around T_N in this study.

T_N for the Cr+0.2 at. % Ir crystal was defined at the minimum point of the $c_{11}-T$ and c_L-T curves of Fig. 1, giving $T_N=377.0\pm0.4$ K. The temperatures $T_{IC}=272.2\pm0.8$ K and $T_N=377.0\pm0.4$ K of the present measurements on single-crystalline Cr+0.2 at. % Ir agree reasonably well with temperatures[9] $T_{IC}=279$ K and $T_N=380$ K as well as with[10] $T_N=371\pm2$ K, determined from electrical resistivity ρ measurements on polycrystalline Cr+0.2 at. % Ir. No hysteresis effects were reported at T_{IC} in the $\rho-T$ measurements of Butylenko and Nevdacha.[9] The ρ anomaly observed by them at T_{IC} is small and weak while such anomalies are absent in the $\rho-T$ measurements of Yakhmi and co-workers[10] on polycrystalline Cr+0.2 at. % Ir. The present measurements show a well-defined and relatively large anomaly in all the single-crystalline elastic constants at T_{IC}.

Katsnel'son and Trefilov[11] recently studied the temperature dependence of the elastic constants of dilute Cr alloys near T_N theoretically. Their microscopic theory shows that an anomaly arises for these materials in the temperature dependence of the elastic constants below T_N. This anomaly is brought about by the disappearance of the antiferromagnetic gap in the electron spectrum when $T\rightarrow T_N$, resulting in changes in the screening and in the phonon spectrum. The result is a softening of the elastic constants below T_N, which explains the observed softening in the Cr+0.2 at. % Ir crystal qualitatively. The theory gives for the magnetic component Δc_{ii} of the elastic constant c_{ii} at temperatures not too close to T_N

$$\Delta c_{ii}\sim\left(\frac{\partial T_N}{\partial \mu_i}\right)^2 (T_N-T)^{-\gamma}, \tag{1}$$

where μ_i are components of the deformation tensor. In Eq. (1) Δc_{ii} is defined as

$$\Delta c_{ii}=c_{ii}(\text{nonmagnetic Cr alloy})$$
$$-c_{ii}(\text{magnetic Cr alloy}),$$

which is of opposite sign as the definition used by Katsnel'son and Trefilov,[11] but conforms with that used in Fig. 2 for ΔB and Δc_{11}. As T_N is particularly sensitive to changes in volume, the bulk modulus $B(T)$ should soften the most from Eq. (1) which explains the softening observed experimentally for B in this study. In Eq. (1), $\gamma=1$ if the density-of-states function in the paramagnetic phase is smooth near the Fermi level and $\gamma=5/4$ if it has a van Hove singularity there.[11]

Equation (1) fits the experimental data for ΔB and Δc_{11} in the CSDW phase of the Cr+0.2 at. % Ir crystal well (see Fig. 2) in the temperature range $280<T<370$ K with $\gamma=0.416\pm0.003$ and $\gamma=0.422\pm0.004$, respectively. This gives a γ value different from the theoretically expected values of either 1 or 5/4. A similar analysis of the $\Delta B-T$ data[12] of a Cr+0.3 at. % Ru crystal gives $\gamma=0.280\pm0.002$ over a temperature range of about 120 K, in the CSDW phase, below T_N.

IV. CONCLUSION

In conclusion, Cr alloy single crystals with group-8 nonmagnetic transition metals Ru and Ir show nearly similar temperature dependences of their elastic constants around the ISDW–CSDW and CSDW-P magnetic phase transition temperatures. The only markable difference is in the details of the hysteresis behavior around the ISDW–CSDW transition. Longitudinal and shear mode constants behave differently in this regard for Cr+0.2 at. % Ir while they behave the same for Cr+0.3 at. % Ru. The temperature behavior of the magnetic component of the bulk modulus is different for the two crystals just below T_N in the CSDW phase. The temperature derivative of ΔB at each temperature in this phase is larger for Cr+0.2 at. % Ir than for Cr+0.3 at. % Ru.

Hall-effect measurements on Cr films deposited on Ge substrates

Chien-Sheng Hsieh and Klaus Schröder
Department of Chemical Engineering and Materials Science, Syracuse University, Syracuse, New York 13244

The Hall effect of Cr films on Ge substrates was measured at room temperature in a high-vacuum system. It was found that the Hall coefficient R_H depends on the pressure in the vacuum system. R_H of films about 1–2 nm thick was about 5×10^{-11} m^3/C for a pressure during Cr evaporation in the 10^{-7} Torr range. The Hall coefficient decreased to less than 10^{-11} m^3/C if pressure decreased into the 10^{-8} Torr range. These R_H values are much lower than found in bulk chromium. They would give in a one-band model about 1 electron hole/atom for the higher-pressure, and about 12 electron holes/atom for the lower-pressure experiments. A two-band model could give the observed low Hall coefficients if the hole current nearly compensated the electron current. Both models cannot be reconciled with presently accepted electron band models for chromium. © *1996 American Institute of Physics.* [S0021-8979(96)57608-3]

INTRODUCTION

The properties at the Ge–Cr interface are unusual at room temperature. The resistance of ultrathin Cr films on a Ge substrate is much lower than expected, and both Ge or Si overlayers reduce the electrical resistance.[1] These films are strongly diamagnetic, although they should be paramagnetic, just like Cr films on glass substrates.[2] The absolute Seebeck coefficients of an ultrathin Cr film on a Ge substrate is, within experimental accuracy, zero.[3] These results would be expected if the Cr–semiconductor interface region is superconducting; however, the films do not show zero resistance. Therefore, we suggested as a possible model that the interface contains superconducting islands.[1–3]

Hall-effect measurements on superconductors by Dascoulidou *et al.*[4] show that the Hall coefficient R_H of their samples approaches zero if the samples change from the normal to the superconducting state. Their work encouraged us to start R_H measurements on Cr films deposited on Ge substrates.

EXPERIMENTAL APPROACH

We prepared films in the same high-vacuum system (base pressure close to 10^{-8} Torr) described previously.[1,2] First Ge films, about 2–3 nm thick, were deposited by evaporating high-purity germanium (resistivity: 40 Ω cm) on a glass plate (1.8×1.8 cm^2) with five electrical silver paint contacts: two for current leads, three for potential leads. Then chromium (99.995% total purity) was evaporated and a Cr film with thickness t formed on the Ge film. The growth rate was of the order of 1 nm/min. Auger spectroscopy studies by Schröder and Walsh[1] showed that this produced clean Cr films. The experimental approach was the same as used for the preparation of films for resistivity[1] and Seebeck coefficient S measurements.[3] For Seebeck coefficient measurements the film was in contact with two Fe wires, forming a differential thermocouple. A second differential thermocouple consisting of two Fe wires and a Constantan wire was placed at the opposite side of the glass plate to measure the temperature gradient. Details are given in Ref. 3. The Hall voltage V_H was measured at a magnetic field B of 0.58 T. Several Cr films were deposited in sequence, and at the end of each Cr-film deposition the Hall voltage was measured at 0.58 T. The main uncertainty in the data is due to the error in the thickness measurements determined with the INFICON XTM/2 thickness monitor. Since the surface of the glass plate and the crystal of the monitor are both initially covered with germanium *in situ*, the sticking probability for chromium should be the same for the films prepared on the glass plate or the crystal of the thickness monitor; however, the glass plate and the thickness monitor crystal are not lined up in the same direction with respect to the Cr source as in previous electrical resistance measurements.[1] We found in our present system, using two thickness monitors, that a few monolayers may form on the glass or quartz crystal substrates first before the films grow on both substrates nearly uniformly. This leads to an uncertainty in the film thickness t which may be as large as 0.5 nm. The resistance per square in our present experiments, shown in Fig. 1, is for sample 3

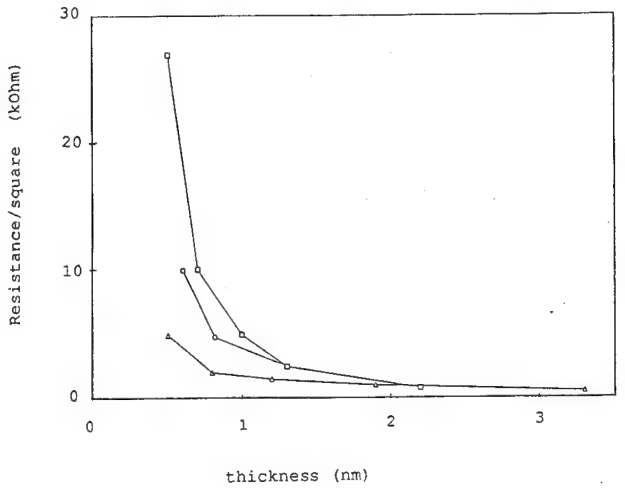

FIG. 1. Resistance per square of sample 1 (circles), 2 (squares), and 3 (triangles) as a function of thickness t. The pressure during evaporation was highest for sample 1 (in the upper 10^{-7} Torr range), slightly lower in sample 2, and lowest for sample 3 (in the 10^{-8} Torr range). Data points are of the size of the error.

 0021-8979/96/79(8)/6522/3/$10.00

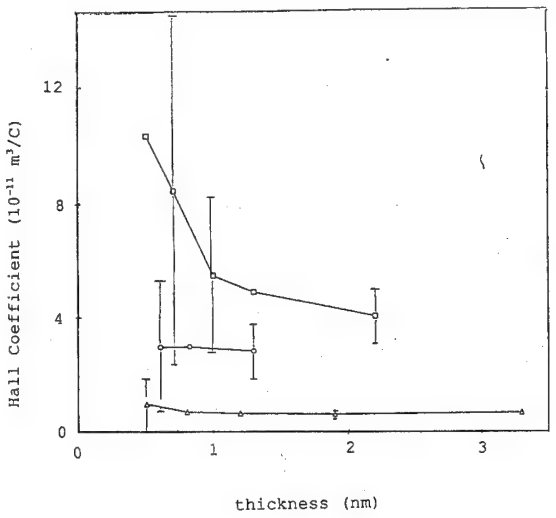

FIG. 2. Hall coefficient of sample 1 (circles), 2 (squares), and 3 (triangles) as a function of thickness.

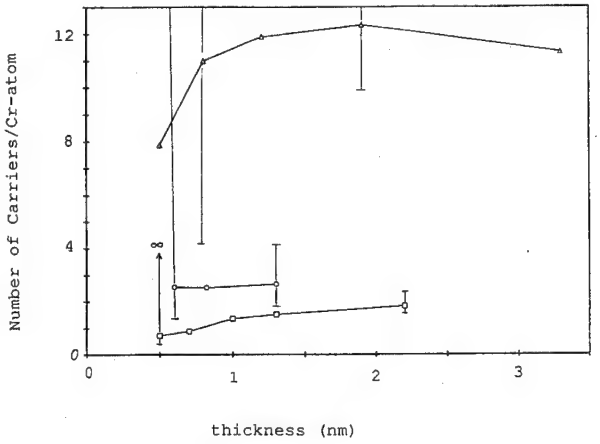

FIG. 3. Number of holes per chromium atom of sample 1 (circles), 2 (squares), and 3 (triangles) as a function of film thickness calculated with the assumption of a one-band model. very similar to what was found in earlier experiments.[1] Sample 3 was prepared at the same pressure as samples for the earlier tests.[1]

RESULTS AND DISCUSSION

Figure 2 gives the Hall coefficient $R_H = V_H t/IB$, with I the current flowing through the sample, as a function of the nominal film thickness t. R_H is positive. As mentioned previously, the uncertainty in the film thickness is estimated to be 0.5 nm. This means that the R_H values for $t<1$ nm have an error of more than 50%. The error for films with $t>2$ nm is less than 25%. The Hall coefficients for $t>1$ nm are within the experimental accuracy constant. R_H of our films is much smaller than R_H of bulk samples for which the Hall coefficient is about 4×10^{-10} m^3/C.[5]

R_H is positive: This suggests that the electric current is carried predominantly by holes. R_H is related to the hole concentration p (number/volume) by

$$R_H = 1/pq, \tag{1}$$

if one can use a one-band model.

Hole concentrations per volume of a Cr atom (p/Cr atom) calculated with Eq. (1) are given in Fig. 3. One finds that p/Cr atom for films more than 0.7 nm thick is about 1–2 if the pressure during Cr evaporation is in the 10^{-7} Torr range. p/Cr atom >10 if the pressure is in the 10^{-8} Torr range, and if one neglects the first data point. (The pressure dependence of the Hall coefficient and p may be due to variations in impurity levels. An increase in base pressure could lead to an increase in the impurity concentration, which in turn modifies the microstructure during growth.) These numbers are, even if one considers the experimental uncertainties, much larger than found for bulk chromium (p =0.2/Cr atom[5]). Values of p/Cr atom >10 cannot be reconciled with any acceptable electron model for chromium.

One should therefore try to use a multiband model. The Hall coefficient of a multiband system is given by

$$R_H = \sum \left(\frac{\sigma_i}{\sigma}\right)^2 R_{H,i}\,, \tag{2}$$

where σ is the electrical conductivity of the sample, σ_i the conductivity in subband i, and $R_{H,i}$ is the Hall coefficient of subband i. This equation shows that if one band carries most of the current it will control R_H, and it is therefore usually adequate to use a one-band model. In a system with parabolic energy bands i, the Hall coefficient for each subband is $R_{H,i} = -1/n_i q$ for electrons, and $R_{H,i} = 1/p_i q$ for holes.

If one assumes that the current in our thin films is due to one hole and one electron band, then one can explain the small value for R_H with the assumption that the current by electrons is nearly as large as the current by holes. In that case $R_H = (\sigma_h/\sigma)^2 R_{H,h} - (\sigma_n/\sigma)^2 R_{H,n}$. The two terms in the right-hand side of this equation essentially cancel each other. This interpretation of the Hall effect would state that the thin Cr films are compensated, independent of film thickness. This model is not confirmed by other experiments. The absolute Seebeck coefficient is close to zero only for about two monolayers of chromium on germanium and that first decreases to about -2 to -4 μV/K for films about 3 nm thick. Such a behavior of S is not expected for a compensated material.

As before we are left with a problem. We have magnetic susceptibility, electrical resistivity, Seebeck coefficient, and Hall coefficient measurements which are unusual. One could try to explain each of the electrical measurements with a conventional model, but the model used to explain the Hall coefficient does not work for the Seebeck coefficient. The strong diamagnetism cannot be explained at all with any standard model. The only model which would explain all results would be the model of disconnected superconducting islands near the surface or the interface with the substrate. This model was already proposed to explain previous measurements.[1–3]

There may be other explanations. Clearly more work is

needed before we understand the electrical transport processes in the Cr–Ge interface.

Modeling the stress dependence of Barkhausen phenomena for stress axis linear and noncollinear with applied magnetic field (abstract)

The almost linear dependence of the maximum Barkhausen noise signal amplitude on stress has made it a tool for nondestructive evaluation of residual stress. Recently,[1] a model has been developed to account for the stress dependence of the Barkhausen noise signal. The model uses the development of Alessandro *et al.*[2] who use coupled Langevin equations to derive an expression for the Barkhausen noise power spectrum. The model joins this expression to the magnetomechanical hysteresis model of Sablik *et al.*,[3] obtaining both a hysteretic and stress-dependent result for the magnetic-field-dependent Barkhausen noise envelope and obtaining specifically the almost linear stress dependence of the Barkhausen noise maximum experimentally.[4] In this paper, we extend the model to derive the angular dependence observed by Kwun[5] of the Barkhausen noise amplitude when stress axis is taken at different angles relative to magnetic field. We also apply the model to the experimental observation that in XC10 French steel, there is an apparent almost linear correlation with stress of hysteresis loss and of the integral of the Barkhausen noise signal over applied field H. Further, the two quantities, Barkhausen noise integral and hysteresis loss, are linearly correlated with each other. The model shows how that behavior is to be expected for the measured steel because of its sharply rising hysteresis curve.[6] [S0021-8979(96)70808-X]

Magnetovolume and magnetoelastic effects in ternary Cr–Ru–Mo alloys

J. T. Mochele, P. Smit, and H. L. Alberts
Department of Physics, Rand Afrikaans University, P.O. Box 524, Auckland Park, Johannesburg 2006, South Africa

The influence of Mo additions on the unusual magnetoelastic properties and Invar-type behavior of a $Cr_{0.997}Ru_{0.003}$ antiferromagnetic alloy was investigated. Measurements were done of the temperature dependence of the thermal-expansion coefficient and bulk modulus of $(Cr_{1-x}Mo_x)_{0.997}Ru_{0.003}$ alloys with $0 \leqslant x \leqslant 0.07$. Well-defined magnetic anomalies were observed at the Néel temperature implying large magnetic contributions to the thermal expansion and the bulk modulus, making these alloys suitable to be analyzed and parameterized in terms of existing theories. The addition of Mo to $Cr_{0.997}Ru_{0.003}$ completely suppresses the presence of the commensurate spin density wave phase for $x \geqslant 0.015$ and does not improve the Invar-type behavior to a desired level that may be useful for practical applications. © *1996 American Institute of Physics.* © *1996 American Institute of Physics.* [S0021-8979(96)57708-4]

I. INTRODUCTION

Alloying Cr with the nonmagnetic transition metal Ru shows unusual magnetoelastic effects[1] due to strong spin density wave (SDW) interactions with the lattice. The coefficient of thermal expansion α of a $Cr_{0.997}Ru_{0.003}$ alloy shows[1] a deep minimum at the commensurate (C) SDW to paramagnetic (P) Néel transition, observed at the Néel point T_N, and a large maximum at the incommensurate (I) to commensurate (C) SDW phase transition temperature T_{IC}. One of the remarkable features of $\alpha(T)$ of $Cr_{0.997}Ru_{0.003}$ is the very small value of α ($\alpha \approx 0$) observed[1] at T_N ($\approx$395 K). This behavior indicates antiferromagnetic Invar[2]-type effects to be present in this alloy around T_N, making it a candidate for practical application. The temperature region in which $Cr_{0.997}Ru_{0.003}$ displays Invar-type effects is relatively small and occurs well above room temperature, thereby limiting its practical usefulness. In order to eliminate this limitation, $Cr_{0.997}Ru_{0.003}$ should be tailored in such a way that T_N, and therefore the temperature where $\alpha \approx 0$, is reduced down to room temperature and that the temperature interval in which α remains close to zero is simultaneously broadened. It was shown[3] that the addition of Mo to Cr acts to weaken the strength of the SDW, thereby decreasing T_N of Cr linearly. Mo is ideally suited for this purpose as it seems from experiment[4] that the magnetic ordering in Cr–Mo alloys is still of a Cr-type SDW ordering, even for relatively high Mo concentrations, up to at least 10 at. % Mo. One can therefore use Mo to adjust the strength of the SDW and study its effects on the Invar-type behavior of the above Cr–Ru alloys. We report in this study on the effects on the thermal expansion and bulk modulus of a $Cr_{0.997}Ru_{0.003}$ alloy when some of the Cr atoms are replaced by Mo.

II. EXPERIMENTAL TECHNIQUE

Polycrystalline ingots of $(Cr_{1-x}Mo_x)_{0.997}Ru_{0.003}$ with x=0, 0.003, 0.007, 0.01, 0.015, 0.03, and 0.07 were prepared from 99.99% Cr and Mo and 99.9% Ru starting materials by means of arc melting. Electron microprobe analyses indicated that the actual concentrations do not differ by more than 5% from the nominal values of x and that the alloys are homogeneous to within less than 5% of the quoted concentrations. Standard strain gauge and ultrasonic (10 MHz) measuring techniques were used[5] to measure the thermal expansion and sound velocity of the alloys as functions of temperature. The thermal-expansion coefficient α was determined for all the alloys, while the bulk modulus B, calculated from longitudinal and shear wave sound velocity measurements, was only determined for alloys with x=0.007, 0.015, and 0.07. $\Delta L/L$ for the $(Cr_{1-x}Mo_x)_{0.997}Ru_{0.003}$ alloys were measured relative to that of a paramagnetic $Cr_{0.95}V_{0.05}$ alloy in order to obtain the contributions of the magnetic ordering to $\Delta L/L$ of the Cr–Ru–Mo alloys. $Cr_{0.95}V_{0.05}$ remains paramagnetic at all temperatures and simulates the paramagnetic component of α and B of the antiferromagnetic Cr–Ru–Mo alloys.[6] The experimental error in the absolute value of $\Delta L/L$ was about 5% while changes with temperature of the order of 2×10^{-6} could be detected. The error estimated in the absolute value of B is about 2%, while changes in the order of one in 10^3 with temperature could be observed. All measurements were conducted within the temperature range 77–450 K. Thermal-expansion measurements were carried out during both heating and cooling runs, in order to check for hysteresis effects around T_{IC}, since it is known[7] that the ISDW–CSDW phase transition in $Cr_{0.997}Ru_{0.003}$ is first-order like, while sound velocity measurements were done only for heating runs.

III. RESULTS AND DISCUSSION

The temperature dependence of α is shown in Fig. 1 for different values of x. Well-defined anomalies, in the form of a sharp minimum for $x \leqslant 0.03$ and in the form of a relatively steep step for x=0.007, are observed in the $\alpha-T$ curves at T_N. Minima were also observed at T_N in the $B-T$ curves for x=0.007, 0.015, and 0.07 as shown in Fig. 2. The results show that the addition of Mo to binary $Cr_{0.997}Ru_{0.003}$ decreases T_N toward room temperature and below, as expected. This results from the weakening effects of Mo on the SDW in $Cr_{0.997}Ru_{0.003}$. Furthermore, the addition of Mo increases the value of α at T_N making ternary $(Cr_{1-x}Mo_x)_{0.997}Ru_{0.003}$ alloys less suitable for practical applications. It is of interest to note that the $\alpha-T$ curve for x=0.07 in Fig. 1 is nearly flat just below T_N in a temperature range of about 50 K, making

 0021-8979/96/79(8)/6526/3/$10.00

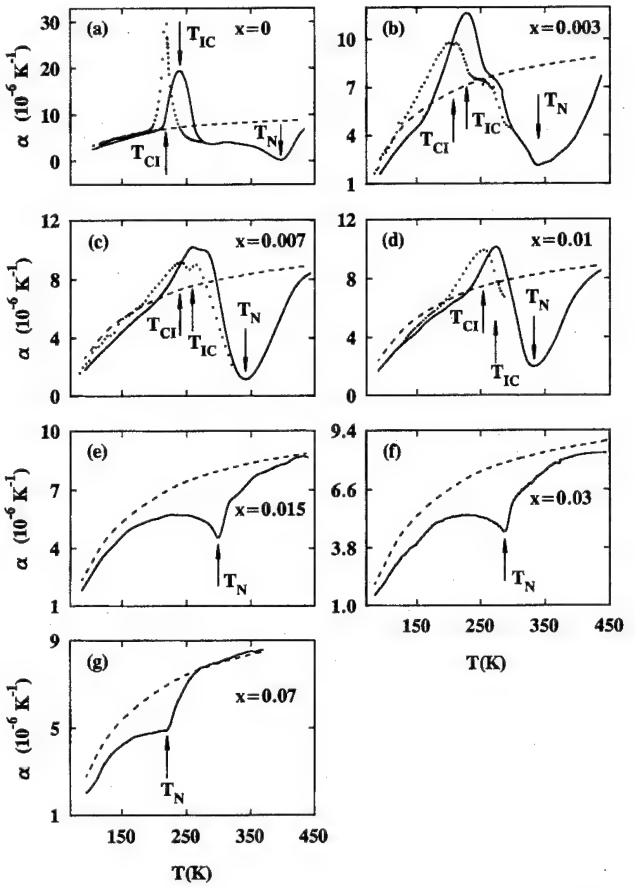

FIG. 1. Temperature dependence of the coefficient of thermal expansion $\alpha=d(\Delta L/L)/dT$ for $(Cr_{1-x}Mo_x)_{0.997}Ru_{0.003}$ where (a) $x=0$, (b) $x=0.003$, (c) $x=0.007$, (d) $x=0.01$, (e) $x=0.015$, (f) $x=0.03$, and (g) $x=0.07$. The solid line and dotted line curves represent the heating and cooling runs, respectively, and they were drawn through the experimental data points which were obtained at 0.1 K intervals. The dashed line curves represent the expected nonmagnetic component of the Cr–Ru–Mo alloys given by α for $Cr_{0.95}V_{0.05}$.

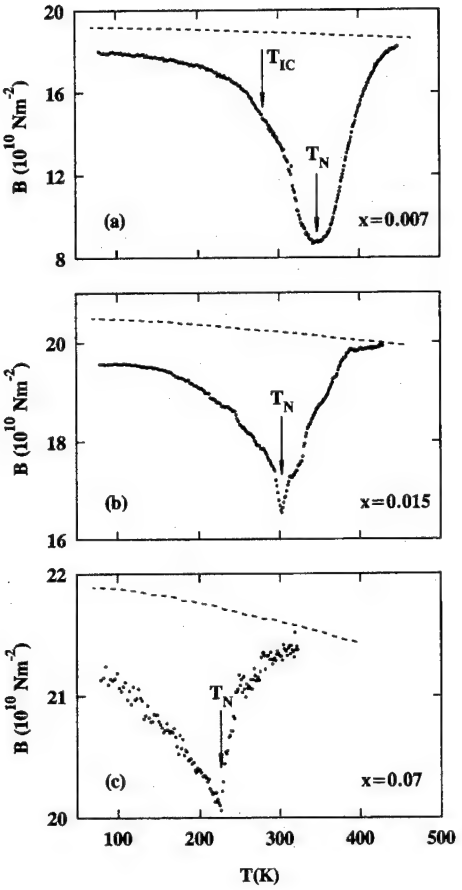

FIG. 2. Temperature dependence of the bulk modulus B for $(Cr_{1-x}Mo_x)_{0.997}Ru_{0.003}$ where (a) $x=0.007$, (b) $x=0.015$, and (c) $x=0.07$. The dashed line curves represent the expected nonmagnetic component of B taken as B for a $Cr_{0.95}V_{0.05}$ alloy that remains paramagnetic at all T.

α nearly invariant with temperature. In this temperature range α is however too large to be of any use in practical applications.

The $\alpha-T$ curves are further characterized (Fig. 1) by a large relative maximum at the ISDW–CSDW phase transitions at T_{IC} on heating and a smaller maximum at the CSDW–ISDW transition temperature T_{CI} on cooling. Although hysteresis effects of width $\Delta T\approx 21$ K were clearly observed during heating and cooling runs through the ISDW–CSDW and CSDW–ISDW phase transitions, the ISDW–P phase transition at T_N showed no hysteresis effects, indicative of its second-order nature. The transition temperature T_{IC} (or T_{CI}) increases with a progressive suppression of the CSDW phase as the Mo content is increased (Fig. 1), thereby suppressing the CSDW phase completely for $x\geqslant 0.015$. The ISDW–CSDW (CSDW–ISDW) phase transition for $(Cr_{1-x}Mo_x)_{0.997}Ru_{0.003}$ alloys is furthermore also accompanied by a shoulder-hump-type feature on the $\alpha-T$ curve between T_{IC} (T_{CI}) and T_N [Figs. 1(a), 1(b), and 1(c)]. The origin of this feature on the $\alpha-T$ curves is presently unknown but it may be mentioned that it was previously also observed in Cr–Pt alloys.[8] This feature progressively moves closer to T_{IC} (T_{CI}) as the Mo content is increased up to $x=0.007$ beyond which it disappears. The ISDW–CSDW phase transition was only barely observable as a very weak anomaly on the $B-T$ curve of the sample with $x=0.007$ (Fig. 2). In the case of $x=0.007$, $\alpha(T)$ measurements clearly indicated the existence of both the ISDW–CSDW and the CSDW–P phase transitions, while the measurements of $B(T)$ revealed a large relative minimum at the CSDW–P phase transition, which overshadows the much smaller ISDW–CSDW phase transition that is normally observed on $B-T$ curves of Cr alloys.[1]

The magnetovolume $\Delta\omega(T)$ and $\Delta B(T)$, which are the magnetic contributions to the volume and the bulk modulus, respectively, were determined from the $\Delta L/L$ and B measurements by applying similar calculation techniques as were used previously.[9] For Cr alloys, $\Delta\omega(T)$ and $\Delta B(T)$ are expected[10] theoretically to vary as

$$\Delta\omega(t)/\Delta\omega(0)=a_0+a_1t^2+a_2t^4,$$

and

$$\Delta B(t)/\Delta B(0)=b_0+b_1t^2+b_2t^4,$$

where $t=T/T_N$ and the a and b are fitting parameters, respectively. As shown by the typical examples of Fig. 3, these equations fit the results for those alloys that do not show

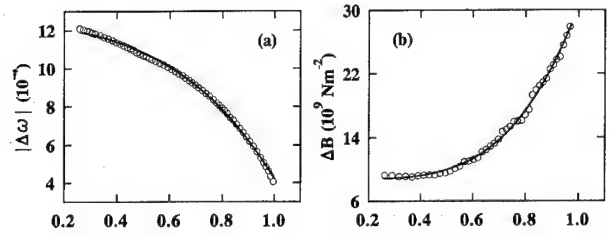

FIG. 3. Temperature dependence of (a) the magnetovolume $\Delta\omega$ and (b) the magnetic contribution to the bulk modulus ΔB for $(Cr_{1-x}Mo_x)_{0.997}Ru_{0.003}$ where $x=0.015$. The solid line curves in (a) and (b) are best fits of the equations $\Delta\omega=a_0+a_1t^2+a_2t^4$ and $\Delta B=b_0+b_1t^2+b_2t^4$, respectively, to the experimental data.

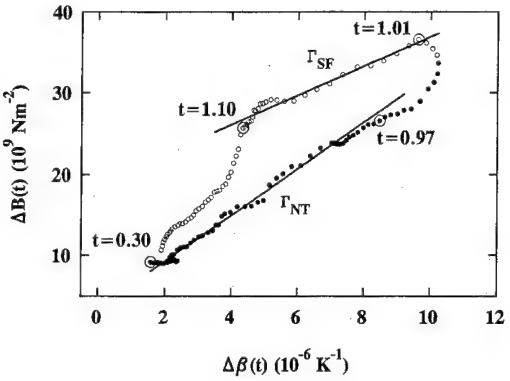

FIG. 4. $\Delta B(t)$ is shown as a function of the magnetic contribution to the volume thermal-expansion coefficient $\Delta\beta(t)$ for $x=0.015$. The solid lines are least-square fits to the data points between and including the encircled points. The values of $t=T/T_N$ ($T_N=299$ K) at the encircled points are shown. The points (●) show the comparison of $\Delta B(t)$ and $\Delta\beta(t)$ for $T<T_N$ and (○) for $T>T_N$.

ISDW–CSDW phase transitions, namely for $0.015\leqslant x\leqslant 0.07$, rather well. This was previously also found to be the case for other Cr alloy systems.[10–12] Theory further predicts[10] that $(a_1/a_0+a_2/a_0)=-1$. For the Cr–Ru–Mo alloys we obtained $(a_1/a_0+a_2/a_0)=-0.66$, -0.60, and -0.84 for $x=0.015$, 0.03, and 0.07, respectively, which are typical values obtained for other dilute Cr alloys.[10]

The parameterization of the magnetoelastic data of the $(Cr_{1-x}Mo_x)_{0.997}Ru_{0.003}$ alloys was obtained by employing the technique described in Ref. 13. The magnetic Grüneisen parameters $\Gamma_{NT}(t<1)$ and $\Gamma_{SF}(t>1)$, giving, respectively, the volume derivative of the logarithmic Néel temperature function $T_{NT}(\omega)$ and the spin-fluctuation-temperature function $T_{SF}(\omega)$, were calculated from the linear sections of plots of $\Delta B(T)$ vs $\Delta\beta(T)$, where β is the volume thermal-expansion coefficient, using the same notations and technique as previously.[13] A typical example of the ΔB vs $\Delta\beta$ curves for $T>T_N$ and $T<T_N$ is shown in Fig. 4. The parameters $\Gamma_{NT}(t<1)$ and $\Gamma_{SF}(t>1)$ were calculated from the linear parts of these curves for the alloys with $x=0.015$ and 0.07 that exhibit only the ISDW phase for all T below T_N. The results are $\Gamma_{NT}=-49$ and $\Gamma_{ST}=-32$ for $x=0.015$ and $\Gamma_{NT}=-39$ and $\Gamma_{SF}=-46$ for $x=0.07$, which are of the same order of magnitude as previously observed in other ternary Cr alloys.[11] For most Cr alloys studied[11,12,14] up to now it was found that Γ_{SF} is much smaller (up to three times or more) than Γ_{NT}. The only exceptions are the members of the $(Cr_{0.97}Mo_{0.03})_{1-y}Si_y$ alloy system, for which[11] $\Gamma_{SF}\approx\Gamma_{NT}$, as is also the case for $(Cr_{1-x}Mo_x)_{0.997}Ru_{0.003}$ with $x=0.015$ and 0.07 of this study.

IV. CONCLUSION

In conclusion, although the addition of Mo to $Cr_{0.997}Ru_{0.003}$ has the desired effect to decrease the Néel temperature down to room temperature, it simultaneously increases the coefficient of thermal expansion to much larger values. We were therefore not successful in our effort to improve the Invar-type properties of the $Cr_{0.997}Ru_{0.003}$ alloy by the addition of Mo.

Magnetoelastic energy in domains separated by 90° walls

A. S. Arrott
Simon Fraser University, Burnaby, British Columbia, V5A 1S6, Canada

An iron whisker with a current along its axis has four domains in a frame about a central core. The domains in the frame are magnetized perpendicular to the axis. The central core is magnetized along the axis. The magnetoelastic energy and its corresponding effective field, found analytically using the calculus of variations, account for the experimental observation that for each current, below a critical current, there is a narrow range of fields for which there are two stable sizes for the central core. [S0021-8979(96)79908-7]

Iron whiskers make ideal substrates for growing ultrathin films of transition metals by molecular beam epitaxy because of the perfection of their surfaces.[1] They are used also to influence the magnetic response of the ultrathin films, e.g., to measure the coupling to a ferromagnetic film separated from the substrate by a nonmagnetic film.[2] This was the motivation for passing a current along the axis of the whisker, with all surfaces [100], to switch the direction of the magnetization at the surface. The current should produce the domain configuration shown in Fig. 1. The direction of circulation of the magnetization in the four transverse domains (referred to collectively as the *frame*) should be determined by the direction of the current. The size and direction of the central longitudinal domain (referred to as the *core*) should be determined by the strength and direction of a magnetic field applied along the axis. Studies of the ac magnetic response for various applied fields and currents showed that the configuration in Fig. 1 accounts for many of the observations. There were some surprising effects[3] which were eventually traced to magnetoelastic energies, arising because the core elongates in the direction of its magnetization while the frame expands circumferentially.[4]

The dc susceptibility deduced from the ac susceptibility measured with a single turn about the central cross section is also shown in Fig. 1 as a function of the applied field in the presence of a current. This response is determined primarily by the competition between the applied field which expands the longitudinal core and the combined effects of the demagnetizing field and the field from the current which shrink the core.[5] This is shown as the heavy dashed line in Fig. 1. The demagnetizing field is proportional to the area of the core. The effective field from the current is proportional to the width of the core. In a low enough field the dc susceptibility should be proportional to the square root of the applied field. In higher fields it should approach a constant value mainly determined by the demagnetizing factor. It appears that the longitudinal core collapses for fields below a critical field, $H_c \cong 0.7$ G. The problem is to account for this loss of response in small positive fields. The domain wall energy is not responsible for this collapse, rather, it favors the expansion of the central core, as does the applied field.

The effective field from the magnetoelastic energy shrinks the core for small core size and expands it for large core size. The present calculation leads to an effective field of the right sign and magnitude to explain the collapse in positive fields. The aim of this work is to be completely analytical and at the same time to find agreement with experiment with no adjustable parameters. As magnetoelastic problems are not generally familiar to workers in micromagnetics, the exposition below contains some pedagogical elements, Eqs. (2), (5)–(8), and (10), and (11), that might otherwise be skipped.

According to Brown,[6] the Helmholtz free-energy density for the magnetoelastic energy when the magnetization is along one or another of the cube edges is

$$a_{\mathrm{mel}} = k_1\left[e_1\left(\alpha^2-\frac{1}{3}\right)+e_2\left(\beta^2-\frac{1}{3}\right)+e_3\left(\gamma^2-\frac{1}{3}\right)\right] + \frac{1}{2}\sum_{j=1}^{6}\sum_{i=1}^{6} c_{ij}e_i e_j, \tag{1}$$

where the direction cosines of the magnetization are α, β, and γ and the six components of the elastic strain are given by the e_i's. In the domain walls the effect of magnetostriction is incorporated into the anisotropy constant; see Brown [Eq. (8-34) in Ref. 6]. Equation (1) is used to find the energy per unit length in the central cross section, where the derivatives of the magnetization with respect to z, along the axis, vanish. The full three-dimensional strain problem is treated approximately by assigning an energy to each cross section as if it were a central cross section with a different size core. The

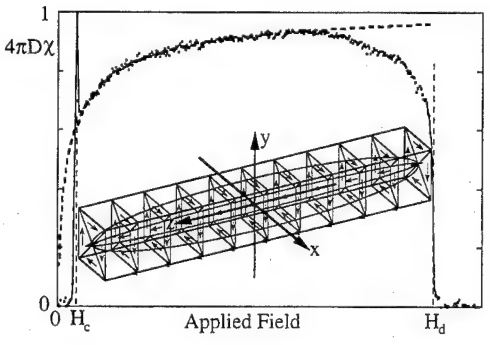

FIG. 1. The field dependence of the dc susceptibility and a schematic drawing of the domain pattern for a [100] whisker with a current along its axis. The calculated response ignoring magnetostriction is shown as the heavy dashed line. Because of magnetoelastic strains, the central core collapses at H_c. The hysteresis at H_c is less than the ac driving field used in obtaining this data. The core fills the central cross section at H_d. The hysteresis at H_d is less than the ac driving field.

 0021-8979/96/79(8)/6529/3/$10.00

effects of the magnetization in cross sections away from the central cross section are taken into account by assuming that the area A of the central core varies as $A(z)=A(0)[1-(z/L)^2]$ where $2L$ is the length of the whisker.[7] This leads to minor changes in the response compared to assuming that the central cross section applies to the whole whisker.

The simplest, but crude, assumption is that the strains in the central cross section are the same in the core and the frame. This properly maintains the square symmetry. It does not let the lattice planes bow and does not allow for the dependence of the strain on $\log y$ and $1/y^2$, which actually occur for a transverse domain magnetized in the x direction. These terms will be added below after carrying out the uniform calculation for its pedagogical value. In the restricted calculation there are but two unknowns, ξ and ζ which characterize the displacements of the atoms in both the core and the frame,

$$u_y=y\xi k_1, \quad u_x=x\xi k_1, \quad u_z=z\zeta k_1 \tag{2}$$

and the corresponding strains:

$$e_1=\frac{\partial}{\partial x}u_x=k_1\xi, \quad e_2=\frac{\partial}{\partial y}u_y=k_1\xi, \quad e_3=\frac{\partial}{\partial z}u_z=k_1\zeta, \tag{3}$$

$$e_4=\frac{1}{2}\left(\frac{\partial}{\partial y}u_x+\frac{\partial}{\partial x}u_y\right)=0,$$

$$e_5=\frac{1}{2}\left(\frac{\partial}{\partial z}u_y+\frac{\partial}{\partial y}u_z\right)=0, \tag{4}$$

$$e_6=\frac{1}{2}\left(\frac{\partial}{\partial x}u_z+\frac{\partial}{\partial z}u_x\right)=0.$$

From Eqs. (1) to (4) the energy density in the frame is

$$a_0^f=k_1^2\{\tfrac{1}{2}[c_{11}(2\xi^2+\zeta^2)]+c_{12}(\xi^2+2\zeta\xi)+\tfrac{1}{3}(\zeta-\xi)\} \tag{5}$$

and the energy density in the core is

$$a_0^c=k_1^2\{\tfrac{1}{2}[c_{11}(2\xi^2+\zeta^2)]+c_{12}(\xi^2+2\zeta\xi)+\tfrac{2}{3}(-\zeta+\xi)\}. \tag{6}$$

The total energy per unit volume of the central cross section is

$$a_{\rm mel}=a_0^f(-r^2+1)+a_0^c r^2, \tag{7}$$

where $r=d_i/d$ is the ratio of the inner, $2d_i$, to outer, $2d$, dimensions of the frame. Minimizing $a_{\rm mel}$ with respect to ξ and ζ yields the strains

$$\xi=-\frac{1}{2(c_{11}-c_{12})}\left(r^2-\frac{1}{3}\right), \quad \zeta=\frac{1}{c_{11}-c_{12}}\left(r^2-\frac{1}{3}\right). \tag{8}$$

When the core fills the cross section ($r=1$), the strain ζ (in the z direction) is the magnetostriction constant λ_{100} which for iron is 2.2×10^{-5}. In terms of λ_{100}, given by

$$\lambda_{100}=\frac{2}{3}\frac{k_1}{(c_{11}-c_{12})}, \tag{9}$$

the energy per unit volume depends on r according to

$$a_{\rm mel}=-\frac{27}{16}(c_{11}-c_{12})\lambda_{100}^2\left(r^2-\frac{1}{3}\right)^2. \tag{10}$$

Note that the energy is lowest when the core fills the cross section. The energy is highest (actually zero) when $r=0.577$ corresponding to the net magnetic moment per unit volume in the central cross section being $M_s r^2=M_s/3$.

The effective field comes from the dependence of the energy per unit volume on the net magnetic moment per unit volume,

$$H_{\rm eff}(r)=-\frac{\partial}{\partial M}(a_{\rm mel})$$

$$=-\frac{1}{M_s}\left(\frac{\partial}{\partial r^2}(a_{\rm mel})\right)$$

$$=\frac{27}{8}\frac{\lambda_{100}^2(c_{11}-c_{12})}{M_s}\left(r^2-\frac{1}{3}\right). \tag{11}$$

The effective field in the limit of vanishing core ($r^2=0$) is

$$H_{\rm eff}(0)=-(9/8M_s)\lambda_{100}^2(c_{11}-c_{12})\equiv -H_{\rm mel}. \tag{12}$$

For iron $H_{\rm mel}=0.30$ G, compared to the experimental collapse fields which are close to 0.7 G. The sign is right and the order of magnitude is right, but in this crude model it is too small. Note that this effective field becomes less negative with increasing magnetization as the core expands. This explains qualitatively the complex behavior seen experimentally. Below a critical current, there are narrow ranges of field for which there are two stable solutions for the area of the central cross section at each field and current. The critical limits of these regions produce interesting and useful magnetic properties.

When calculation is carried out for less restrictive strain fields, $H_{\rm eff}$ for small r becomes larger. The linear dependence of $H_{\rm eff}$ on r^2 will be joined by a term in $r^2\log r^2$ that amplifies the critical effects. The next order of approximation yields an energy density given by

$$a_{\rm mel}=\frac{3}{2}M_s H_{\rm mel}\left(\frac{2(c_{11}-c_{12})(-2r^2\log r^2+r^4-1)}{c_{44}+12c_{11}}-\left(r^2-\frac{1}{3}\right)^2\right) \tag{13}$$

and the corresponding effective field

$$H_{\rm eff}(r)=3H_{\rm mel}\left(\frac{2(c_{11}-c_{12})(-\log r^2+r^2-1)}{c_{44}+12c_{11}}-\left(r^2-\frac{1}{3}\right)\right). \tag{14}$$

The energies and effective fields for the two approximate calculations are compared in Fig. 2. Equations (13) and (14) follow from assuming that the strain in a transverse domain

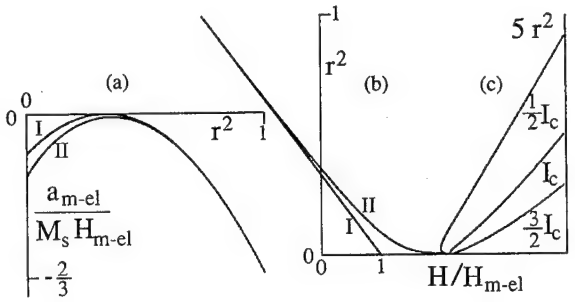

FIG. 2. (a) The dependence of the magnetoelastic energy on the relative area r^2 of the core domain for the simple argument I and the more detailed calculation II. (b) The relation between r^2 and the effective field from the magnetoelastic energy for I and II. (c) The dependence of r^2 on small applied fields for a particular whisker geometry using Eqs. (22) and (23) for the critical current I_c, for $I_c/2$, and for $3I_c/2$. For I_c, the external dc susceptibility is continuous, reversible, and infinite at the critical applied field.

magnetized in the x direction depends on y while maintaining the walls between transverse domains at 45° with respect to the axes. The displacements are

$$u_x=xg(y)k_1, \quad u_y=yg(y)k_1, \quad u_z=z\gamma k_1. \tag{15}$$

These displacements do not permit bowing of the atomic planes; a more complicated calculation shows this is not important. The corresponding strains are

$$e_1=k_1g(y), \quad e_2=k_1\left(y\frac{\partial}{\partial y}g(y)+g(y)\right),$$

$$e_3=\gamma k_1, \quad e_4=\frac{1}{2}xk_1\frac{\partial}{\partial y}g(y), \quad e_5=e_6=0. \tag{16}$$

By the calculus of variations,

$$g(y)=\frac{\rho}{y^2}-\frac{6}{c_{44}+12c_{11}}\log y+\sigma \tag{17}$$

which introduces the parameters ρ and σ which along with ζ describe the displacements in the frame. (The parameter σ could be transferred to the term in $\log y$.) The core is described as before by ξ and ζ, but now ξ is determined by $\xi=g(r)$ by continuity of e_1 at the boundary $y=r$. The parameters that minimize the energy are

$$\rho=-\frac{3r^2}{c_{44}+12c_{11}}d^2, \tag{18}$$

$$\sigma=-\frac{r^2-\frac{1}{3}}{2(c_{11}-c_{12})}+\frac{3(r^2+2\log d)}{c_{44}+12c_{11}}, \tag{19}$$

and

$$\zeta=\frac{1}{c_{11}-c_{12}}\left(r^2-\frac{1}{3}\right). \tag{20}$$

Note that ρ vanishes when the core collapses. Also note that ζ is an expansion along z when $r=1$ and a contraction when $r=0$. With these parameters, Eq. (17) becomes

$$g(y)=\frac{-6\log\frac{y}{d}+3r^2\left(-\frac{d^2}{y^2}+1\right)}{c_{44}+12c_{11}}-\frac{1}{2(c_{11}-c_{12})}\times\left(r^2-\frac{1}{3}\right). \tag{21}$$

The field dependence of the magnetization is found parametrically from

$$M=M_sr^2 \tag{22}$$

and

$$H=4\pi DM_sr^2+C_Ir-\frac{C_\sigma}{r}+3\left(\frac{2(c_{11}-c_{12})}{c_{44}+12c_{11}}\times(\log r^2+1)-r^2+\frac{1}{3}\right)H_{\rm mel}, \tag{23}$$

where $H_{\rm mel}$ is defined in Eq. (12). The first term is the demagnetizing field for demagnetizing factor D. The coefficient for the effective field from the current is $C_I=Id/(4\sqrt{\pi c})$. The coefficient for the effective field from the wall energy is $C_\sigma=-(4\sigma_{100}-2\sqrt{2}\sigma_{110})/(dM_s)$ or $C_\sigma=0.9\sigma_{100}/(dM_s)$ for wall energies per unit area $\sigma_{110}=\sqrt{3}\sigma_{100}$. The wall energy restricts the complete collapse of the core at low fields, elsewhere it has negligible effects.

Equations (22) and (23) account for the dc magnetic response of the iron whisker with fields and currents along the z axis. Note the richness of the phenomenology with its dependence on r^2, r, $\log r$, and $1/r$, e.g., see Fig. 2(c). The full treatment of the ac susceptibility, to be published elsewhere, takes into account the effects of eddy currents and the influence of finite amplitude of the ac driving field at the critical fields. Agreement with experiment is excellent, accounting for the spectacular properties that accompany the existence of a critical point, with a critical field and a critical current. At the critical point the external dc susceptibility is infinite, continuous, and reversible.

The author thanks Dr. Alex Hubert for convincing him that the simple pedagogical argument was not sufficient.

High frequency (1–1200 MHz) magnetoimpedance in CoFeSiB amorphous wires (abstract)

Magnetoimpedance (MI) in Co-based amorphous alloys has been shown to be a very sensitive, quick-response new method for measurements of magnetic fields. At present, the experimental results on MI in amorphous wires are obtained for frequencies $f<200$ MHz. For quick-response magnetic heads used in high density magnetic recording, the carrier current frequency of the MI element is needed to be increased up to 1 GHz to detect recorded signals of 50–100 MHz. Here we present the experimental data on MI in CoFeSiB amorphous wires for a broad waveband of 1–1200 MHz. The experimental technique is based on the measurement of the complex reflection coefficient from a coaxial waveguide having an amorphous wire as an internal conductor. This method avoids the radiation effects, inevitable at high frequencies, $f>100$ MHz, in simpler techniques utilizing an oscilloscope or an impedance analyzer with a lead wire. From the data on reflection coefficient, the real and imaginary parts of the wire impedance Z and permeability μ are found as functions of a frequency and an external longitudinal field. The impedance versus field behavior changes with increasing the frequency. For $f<1$ MHz the absolute value of the impedance $|Z|$ decreases with increasing the field. As the frequency is increased, a maximum appears in the impedance-field dependence. In the case of high frequencies, $f>800$ MHz, $|Z|$ increases with the field. For all frequencies, a higher sensitivity is seen in small fields less than 2 Oe. The sensitivity has a maximum of about 100%/Oe at the frequency of 600 MHz, and it is still very high (~20%/Oe) up to $f\sim1$ GHz. These results are in satisfactory agreement with the theoretical ones based on the skin effect in a magnetic wire with a tensor rotational permeability.

Enhancement of magnetoresistance in Co(1$\bar{1}$00)/Cr(211) bilayered films on MgO(110)

Epitaxial Co/Cr bilayered films have been successfully grown on the MgO(100) and MgO(110) substrates by molecular-beam epitaxy. According to the reflection high-energy electron-diffraction and x-ray-diffraction measurements the crystal structure of the film depends on orientation of the buffer and substrate. Epitaxial growth of biaxial Co(11$\bar{2}$0)/Cr(100) on MgO(100) substrate and of uniaxial Co(1$\bar{1}$00)/Cr(211) on MgO(110) substrate has been confirmed. The anisotropy magnetoresistance (AMR) is strongly influenced by the orientation of the Cr buffer. In Co(11$\bar{2}$0)/Cr(100) on MgO(100) AMR is isotropic for all in-plane fields. However, for Co(1$\bar{1}$00)/Cr(211) on MgO(110) we observed enhancement of AMR along the easy axis for temperatures below 150 K, while along the hard axis AMR has a local maximum at about 150 K. The easy axis data suggest that the longitudinal spin density wave of Cr and the crystal anisotropy of Co on Cr(211) plane dominate the enhancement of the AMR. © *1996 American Institute of Physics.* [S0021-8979(96)57808-1]

In previous studies of the Co/Cr multilayer system[1–3] its magnetoresistance (MR) was shown to be quite small in comparison with other giant MR (GMR) multilayer systems.[4] Recently it was realized[5,6] that the magnetic properties of the Co/Cr multilayer system are sensitive to anisotropy and to the orientation of the applied magnetic field with respect to crystallographic axes and MR as high as 18% as has been observed in the Co/Cr(211) superlattice system. However, the mechanism of this effect is presently not clear and this motivated us to investigate the simpler case of anisotropy of MR (AMR) in the epitaxial bilayered Co/Cr film system.

Epitaxial Co/Cr bilayer films have been simultaneously prepared on MgO(110) and MgO(100) substrates by using an Eiko EL-10A molecular-beam-epitaxy (MBE) system with base pressure of 2×10^{-10} Torr. To enable the growth of high-quality film samples, polished and epitaxial grade MgO(110) and MgO(100) substrates were chemically precleaned and rinsed in an ultrasonic cleaner. They were then outgassed at 900–1000 °C for at least 0.5 h under ultrahigh vacuum in the MBE chamber. High-purity Co and Cr elements (>99.99%) were evaporated from two independent e-beam evaporators. During deposition of the films, the substrate temperature was kept between 300 and 350 °C, the growth pressure was controlled at below 5×10^{-9} Torr, and the deposition rate kept at ~0.1 Å/s. The film thickness and deposition rate were measured by a quartz-crystal thickness monitor. The crystallographic structure of the surface of the films was *in situ* examined throughout the growth by 15 keV reflection high-energy electron diffraction (RHEED). The crystal orientation was *ex situ* characterized by x-ray diffraction (XRD). The magnetic properties of all samples were studied using a superconducting quantum interference device (SQUID) magnetometer. The AMR measurements were carried out by standard four-probe technique in a magnetic field up to 5 T at temperatures ranging between 10 and 300 K. Typical area of the film sample was roughly 1.5×6.0 mm^2.

The structure arrangement of both Co and Cr layers in the Co/Cr bilayered films is considerably affected by the choice of the interface direction of the MgO substrate. In this study, the epitaxial Co/Cr bilayer films were simultaneously grown on MgO(100) and on MgO(110) substrates. Their crystalline orientation and quality were determined by RHEED and XRD. Figures 1(a) and 1(b) show schematic diagrams of the 3D geometry of the Co(1$\bar{1}$00)/Cr(210)/MgO(110) and Co(11$\bar{2}$0)/Cr(100)/MgO(100) bilayer films. These epitaxial relationships were also confirmed by both RHEED and XRD studies. Part of the structural analysis related to the Co/Cr superlattice films will be published elsewhere,[5,6] in this study only the bilayer case is discussed. In Fig. 1(a) the lattices of the Co and Cr layers appear to be rectangular, in acccordance with the 4.21×2.98 Å^2 unit cell of the MgO(110) surface. The unit cell of Co(1$\bar{1}$00), 4.07×2.51 Å^2, matches perfectly that of Cr(211), 4.07×2.50 Å^2, and even though the match between Cr(211) and MgO(110) is poorer, we did experimentally observe a twofold symmetry for the whole system and confirmed that the *c* axis of Co is in the film plane and in the Cr[0$\bar{1}$1] direction only. On the other hand, for the Co(11$\bar{2}$0)/Cr(100)/MgO(100) system, because the bcc Cr(100) plane has fourfold symmetry with unit cell of 2.88×2.88 Å^2, the hcp Co(11$\bar{2}$0) plane possesses only pseudotwofold symmetry with unit cell of 4.34×4.07Å^2. This suggests that the Co(11$\bar{2}$0) layers behave

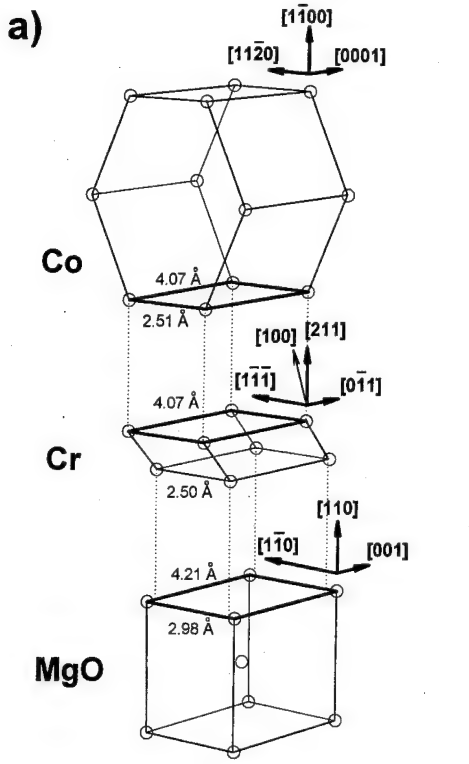

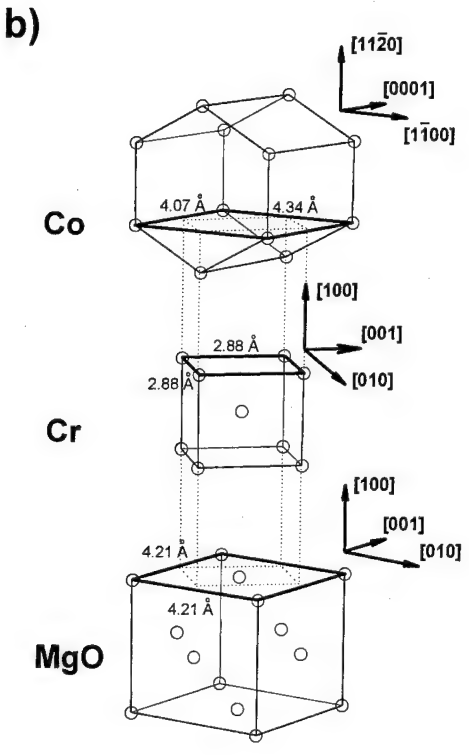

FIG. 1. Schematic diagram of the 3D geometry, unit cell (indicated by bold lines), and epitaxial relationships for (a) Co(1$\bar{1}$00)/Cr(211)/MgO(110) films, and (b) Co(11$\bar{2}$0)/Cr(100)/MgO(100) films.

like a bicrystalline structure; i.e., that the Co[0001] easy axis can either be parallel to MgO[001] or to MgO[010] as shown in Fig. 1(b).

The thickness of the Co layer for all the samples in this study is fixed at 200 Å and the thickness of the Cr layer is

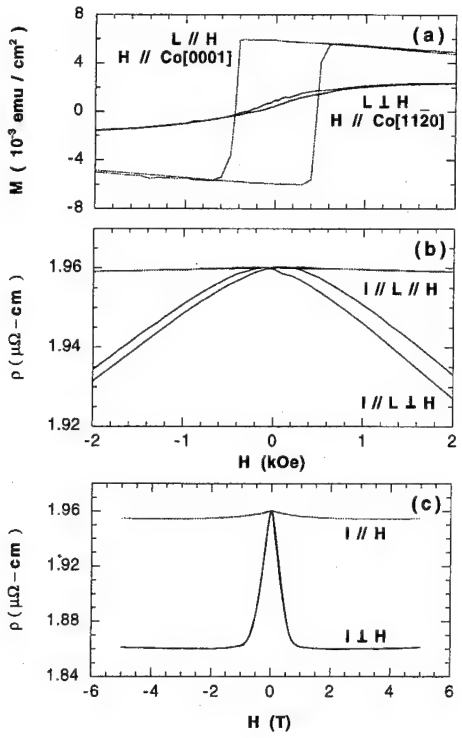

FIG. 2. (a) The magnetization M and (b) and (c) the surface resistivity for $Co_{200\ Å}(1\bar{1}00)/Cr_{6\ Å}(211)/MgO(110)$ films at $T=10$ K as functions of magnetic field applied parallel to the film surface.

varied between 6 and 100 Å. As an example, Fig. 2 shows the magnetic hysteresis loops and the corresponding surface resistivity of the $Co_{200\ Å}(1\bar{1}00)/Cr_{6\ Å}(211)/MgO(110)$ sample at 10 K for field applied parallel to the film surface. For H parallel to the easy axis of the Co layers a square $M-H$ hysteresis loop and small variation of resistivity have been observed. We interpret the magnetization reversal process as being mainly due to domain-wall motion. On the other hand, for H applied parallel to the hard axis of Co layers the magnetization varies slowly with increasing H while electric resistivity decreases very fast below roughly $H=1$ T and saturates then at $H>1$ T. The (very small) values of coercivity deduced from the $M-H$ loop are consistent with the peak positions on the resistivity curve.

In Fig. 3 we plot the magnetization M and surface resistivity as functions of applied field H for a $Co_{200\ Å}(11\bar{2}0)/Cr_{6\ Å}(100)/MgO(100)$ sample at 10 K. According to our structure analysis above, the easy and hard axes of the Co layers are randomly distributed in both MgO[001] and MgO[010] directions. The $M-H$ curves for H applied parallel or perpendicular to the long axis of the sample are roughly the same, apart from a difference due (presumably) to demagnetization factors [see the geometry of Fig. 1(b)]. The coercive force obtained from the $M-H$ curves coincides with the location of a minimum (maximum) of the resistivity with current parallel (perpendicular) to the applied field.

The temperature dependence of the AMR of the saturation magnetization M_S and of the coercive force H_c between 10 and 300 K for both $Co_{200\ Å}/Cr_{6\ Å}/MgO(110)$ and

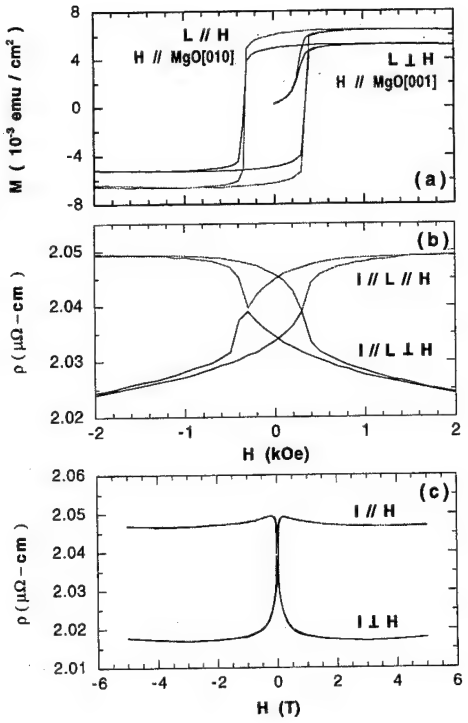

FIG. 3. (a) The magnetization M and (b) and (c) the surface resistivity for $Co_{200\ Å}(11\bar{2}0)/Cr_{6\ Å}(100)/MgO(100)$ films at $T=10$ K as functions of magnetic field applied parallel to the film surface.

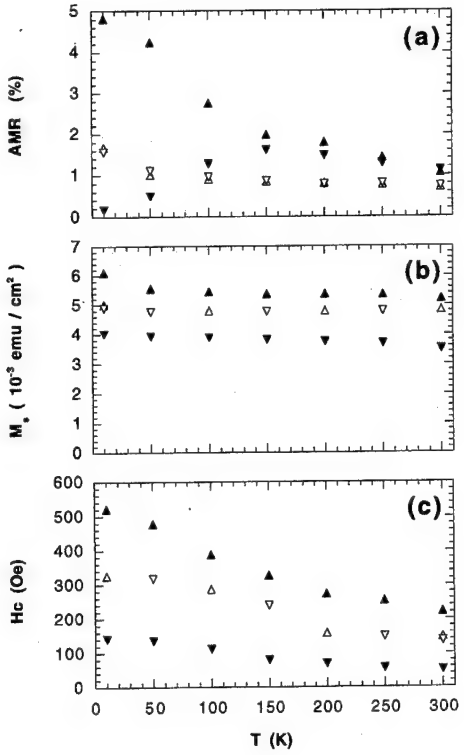

FIG. 4. (a) The AMR, (b) the saturation magnetization, and (c) the coercive force as functions of the temperature between 10 and 300 K for (L: long side of film): (▲) $Co_{200\ Å}/Cr_{6\ Å}/MgO(110)$ with $L\|$ easy axis of Co surface;(▼) $Co_{200\ Å}/Cr_{6\ Å}/MgO(110)$ with $L\|$ hard axis of Co surface; (△) $Co_{200\ Å}/Cr_{6\ Å}/MgO(110)$ with $L\|MgO[001]$ direction; and (▽) $Co_{200\ Å}/Cr_{6\ Å}/MgO(110)$ with $L\|$ MgO[010] direction.

$Co_{200\ Å}/Cr_{6\ Å}/MgO(100)$ are presented in Fig. 4. For samples of $Co_{200\ Å}/Cr_{6\ Å}/MgO(110)$ with their long axis parallel to the easy axis of Co, i.e., in the direction of Co[0001] as shown in Fig. 1(a), we observed a significant enhancement of AMR for temperatures roughly below 150 K [▲ in Fig. 4(a)] while AMR [▼ in Fig. 4(a)] decreases with decreasing temperature below roughly 150 K for samples with long axis parallel to the hard axis of Co, i.e., in the direction of $Co[11\bar{2}0]$ as shown in Fig. 1(a). Our data points between 100 and 150 K are not sufficiently dense, however, this characteristic temperature T_f (~150 K) may be very close to the spin-flip temperature $T_{sf}=123$ K of Cr and we conjecture that magnetization reversal in these samples may be explained by a mechanism similar to that reported for the Fe/Cr system.[7] By contrast, in $Co_{200\ Å}/Cr_{6\ Å}/MgO(100)$ samples the AMR as shown in Fig. 4(a) is almost independent of temperature. The saturation magnetization M_s and the coercive force H_c as functions of temperature between 10 and 300 K are plotted in Figs. 4(b) and 4(c), respectively. Both the M_s vs T and the H_c vs T curves completely coincide for the $Co(11\bar{2}0)/Cr(100)/MgO(100)$ samples; however, a slight shift in these data, perhaps again explainable by the presence of demagnetizing fields, exists in the observed values for the $Co(1\bar{1}00)/Cr(211)/MgO(110)$ samples. All H_c vs T curves show a marked change in their slope at approximately 150 K.

In conclusion, this is the first time that AMR enhancement roughly below the spin-flip temperature was observed in epitaxial $Co(1\bar{1}00)/Cr(211)$ bilayered films on MgO(110), with current in the Co[0001] direction.

Magnetic and electrical properties of CoFeSiB:O thin films near the percolation threshold

R. Banerjee, A. P. Valanju, G. Choe,[a] and R. M. Walser[b]
I/UCR Center for Magnetics, University of Texas at Austin, Austin, Texas 78712

Nanocomposite thin films with coexisting magnetic metal and magnetic nonmetal amorphous phases were synthesized by reactively sputtering CoFeSiB:O thin films with a large silicon (15 at.%), and varying oxygen concentrations. The microstructure, magnetization, and hysteresis loops were measured for films with resistivities near the metal–nonmetal transition. These data revealed that, below the metal–nonmetal transition, conductive transport was along the soft magnetic, metallic backbone of the percolation network; the nonmetal phase was a discontinuous, randomly distributed, hard magnetic oxide. The metallic resistivity and exchange anisotropy were both maximized in a nanocomposite with a resistivity at the metal–nonmetal transition. © *1996 American Institute of Physics.* [S0021-8979(96)57908-0]

I. INTRODUCTION

It is surprising that the metallic resistivities of sputtered, heteroamorphous magnetic thin films can be increased by more than one magnitude by sputtering in reactive gases.[1,2] As the percolation threshold is approached from the metallic side, the resistivity of these metal–nonmetal nanocomposites is determined primarily by electrical transport along the backbone of the continuous metallic network, formed in the growing film by complex reactive processes. It is of scientific and technological interest to understand these processes that permit independent manipulation for the magnetic and electrical properties of these nanocomposites.

Previous studies[2–5] concentrated on obtaining magnetically soft nanocomposite films with a maximum resistivity. To achieve this goal, the reactive gas species (O, F, or N) must preferentially bond with the metalloid (Al, B, or Si) in the film, form a nonmagnetic, insulating complex (e.g., B_2O_3), and segregate from the metallic backbone of the Co- or Fe-rich percolation network. In addition to technologically important soft magnetism,[2] giant magnetoresistance tunneling has been observed in these magnetic-metal–nonmagnetic-nonmetal nanocomposites.[6]

Additional interesting behavior could be expected from reactively sputtered magnetic-metal–magnetic-nonmetal nanocomposites. The reactive gas must now substitutionally bond in the film to form a stable nonmetallic magnetic phase. In a previous study[7] we demonstrated that this type of nanocomposite could be produced by reactively sputtering amorphous CoFeSiB alloy thin films in oxygen. A stable, magnetic, nonmetal phase was formed in CoFeSiB:O alloy films with sufficiently large silicon concentrations. The interaction of the two magnetic phases in the nanocomposite gave rise to an exchange anisotropy in the magnetic hysteresis which directly confirmed their existence. The present study was conducted to determine the relative concentrations of incorporated oxygen that produce maxima in the low-field unidirectional hysteresis and metallic resistance of these nanocomposites, and to systematically characterize their magnetic and electrical transport properties.

II. EXPERIMENT

CoFeSiB:O films were deposited onto glass substrates by oxygen reactive sputtering from a $Co_{70.5}Fe_{4.5}Si_{15}B_{10}$ alloy target in a rf magnetron sputtering system. A partial pressure controller on a residual gas analyzer was used to vary, and feedback control, the partial pressure of reactive oxygen in the argon sputtering gas. The background pressure in the deposition chamber prior to introducing argon and oxygen gases was 5×10^{-7} Torr. The sputtering argon pressure was fixed at 7 mTorr, while the oxygen to argon pressure ratio was varied. The sputter input power was set at 800 W and all the depositions were made in the static mode. The film thicknesses in the 800–900 Å range were measured using a surface profilometer. The film structure and magnetic and electrical properties were studied, respectively, with transmission electron microscopy (TEM/TED), a B–H hysteresisgraph and vibrating sample magnetometer (VSM), and a four-point resistivity probe. The low-temperature resistivity measurements were performed using an ac four-point-probe setup with the sample placed on a refrigerator cold stage.

III. RESULTS AND DISCUSSION

The variations of saturation magnetization $4\pi M_s$, remanence $4\pi M_r$, and resistivity ρ of the CoFeSiB:O thin films are plotted in Fig. 1 as a function of the O_2:Ar flow ratio. The oxygen incorporated in the film was not determined, but can be crudely calibrated by noting that the ~8% O_2:Ar flow ratio measured at the onset of tunneling (not shown in Fig. 1), would, on the basis of previous research,[2] correspond to a minimum of ~20 at.% oxygen. The incorporated oxygen is not expected, however, to vary linearly with the flow ratio. The metallic region of flow ratio was determined from the temperature coefficients of the film resistivities measured in the 77–300 K temperature range. Figure 2 plots the fractional changes in resistivity measured for CoFeSiB:O films sputtered with O_2:Ar flow ratios of 1.4%, 3.5%, and 7%. The resistivities of each film were normalized to their values at 300 K and extrapolated to $T>300$ K. A negative temperature

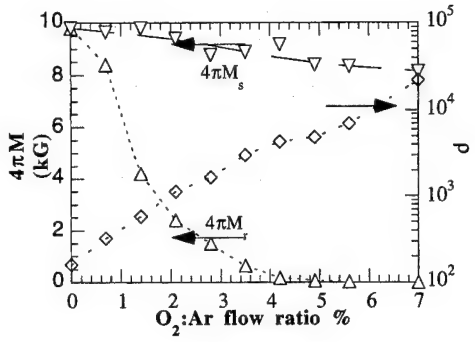

FIG. 1. Variation of $4\pi M_s$, $4\pi M_r$, and ρ ($\mu\Omega$ cm) for CoFeSiB:O thin films deposited at varying O_2:Ar flow ratios.

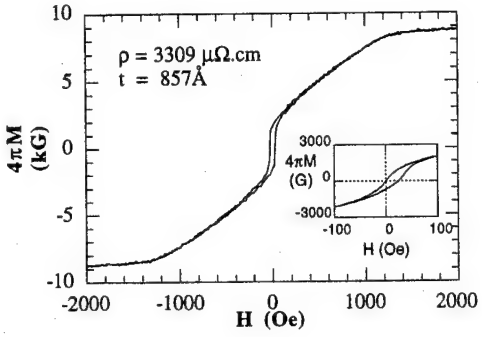

FIG. 3. B–H loop of 857 Å CoFeSiB:O thin film. Inset shows low-field B–H loop.

coefficient likely indicates that the conduction was dominated by thermally assisted tunneling; a positive coefficient was taken to indicate the dominance of metallic conduction. At 300 K, a crossover from metal to nonmetal conduction occurred at a critical flow ratio of 3.5%, for which a maximum unidirectional exchange shift had been observed previously.[7]

When the flow ratio increased above that at the metal–nonmetal crossover, the resistivity slope was much smaller than observed in granular films produced by cosputtering relatively immiscible metal/nonmetal materials.[8] This behavior indicates that the morphology of the metallic backbone has a large interfacial contact with the nonmetal phase. This morphology could support a large number of thin tunnel junctions and broaden the metal–nonmetal transition.[9]

With increasing O_2 content, $4\pi M_s$ decreased as the volume fraction of the oxidized nonmetallic regions grew at the expense of the metallic regions. With increasing flow ratio, $4\pi M_s$ decreased by less than 20% throughout the metallic region, but the magnetic remanence vanished for flow ratios >4%. These changes confirmed that, in the metallic region, the incorporated oxygen substitutionally bonded to form a random, magnetically harder phase in which the total magnetic moment was nearly conserved.

Figure 3 shows the in-plane B–H hysteresis loop of an 857-Å-thick critically percolated film, deposited with the 3.5% flow ratio that corresponds to the transition from metal to nonmetal behavior. The inset clearly shows the ~9 Oe exchange shift in the low-field loop. The remanence of the soft magnetic phase was less than 10% of $4\pi M_s$. A dc field of more than 1 kOe was required to saturate the random, magnetically hard phase.

As shown in Fig. 4, the CoFeSiB film sputtered without oxygen had a well-defined uniaxial anisotropy (H_k=40 Oe) with coercivity H_c of 6 Oe. Annealing in a rotating field at 350 °C reduced the anisotropy to 28 Oe.[10] Figure 4 also shows that H_c of the low-field hysteresis (associated with the soft magnetic metal phase) initially increased, then decreased with the concentration of incorporated oxygen. These low-field hysteresis loops were observed only after the film was first saturated by a 1 kOe in-plane dc field. The variation of H_c with flow ratio (Fig. 5) shows that a maximum H_c occurred for a 1.5% flow ratio; the minimum flow ratio for which an exchange anisotropy was observed in the CoFeSiB:O films.[7] H_c then decreased to a minimum of ~16 Oe for the 3.5% flow ratio at the metal to nonmetal transition. Only small changes in H_c were observed for films with nonmetal conduction.

IV. SUMMARY AND CONCLUSIONS

The observation of exchange-shifted, low-field hysteresis loops revealed the presence of two magnetic phases in reactively sputtered CoFeSiB:O films. From the temperature coefficients of the film resistivities measured in this study it was shown that, in the range where the exchange anisotropy was observed, the film nanocomposite consists of a continuous metallic backbone in the percolation network. From the changes in the $4\pi M_s$, $4\pi M_r$, and ρ of these films, produced by varying the oxygen flow ratio, the metallic backbone was determined to be the softer of the two magnetic phases. This phase exhibited a low-field, in-plane, uniaxial anisotropy. The harder magnetic phase was determined to be a discontinuous, randomly distributed, nonmetallic, magnetic oxide. The nature of the oxygen bonding in this phase approximately conserved the metallic magnetic moments. Applied magnetic fields of several kOe were required to saturate this phase.

The results also showed that the exchange anisotropy was a maximum when the incorporated oxygen concentration produced the maximum metallic resistivity. The increase in the H_c of the soft metallic phase with small oxygen concentrations was arrested with the initiation of the exchange interaction between the two phases that was responsible for the low-field unidirectional hysteresis observed for flow ratios of approximately 1%–7%.[7] H_c subsequently decreased as the exchange anisotropy increased, and was a minimum at the metal–nonmetal transition. It is reasonable to assume that the interfacial surface area is a maximum at the metal–nonmetal transition and maximizes both properties. This conclusion is supported by the gradual nature of the metal–nonmetal transition which requires a similar morphology.

This study, and those of other investigators,[1–7] indicates that reactive sputtering of amorphous magnetic thin films can be used to synthesize magnetic nanocomposites with a prescribed compositional heterogeneity and morphology. These nanocomposites are expected to exhibit a variety of novel magnetic and electrical properties.

The total impedance, Z, of low magnetostriction wires $(Co_{0.94}Fe_{0.06})_{72.5}B_{15}Si_{12.5}$ was measured at 100 kHz under ac currents of various amplitudes, i, for as-cast and current annealed samples. We show that curves Z vs i can represent circumferential permeability curves and that the features observed on these curves as a consequence of annealing can be interpreted due to the induced magnetic anisotropy by the effect of the current annealing. © *1996 American Institute of Physics.* [S0021-8979(96)80008-6]

I. INTRODUCTION

Giant magnetoimpendance (GMI) has recently been of great interest because of its many potential applications in miniature sensors and devices.[1,2] GMI has been observed in materials with a substantial portion of circumferential domains; it is interesting, from a basic point of view, to elucidate magnetization processes in such magnetic structures.

GMI can be defined as a decrease in the impedance response of a ferromagnetic material, submitted to an ac current, when a dc magnetic field is applied. It is now clear that the impedance response of a magnetic material depends essentially on the interaction between its circumferential domains and the circular field generated by the ac current. At high frequencies, the skin-depth effect plays a central role in GMI by affecting the cross section of the wire where the circular field is concentrated. When the dc field is applied (especially in a longitudinal direction with respect to the material), a rotational component appears in circumferential domains,[1] leading to a decrease in circular permeability, an associated variation in penetration depth, and therefore to a decrease in the interaction. If the dc field is high enough, it can suppress the circular domains and lead to an impedance response as small as that of a nonmagnetic material. GMI is a classical electrodynamics phenomenon.[3,4]

While GMI has been observed in a wide variety of materials, low, negative magnetostriction wires in the as-cast state have been shown to meet the requirements for a particularly strong dependence of impedance on field. Some efforts have been made[4] to improve GMI by annealing various materials under a variety of techniques; to our knowledge, however, the observed changes in impedance response in annealed CoFeSiB wires have not been fully explained. The aim of this article is to contribute to the understanding of changes introduced by current annealings in the domain structure of the wire the analyzing their impedance response.

II. EXPERIMENTAL TECHNIQUES

Amorphous wires of nominal composition $(Co_{0.94}Fe_{0.06})_{72.5}B_{15}Si_{12.5}$, prepared by in-water-rotation technology,[5] kindly provided by Unitika Ltd. Japan, were cut in pieces of 10 cm. Current-annealing treatments were performed by submitting the wire to dc currents of 360, 400, and 425 mA for a duration of 30 min in air, with no applied stress. Complex impedance measurements were done at various frequencies with a Stanford Research Systems SR 850 lock-in amplifier. Current and voltage leads were made by pasting copper wires with Ag paste. A high-quality resistor was connected in series with the wire, to measure the current amplitude flowing through the wire in all measurements. The current amplitude, i, was varied between 0.1 and 40 mA (rms). The impedance was also measured as a function of axial field, H_z, which was produced by a solenoid. All measurements were performed with the wire oriented perpendicular to the earth's magnetic field.

III. EXPERIMENTAL RESULTS

The dependence of total impedance, Z, as a function of axial field, H_z, at $f=100$ kHz is shown in Fig. 1 for an as-cast sample as well as for a sample annealed at 360 mA. The measurements were made at various values of ac current amplitude, i. The as-cast sample exhibits the well-known, decreasing behavior of Z as H_z increasingly produces a rotational component on spins of the circular domains.[1,3,4] For the current-annealed sample, an impedance maximum ap-

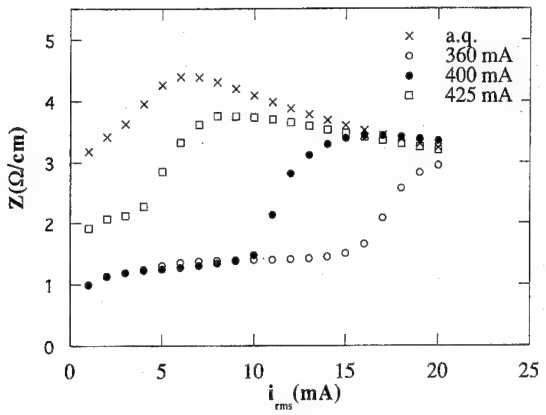

FIG. 2. Total impedance as a function of ac current amplitude at 100 kHz, for samples current annealed under various current values.

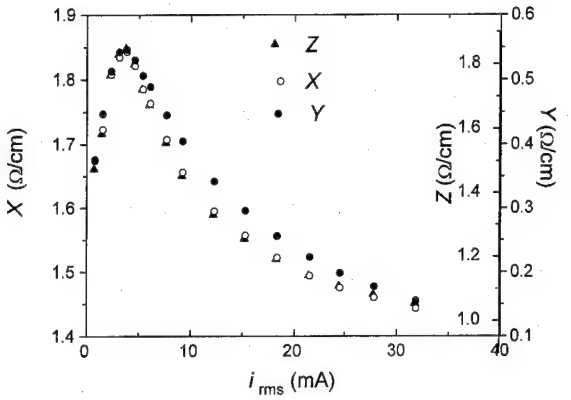

FIG. 3. Real, X, imaginary, Y, and total, Z, impedance measured as a function of ac current amplitude, at 100 kHz, for the as-cast sample.

pears for nonzero axial fields, and a dependence of i is exhibited. For high axial fields, all curves show a tendency to merge into a common behavior. As we have shown elsewhere,[6] the current amplitude, i (and therefore the circular field magnitude), has an important effect on the Z response.

In order to investigate the influence of the circular field, we have measured Z as a function of i at 100 kHz, for all the samples (Fig. 2). All of the curves show a maximum, and except for the as-cast sample, all of them exhibit a propagation field, i.e., a field necessary to initiate domain wall unpinning and displacement. This propagation field is at maximum for the sample annealed at low current (360 mA), and decreases for samples treated at medium (400 mA) and high (425 mA) annealing currents.

IV. DISCUSSION AND CONCLUSIONS

In order to draw conclusions from these measurements, it is important to establish first whether the total impedance, Z, can be associated with a clear physical meaning. Recently, an approach based on equivalent circuits (EC) has been proposed[6] to represent the impedance response of low magnetostriction wires. According to this approach, wire response can be modeled by a R_sL_s series circuit, in series with a R_pL_p parallel arrangement. In short, R_s represents the wires dc resistance, L_s its rotational permeability, L_p the wall permeability of circumferential domains, and R_p the viscous damping of circumferential walls. The EC equations for the real, X, and imaginary, Y, components of impedance are written as

$$X=R_s+R_pL_p^2\omega^2/(R_p^2+L_p^2\omega^2), \tag{1}$$

$$Y=\omega L_s+R_p^2L_p\omega/(R_p^2+L_p^2\omega^2), \tag{2}$$

where ω is the angular frequency ($\omega=2\pi f$). While the series circuit is quite insensitive to frequency, the parallel arrangement exhibits a relaxation behavior for a frequency ω_x where

$$\omega_x=R_p/L_p. \tag{3}$$

For this condition. Eqs. (1) and (2) become, respectively,

$$X=R_s+\omega_xL_p/2, \tag{4}$$

$$Y=\omega_xL_s+\omega_xL_p/2. \tag{5}$$

Since $Z=(X^2+Y^2)^{1/2}$, and both X and Y include the term $\omega_xL_p/2$, total impedance can accurately represent the variations in circumferential permeability. At frequencies close to the relaxation frequency, total impedance measurements can therefore be used to monitor circumferential wall permeability.

Such a relaxation frequency has been found in these wires in the 10–100 kHz range[6] for the as-cast state. A confirmation of this approach is given in Fig. 3 for the as-cast sample, where X, Y, and Z are measured as a function of i. Except for a constant term (note the difference in scales), all of the curves show the same variations as a function of the circular field. At frequencies far from the domain wall relaxation frequency, X is insensitive to circumferential permeability.

Variations in Z at measuring frequencies near the relaxation frequency therefore represent the variations in domain wall permeability of circumferential domains. The curves in Fig. 2 effectively exhibit the basic features of wall permeability behavior as a function of applied field: a practically constant range of low fields (the initial permeability range), followed by a strong increase (propagation of the walls), passage through a maximum (maximum permeability), and finally, a hyperbolic decrease for high fields (approach to saturation). By comparing the curves, we can say that the main difference between them is the propagation field: it is extremely small for the as-quenched sample, increases for the 360 mA sample, and then decreases for the 400 and 425 mA sample.

In order to explain these results, we assume that a directional ordering of Co–Co atom pairs[7] takes place during cooling of the samples. While these pairs are expected to be oriented parallel to the magnetization direction in circumferential domains, they form a complex arrangement in domain walls, where atom pairs tend to follow the spin orientations. The formation of such ordering results in an additional stabilization energy of walls; therefore, an additional energy has to be supplied to initiate wall propagation.

In the stationary state, annealing currents result in well-defined average temperatures in wires; For 360, 400, and 425 mA (leading to current densities of 29.3, 32.6, and 34.6 A/mm^2, respectively), the corresponding temperatures[8] are 559, 590, and 610 K, respectively. Crystallization during current annealing is ruled out since the crystallization temperature is substantially higher (810 K).

In the case of the 400 and 425 mA annealings, the observed domain wall pinning seems unrelated to the annealing temperature itself, since these treatments occur at temperatures higher than the Curie point for this alloy (T_C=568 K). The low current annealing takes place at $T<T_C$; however, the circular field produced by the current is high enough to eliminate the domain walls and saturate the wire. The domain wall pinning associated with directional ordering can therefore occur only during the cooling process, as the wire cools down through T_C and the domain structure is again formed. No large differences in cooling rate can be expected among the various annealings; therefore, the increase in pinning field exhibited for the low annealing temperature could be ascribed to the formation of a stronger circular anisotropy for this sample. As the annealing current is switched off and the domain structure is formed, the directional ordering created on domain wall sites seems to become stronger as the annealing temperature is lower. This directional ordering could be explained in terms of induced anisotropy.[7]

In conclusion, we say that total impedance measurements can be used as an important tool in GMI investigation, and that for the particular case of current-annealed CoFeBSi wires, directional ordering of atom pairs can explain the observed features in impedance response.

A technique to observe magnetization dynamics in amorphous wires is described. When an ac current passes through the amorphous wire, voltages induced between both ends of the wire and in a pickup coil wound around the wire are observed. These voltages indicate circumferential and axial components of magnetization changes in the wire, respectively. Observations in a Co-rich wire having slightly negative magnetostriction and an Fe-rich wire having positive magnetostriction under various bias fields showed quite different wave forms which indicate their domain structure. © *1996 American Institute of Physics.* [S0021-8979(96)58008-7]

I. INTRODUCTION

Amorphous magnetic wires provide attractive features, including the magnetoelastic wave[1] and the magnetoimpedance effect.[2] The magnetoelastic waves in magnetostrictive Fe-rich amorphous wires are detected usually by a pickup coil wound around the sample wire. Changes of the axial component of the magnetization in the wire induce voltages in the pickup coil.

An ac voltage is also induced in the pickup coil when an ac current passes through the amorphous wire. Ogasawara[3] has reported this phenomenon as "inverse-Matteucci effect." Tekemura *et al.*[4] showed that two signals can be transported individually by the magnetoelastic wave and the ac current passing through the same amorphous wire.

The magnetoimpedance effect in Co-rich amorphous wires, which have slightly negative magnetostriction, has attracted much interest because it has been considered to be applicable as a sensitive method to measure magnetic field. Mohri *et al.*[5] have shown that the magnetoimpedance effect originates from the electromotive force induced between both ends of the wire by changes of the circumferential component of the magnetization, and have described the domain dynamics of the wire based on the domain structure model of the negatively magnetostrictive amorphous wire.

In the present article we discuss magnetization dynamics in FeCoSiB and FeSiB amorphous wires. In order to observe the magnetization process, axial and circumferential components of the magnetization in the wire are simultaneously measured by observation of the wave forms of induced voltages in the pickup coil and between the ends of the sample wire, respectively.[6]

II. EXPERIMENT

The experimental arrangement is illustrated in Fig. 1. An ac current i_z, passing through the sample wire causes a circumferential magnetic field. A voltage v_c, induced in a pickup coil (80 turns, 4.8 mm length, 600 μm inner diameter) turned around the sample wire is proportional to the axial component of magnetization change in the wire. A voltage v_z, observed between both ends of the sample wire is considered as a sum of the ohmic voltage and the voltage induced by the circumferential component of the magnetization change in the wire.

Amplitude and frequency of the ac current were chosen as 12 mA_{p-p} (for the Co-rich wire), 30 mA_{p-p} (for the Fe-rich wire), and 500 kHz, respectively. An external dc bias field, H_{zb}, was applied along the wire axis using a solenoidal coil.

An amorphous $Fe_{4.3}Co_{68.2}Si_{12.5}B_{15}$ wire having slightly negative magnetostriction and a positively magnetostrictive $Fe_{77.5}Si_{7.5}B_{15}$ wire (both of them are prepared by Unitika Ltd., Japan) were used as samples. The Co-rich wire was cold drawn to its diameter d_W=30 μm, and then annealed at 475 °C with a tension of 40 kg/mm^2. The Fe-rich wire was also drawn to d_W=90 μm and annealed at 400 °C with no tension.

III. RESULTS AND DISCUSSION

Waveforms of v_z and v_c observed in the Co-rich amorphous wire under various bias fields H_{zb} are shown in Figs. 2(a) and 2(b), respectively. These wave forms are shown as Lissajous figures, and abscissas show ac current i_z.

The wave forms of v_z are similar to those already reported:[2,7] The frequency of v_z agrees with that of i_z; the

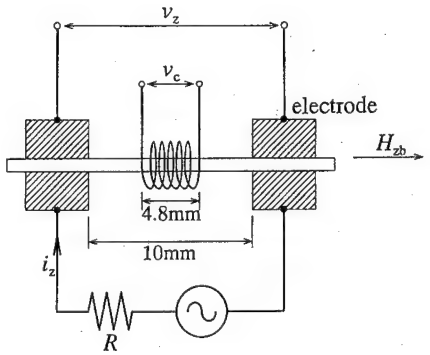

FIG. 1. Experimental arrangement.

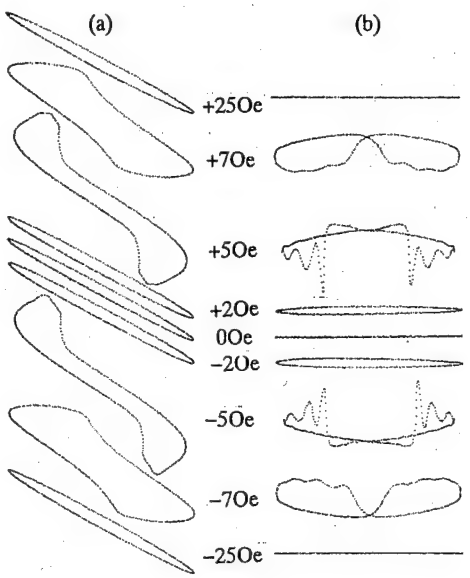

FIG. 2. Wave forms of (a) voltages between both ends of the sample wire v_z and (b) voltages induced in the pickup coil v_c, observed in the amorphous $Fe_{4.3}Co_{68.2}Si_{12.5}B_{15}$ wire under various values of the bias field H_{zb} applied to the axis direction of the wire. The wave forms are shown as Lissajous figures and abscissas show the ac current through the wire i_z (500 kHz, 12 mA_{p-p}).

amplitude of v_z is markedly influenced by H_{zb} as shown in Fig. 3(a), whereas the polarity of H_{zb} does not affect the wave form of v_z.

Observation of v_c provides interesting information of the magnetization dynamics in the sample wire:

(1) The frequency of v_c is double of that of i_z except in a range of H_{zb} near zero;
(2) the polarity of v_c reverses when the polarity of H_{zb} reverses;
(3) in the range of H_{zb}, $\pm 4 - \pm 6$ Oe, steep pulses of v_c which indicate jumps of axial component of magnetization are observed.

A domain model for tension-annealed, negatively magnetostrictive amorphous wires, in which circumferential anisotropy is postulated in the whole cross section, has been proposed.[2] The above-mentioned observation seems to support the proposed model, as follows.

(1) During the bias field H_{zb} is zero, magnetization in the wire has no axial component regardless of the circumferential field.

(2) When a small H_{zb} is applied, a reversible magnetization rotation occurs and the axial component of it is observed as v_c.

(3) When H_{zb} exceeds an appropriate value, an irreversible magnetization process takes place. Each time the irreversible change occurs, axial and circumferential components of the magnetization induce steep pulses in v_c and v_z, respectively.

(4) When H_{zb} becomes sufficiently large, the magnetization vector is restricted to the axial direction and vibrates with a small amplitude;

(5) In the cases of (3) and (4), the magnetization vector vibrates across the axial direction where the axial component of the magnetization has maximum value. Therefore, the frequency of v_c is double of that of i_z.

Figures 4(a) and 4(b) show wave forms of v_c and v_z, respectively, observed in the Fe-rich amorphous wire. Relationships of these wave forms and H_{zb} are quite different from those observed in the Co-rich wire:

(1) The frequency of v_c and v_z is equal to that of the ac current regardless of H_{zb};
(2) H_{zb} dependence of v_c and v_z has a hysteresis and their polarities are independent of the polarity of H_{zb};
(3) wave forms of v_c and v_z are approximately sinusoidal and noticeable jumps of magnetization are not observed.

In Figs. 5 and 6, phase shift from the ac current and amplitude of v_c and v_z in the Fe-rich wire are shown as functions of H_{zb}. H_{zb} dependence of v_c and v_z is quite different from that of the Co-rich wire. The magnetization vector in the Fe-rich wire is most movable when H_{zb} is near zero.

As shown in Fig. 5, magnetoimpedance effect (about

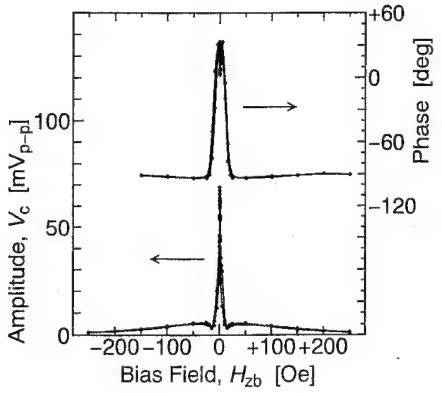

FIG. 6. Amplitude and phase shift of v_c observed in the Fe-rich amorphous wire as functions of H_{zb}.

20% amplitude change) is observed. Atkinson *et al.*[8] have reported magnetoimpedance effect in the Fe-rich amorphous wire, and our result is similar to theirs.

Behavior of the magnetization in Fe-rich wire and its relationships to the domain model[5] and to the characteristics of the magnetoelastic wave[1] will be discussed in a future study.

IV. CONCLUSION

When an ac current passed through an amorphous wire, voltages induced between both ends of the wire and in a pickup coil wound around the wire were observed as functions of bias field applied to the axial direction of the wire. These voltages indicate circumferential and axial components of magnetization change in the sample wire, respectively.

Observations in a Co-rich wire having slightly negative magnetostriction and an Fe-rich wire having positive magnetostriction showed quite different wave forms which indicate the differences between their domain structures.

The goal of our study is to clarify the domain structures and the magnetization dynamics of amorphous wires. Results obtained in the present study show that the proposed method is a powerful way to observe two-dimensional magnetization dynamics.

Transport properties of amorphous CoZrNd thin films with very low Nd content (abstract)

C. de Francisco and J. M. Muñoz
Departamento de Electricidad y Electrónica, Universidad de Valladolid, 47071 Valladolid, Spain

J. F. Calleja, M. Rivas, and M. C. Contreras
Departamento de Física, Universidad de Oviedo, 33007 Oviedo, Spain

The composition and temperature dependence of electrical resistivity were studied for a series of amorphous $(Co_{93}Zr_7)_{100-x}Nd_x$ for $x<3.4$ and for a temperature range between 77 and 300 K. The films were deposited by rf sputtering. Measurements of electrical resistivity were performed by the standard four probe technique with ac currents of 10 mA. The rate of heating and cooling was 1 K/min. The electrical resistivity is very sensitive to the presence of Nd ions, as the resistivity clearly increases with a very slight increase of Nd content. The temperature dependence of resistivity does not obey the T^2 law predicted by the diffraction model as proposed by Meisel and Cote[1] but follows very nicely the law $\rho(T)=aT^{3/2}-bT+c$, a result also found for amorphous Gd–Co. The first term corresponds to the electron scattering from the magnetic spin and the second term to the electron scattering from the disordered configuration of atomic potentials. By longitudinal magneto-optical Kerr effect microscopy we analyzed the development of the domain structure in $Co_{70.4}Fe_{4.6}Si_{15}B_{10}$ amorphous ribbons for which giant magneto-impedance had been observed. Using transverse and longitudinal magneto-optical Kerr effect magnetometry we measured the magnetization direction around the hysteresis loop. These results allowed us to model the domain structure of the sample during the giant magneto-impedance measurements. © *1996 American Institute of Physics.* [S0021-8979(96)58108-2]

I. INTRODUCTION

Recently some authors have reported[1,2] observations of giant magneto- impedance (GMI) in amorphous ribbons of composition $Co_{70.4}Fe_{4.6}Si_{15}B_{10}$. Recent literature[3] explains GMI in amorphous wires in terms of classical electromagnetism. For wires, the symmetry of the samples greatly simplifies the theoretical calculations, but makes domain observations very difficult. Thus there is always some doubt as to whether the model describes the actual physical situation. On the other hand, for ribbons, the geometry makes the theoretical modeling somewhat more difficult, but greatly simplifies domain observations. This motivated us to characterize the development of the domain structure of amorphous ribbons under conditions encountered in the GMI measurements. In the present work we employed variations of the magneto-optic Kerr effect (MOKE) to study the evolution of the domain structure and magnetization during GMI measurements.

II. EXPERIMENT

Samples of composition $Co_{70.4}Fe_{4.6}Si_{15}B_{10}$ were produced by a single-roller melt-spinning technique. For the GMI measurements, they were field-annealed in vacuum at 300 °C for 15 min under an in-plane magnetic field of 3 kOe, perpendicular to the ribbon axis. For the magneto-optical (MO) measurements, the ribbons were mechanically polished using 1 μm diamond paste and then electrolytically polished using a HCl/methanol solution. Finally, they were covered with a 33 nm ZnS antireflection coating. A transverse and longitudinal magneto-optical Kerr effect (TLMOKE) magnetometer[4,5] allowed the determination of MO signals for different polarization directions. In this system a p-polarized incident wave from a diode laser ($\lambda = 670$ nm) is reflected by the sample and detected by a photodiode after passing through an analyzer. Adjusting the analyzer allowed operation in the transverse or longitudinal modes, or in a complex mixture of both.[6]

III. RESULTS

A. Magnetization measurements

In Figs. 1(a) and 1(b), we show the hysteresis loops obtained for analyzer positions corresponding to $+45°$ and $-45°$ in relation to the p-polarization direction. The frequency of the magnetic field was 0.03 Hz and in both cases, an offset signal was applied to center the loops. From these data, by point-to-point algebraic summation and subtraction,[7] we can reconstruct the hysteresis loops corresponding to the magnetization components parallel ($M_{\parallel}$) and perpendicular ($M_{\perp}$) to the applied magnetic field. The results for $M_{\parallel}$ and $M_{\perp}$ are shown in Figs. 1(c) and 1(d), respectively. As is usual for MO measurements, the vertical axes are in arbitrary units, but, in this case, the scale factor is the same (500) for both magnetization components. Figure 1(c) is similar to results obtained using TMOKE or a hysteresis loop tracer (not shown here) and reflects a transverse in-plane anisotropy. In Fig. 1(d) we have a large signal for $|H| < 2.5$ Oe which goes to zero as the sample is saturated. This indicates that in zero field, the magnetization remains near the direction of the annealing field. From the two components of the in-plane magnetization, we can determine the evolution of the magnetization direction, as shown in Fig. 1(e). We can see in the range 1.3–3 Oe, an almost linear variation of the magnetization direction, corresponding to the rotation of the magnetization in an applied field.

Using the same setup, but synchronizing the lock-in amplifier on an alternating current passing along the axis of the sample, we obtained the magnetic field dependence of the transverse susceptibility (χ_t). We show in Fig. 1(f) the χ_t vs H loop for a 10 kHz, 10 mA sinusoidal current. This figure is quite similar to Fig. 1 of Ref. 2, and has a peak corresponding to the GMI peak, in the region where the magnetization direction has a linear variation. The low field peaks are due to domain wall motion close to the coercive field.

B. Domain observations

For the domain observations we used the longitudinal magneto-optical Kerr effect (LMOKE). A Jenapol optical

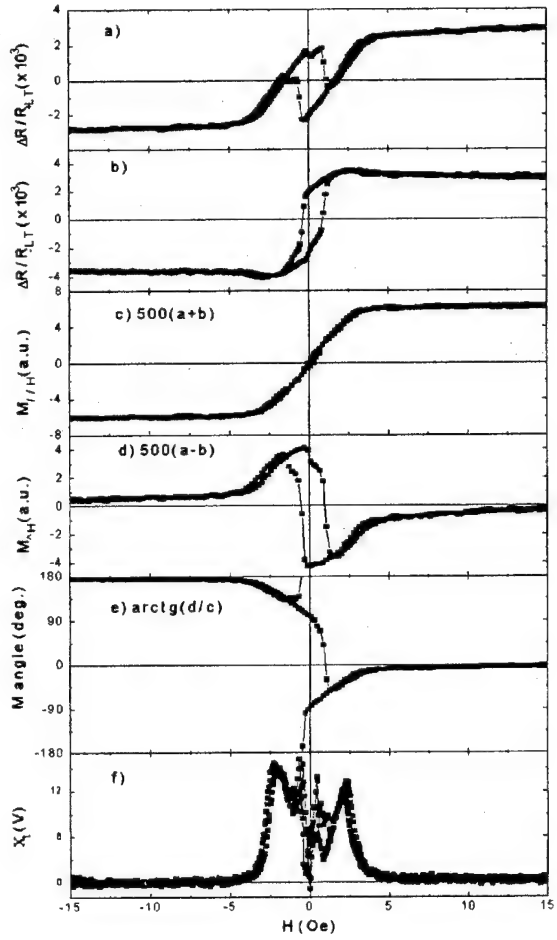

FIG. 1. TLMOKE hysteresis loops for (a) analyzer at 45°; (b) analyzer at −45°; (c) summation of (a) and (b); (d) difference of (a) and (b); (e) magnetization direction; and (f) χ_t.

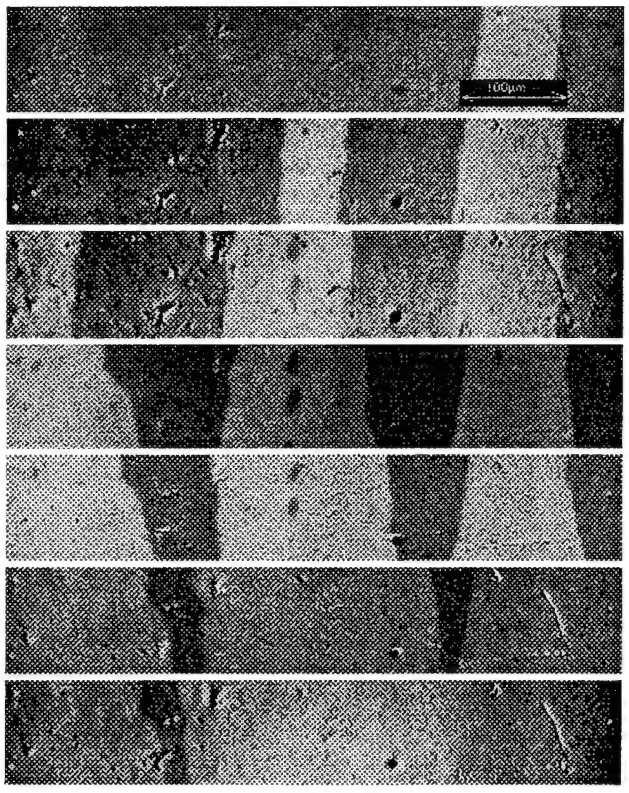

FIG. 2. LMOKE domain observation for the same sample position. From top to bottom, the longitudinal magnetic field is $H=0.08$; 0.11; 0.27; 0.45; 0.57; 0.68; and 0.72 Oe.

microscope coupled to a 10^{-3} lux Hamamatsu video camera and a DT2867 Data Translation video board allowed real time image capture and processing, using capabilities such as frame averaging and background subtraction. The sample could be simultaneously submitted to a variable longitudinal magnetic field up to 70 Oe and an alternating current of 10 mA, flowing along the sample axis. In Fig. 2 we present a sequence of images, obtained at the same position on the sample, for applied magnetic fields in the range from 0.08 to 0.72 Oe, after saturation of the sample in the reverse direction. The horizontal direction in the figure is the ribbon axis. We can see the dark domains shrinking as the longitudinal magnetic field grows, and finally disappearing in a field of about 0.8 Oe. Comparing with Fig. 1, this range corresponds to that of strong variation in the magnetization direction, near the coercive field. Thus, for magnetic fields above about 0.8 Oe, only magnetization rotation occurs in the sample.

In Fig. 3 we show, for the same sample position, the variation of the domain structure due to a current having the form of a square wave of amplitude 10 mA and frequency 5 Hz. This low frequency current generates a magnetic field in the sample that is parallel to the surface and perpendicular to the axis of the ribbon. The sense of the field is inverted on either side of the sample. This means that the magnetization is closed upon itself and that the demagnetizing factor in the transverse direction can be neglected. Figures 3(a), 3(b), and 3(c) were obtained with longitudinal fields $H=0.21$, 0.25, and 0.33 Oe, respectively. The images were obtained by averaging 64 frames after the subtraction of the magnetically saturated background. We then obtained a three-level gray image where the bright and dark areas are the regions where

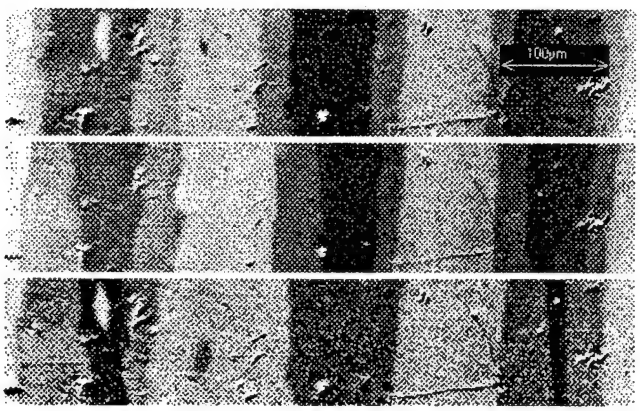

FIG. 3. LMOKE domain observation applying a longitudinal current square wave of amplitude 10 mA. From top to bottom, the longitudinal field is $H=0.21$; 0.25; and 0.33 Oe.

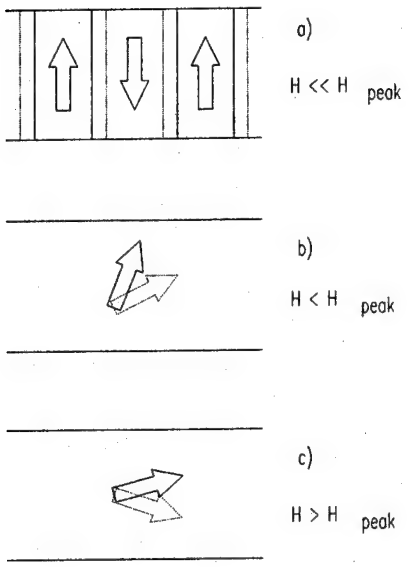

FIG. 4. Model for the domain structure during the GMI measurements.

the magnetization is stable, and the intermediate gray level corresponds to the displacement of the domain walls due to the applied current. The effect of the current is strong: in Fig. 3(a) the displacement of the domain wall is of the order of 30% of the domain dimension. From Fig. 3(c) it is possible to see that, for one sense of the current, the domain structure almost disappears. For larger values of longitudinal field, but certainly below 1 Oe, this side of the sample presents a uniform magnetization.

IV. DISCUSSION

From the experimental results presented here, we can propose a model for the domain structure for the three different field regions of interest. This model is presented in Fig. 4.

(1) For $H \approx 0$, shown in Fig. 4(a), we have a transverse stripe domain structure, where the effect of the current is to displace the domain walls longitudinally. The dashed and solid lines correspond to the position of the domain walls for peak values of the electric current.

(2) For $0 \ll H < H_{\text{peak}}$, H_{peak} being the magnetic field of the GMI or χ_t maximum. In this case, shown in Fig. 4(b), we have a uniform magnetization whose average direction is close to the easy axis. Then the current will produce a small variation of the magnetization direction around this equilibrium direction.

3) For $H > H_{\text{peak}}$, shown in Fig. 4(c), the equilibrium direction is close to the longitudinal one, as the field nears saturation. Then, for both directions of the current, the magnetization direction will alternate between directions symmetrical in relation to the axis of the ribbon.

As the magnetic field generated by the current has a different direction on each side of the ribbon, we can represent the other side by simply reflecting Fig. 4 in a longitudinal plane, perpendicular to the ribbon. Then, for $H \gg 0$, the magnetic behavior of the sample can be represented by an in-plane rotation of the magnetization in a helical domain structure, whose period along the direction of the magnetization is a function of the current and the longitudinal magnetic field. Nevertheless, our measurements do not clarify what happens in the central plane, parallel to the surface of the ribbon. However, we can suppose that the magnetization remains longitudinal, because there is no magnetic field generated by the current in this region.

V. CONCLUSIONS

From the MOKE measurements we completely characterized the domain structure for the conditions of the GMI measurements. It was possible to demonstrate that the maxima in χ_t and GMI correspond to a rotation of the magnetization in a longitudinal helical domain structure.

A position sensor based on magnetoimpedance

R. Valenzuela,[a] M. Vazquez,[b] and A. Hernando
Instituto de Magnetismo Aplicado, UCM, and Instituto de Ciencia de Materiales, CSIC, P.O. Box 155, 28230 Las Rozas, Madrid, Spain

A magnetic-field sensor based on the giant magnetoimpedance phenomenon is presented. It is shown that a low, negative magnetostriction CoFeBSi amorphous wire can be used to detect the presence or passage of moving pieces or vehicles, simply by pasting a small permanent magnet on the vehicles/pieces. The detection is observed as a decrease in the ac voltage on the wire's ends. A system of such devices can be used to monitor and control a number of industrial processes. © *1996 American Institute of Physics.* [S0021-8979(96)58208-X]

I. INTRODUCTION

Some ferromagnetic materials subjected to an ac electric current exhibit a strong decrease in their impedance in the presence of a dc magnetic field. This phenomenon is known as giant magnetoimpedance[1–4] (GMI) and is receiving considerable attention because of its applications in magnetic sensors.

GMI is a classical electrodynamics phenomenon[1,2] which depends essentially on the interaction between the magnetic field created by the ac current and magnetic domains of the sample. GMI has been reported for ribbons and wires; however, it has been observed to be more efficient in low, negative magnetostriction wires, which spontaneously form[5] an outer shell with circumferential domains, and still have a weak circular magnetic anisotropy. Since the magnetization direction in such domains has an alternate circumferential orientation, the interaction between magnetization and the magnetic field created by the ac current is strong. At high frequencies, where the impedance response becomes stronger, GMI shows a further complexity[1,2] due to skin effect, which tends to concentrate the ac field on a small cross section near the surface of the wire.

In this article, an application of GMI as a magnetic-field sensor, adapted to monitor the passage of moving pieces or vehicles typical in many industrial processes, is presented. The development of a system of sensors with a feedback loop to monitor and control the process is also discussed.

II. EXPERIMENTAL TECHNIQUES

We used amorphous wires of composition $(Co_{0.94}Fe_{0.06})_{72.5}B_{15}Si_{12.5}$, of low, negative magnetostriction in the as-cast state, kindly supplied by Unitika Ltd., Japan, prepared by the in-rotating-water technology.[6] A piece of approximately 9 cm was cut, and current and voltage leads were pasted on its ends with Ag paint, after cleaning with a soft acid solution. In order to improve its sensitivity to small, localized magnetic fields, the wire was carefully bent and placed inside a small, acrylic cylinder of 5 and 8 mm inner and outer diameter, respectively, and 4 cm in length. In this way, two sections of the middle part of the wire were exposed to small, localized magnetic fields. The highest sensitivity of wires has been observed[7] to axially applied fields.

To produce an ac current along the wire (in the range up to 20 mA rms), a conventional signal generator (Hameg HM 8030) was used. Voltage measurements were made with a Fluke model 45 multimeter. A dc magnetic field was applied by means of a pair of Helmholtz coils. In other experiments, a small, disk-shaped (5 mm diameter, 2 mm thickness) NdFeB permanent magnet, axially magnetized was used to produce the dc magnetic field on the wire. During all measurements, the wire axis was perpendicularly oriented with respect to the earth's magnetic field.

III. BASIS OF THE SENSOR

The sensor is based on the dependence of total impedance Z on dc applied magnetic field. As is now well documented,[1–4] Z decreases steeply as H increases, see Fig. 1. This behavior can be explained on the basis of the magnetic domain structure[5] of low, negative magnetostriction wires. It can be described as formed by an inner core with axial magnetization, and an outer shell composed of circumferential domains with alternate magnetization. Evidence showing deviations in magnetization directions in both axial and circumferential domains has been recently reported.[8]

As axial field increases, the inner core is first saturated in the field direction; on further increase, the spins in circumferential domains are deviated toward the axial field direction in a nearly pure rotational process.[9] The circumferential

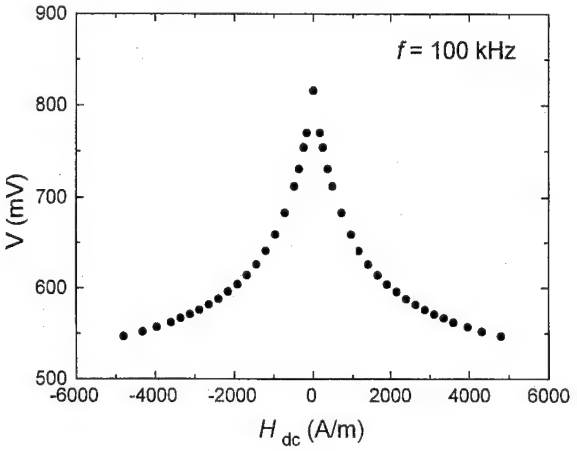

FIG. 1. Voltage response of the CoFeBSi wire, as a function of dc axial field.

[a]On sabbatical leave from the National University of Mexico.

 0021-8979/96/79(8)/6549/3/$10.00

component of magnetization is thus decreased, as well as its interaction with the circular field. Therefore, a decrease in impedance response occurs. This process depends both on ac current frequency and amplitude.

At low frequencies ($f<500$ Hz), the decrease in impedance response associated with the presence of axial fields can be extremely small. For as-cast, CoFeBSi wires, a maximum sensitivity to axial fields is observed[10] in the 10 kHz–1 MHz. For $f>100$ kHz, due to the skin-depth effect, field penetration depth becomes smaller than the actual dimensions of the wire. Then, an additional component of impedance appears, which depends on frequency and local permeability values in a complex way.[1,2] Finally, the difference in response due to H becomes unnoticeable[10] for $f>20$ MHz.

In most reported results, the ac current amplitude is kept constant in spite of the impedance variations, by monitoring the current for each H value. Since we are interested in application conditions, particularly in the voltage response, we have measured the voltage decrease on the wire ends at an initial (at $H=0$) constant current amplitude of 10 mA (rms), as a function of magnetic field, Fig. 1. As the dc field increases, the impedance decreases, leading to an increase in current amplitude. A comparison of Fig. 1 with published Z vs H plots shows that variations of V are smaller than variations in Z for similar experimental conditions. This is due to the fact that Z depends also on the ac current amplitude i. As we have shown elsewhere[11] circumferential magnetization processes occur in a way similar to any domain-wall magnetization process. Since the imaginary part of impedance is associated with inductance and, in turn, magnetic permeability is proportional to inductance,[11] Z reflects these magnetization processes. Z exhibits, therefore, an increase for small i values (start of wall propagation); as i increases, Z goes through a maximum (corresponding to the maximum value in circumferential permeability; about 5 mA for CoFeBSi wires) and then a hyperbolic decrease, as magnetization approaches the saturation value.

As a summary, the most convenient conditions for a maximum sensitivity in GMI are: frequency work in the range 50–500 kHz; and ac current amplitude i in the 8–15 mA range.

IV. EXPERIMENTAL RESULTS AND DISCUSSION

In order to test the capability of the device, the wire (bent inside the plastic cylinder, as discussed above) was submitted to an ac current of 10 mA (rms), at a frequency of 100 kHz. A small permanent magnet was then brought near the wire and the voltage response V was monitored, as a function of the distance between the wire and the permanent magnet (see Fig. 2). As can be observed, V decreases from 770 mV for large distances D to 605 mV, for physical contact. For practical purposes, a minimum distance of 2 cm between the sensor and the magnet can be considered, which leads to a threshold voltage of 680 mV. A decrease from 770 to any value $V\leqslant 680$ mV should then be taken as a detection.

The practical application is schematically shown in Fig. 3. In any industrial process involving the detection of moving objects (assembling parts in a fabrication process, moving vehicles in a storage yard, etc.), a precise control of objects passing nearby a sensor can be performed by monitoring the voltage response in the wire. A decrease to or below 680 mV indicates the passage of an object. The ac signal can be easily rectified to a dc signal, which can then be fed to a data acquisition system and, using a simple computer program including a feedback loop, the whole process can be monitored and controlled. In a process involving paths with several bifurcations, for instance, these can be opened or closed after a given number of vehicles have passed.

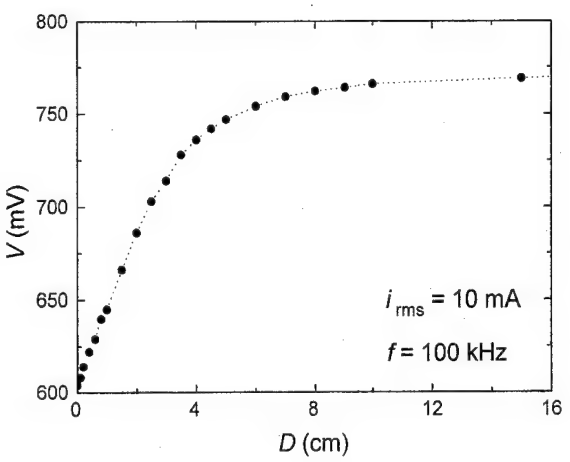

FIG. 2. Voltage dependence on the distance between the sensor and the NdFeB permanent magnet. The magnetic field of the magnet was oriented axially to the wire.

A variety of magnetic-field sending technologies have been recently reviewed.[12,13] One of the most efficient devices is based on a multivibrator circuit whose tuning frequency depends on the effective permeability of two ferromagnetic cores.[14] The external field is detected by its influence on the core's permeability. A related device,[15] which includes an amorphous wire in a resonant circuit, has also been developed. While these devices are certainly more sensitive than the one presented here, they are also more complex and, presumably, more expensive. For our purposes of position sensing, a well-defined threshold in the voltage response is acceptable, instead of a sensitive detection of the magnitude of the dc field. Concerning other sensing technologies, the magnetic sensor presented here has an advantage over moni-

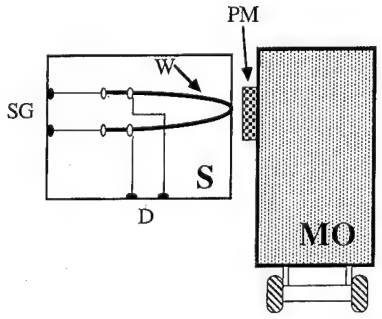

FIG. 3. Layout of the sensor and the moving vehicle, showing the sensor (S), the wire (w), the moving vehicle (MO), the permanent magnet (PM), and the signal generator (SG) and detector circuit (D) contacts, respectively.

toring and control systems based on optical devices in the case of industrial processes involving (nonmagnetic) dusty atmospheres.

As a conclusion, a magnetic sensor based on magnetoimpedance has been presented. Its basic principles, as well as its capabilities have been analyzed.

The field-annealing effect on magnetoimpedance of a zero magnetostrictive metallic glass

S. U. Jen and Y. D. Chao
Institute of Physics, Academia Sinica, Taipei, Taiwan, 11529 Republic of China

A commercially made metallic glass, VAC6030, was used for the magnetoimpedance (MI) measurement. Some samples were annealed at a temperature (T_a=340 °C) slightly below its Curie point, and cooled in a transverse or longitudinal field. The frequency of the probe current was from 10 kHz to 10 MHz. MI is defined as $\Delta R/R \equiv [R(0)/R(H_s)]-1$ and $\Delta X/X \equiv [X(0)/X(H_s)]-1$, where H_s is the saturating field along sample length, R is the resistance, and X is the reactance. At relatively low frequencies MI is mostly inductive, at relatively high frequencies it is resistive, and a crossover could be defined at a characteristic frequency f_0. When the sample is in the as-cast state, f_0=890 kHz. If samples have been field annealed, f_0 could be shifted either downward or upward; f_0 becomes 30 kHz after a transverse anneal, and 8 MHz after a longitudinal anneal. The field annealing would also change the magnitudes of MI. In theory, if $f<f_0$, $\Delta R \propto f^2$ and $\Delta X \propto f$; however, if $f>f_0$, both ΔR and ΔX are dominated by the skin-depth effect, and therefore proportional to $f^{1/2}$ instead. © *1996 American Institute of Physics.* [S0021-8979(96)58308-6]

I. INTRODUCTION

Magnetoimpedance (MI) effect is a high-frequency phenomenon, which describes the changes of impedance (including both resistance R and reactance X) in any ferromagnetic sample, when a magnetic field is applied on it. MI is defined as $\Delta R/R \equiv [R(0)/R(H_s)]-1$ and $\Delta X/X \equiv [X(0)/X(H_s)]-1$, where H_s is the saturating field along the long side of the sample. Note, both $\Delta R/R$ and $\Delta X/X$ are dimensionless. However, sometimes it is also necessary to discuss the absolute MI, namely, $\Delta R \equiv R(0)-R(H_s)$ and $\Delta X \equiv X(0)-X(H_s)$. Then, it is self-explanatory that R in $\Delta R/R$ means $R(H_s)$, instead of $R(0)$. The same applies for X.

In the past, we have taken some nonzero magnetostrictive metallic glasses (in ribbon forms) as samples, and measured their MI responses.[1,2] Two conclusions were reached:

(i) MI effect ($\Delta R/R$ and $\Delta X/X$) is always positive, as found by others;[3,4] and
(ii) at relatively low frequencies MI is mostly inductive, at relatively high frequencies it is resistive, and a crossover occurs at a characteristic frequency f_0 between them.

In this article, a more detailed discussion is given along this line, and the field-annealing effect on MI of a zero magnetostrictive glass is presented as an example.

II. EXPERIMENTS

Amorphous VAC6030 ribbons, from Vacuumschmelze GmbH, were taken as samples. Although it is not our primary interest to compare the absolute changes of ΔR and ΔX due to field annealings, we tried to keep the sizes of all samples roughly the same: $20(l)\times 2(w)$ mm^2. The average thickness is $t \cong 23$ μm. The ribbon could be thinned in a 5% nital solution at a 0.38 μm/min rate.

The details of a MI measurement were described before.[1,2] The rms magnitude of the ac probe current at frequency f is kept constant, I=4.8 mA. In this study, there were two kinds of quasistatic scans:

(i) the field scan ($|H| \leqslant 300$ Oe) at a fixed f (Fig. 1), and
(ii) the frequency scan (10 kHz$\leqslant f \leqslant$10 MHz) either in a zero or saturating field.

Some samples were annealed at a temperature slightly below the Curie point (T_c=350 °C) in vacuum. During an anneal, a field of 300 Oe was applied either longitudinally ($\parallel$) or transversely ($\perp$) with respect to sample length. In the end, the samples were field cooled at a rate of 1–3 °C/min.

III. RESULTS AND DISCUSSION

Since the sample is in a thin sheet form, MI behaviors are classified into two parts: one with $\delta > t/2$ and the other with $\delta < t/2$. $\delta \equiv (2\rho/\omega\mu)^{1/2}$ is the skin depth, ρ is the dc resistivity, $\omega = 2\pi f$, and μ is the permeability of the material. In the former, since both the current and field penetrate through the sample (for $|z|<t/2$), the current distribution is $J(z)=J_0=I/(tw)$, independent of z, and MI is resistance limited. In the latter, as the current and field are attenuated, the current distribution becomes $J(z)=J_1 e^{-|z\pm(t/2)|/\delta}$, and MI is inductance limited. Obviously, when f is scanned, there will exist a transition frequency f_0 from the resistance-

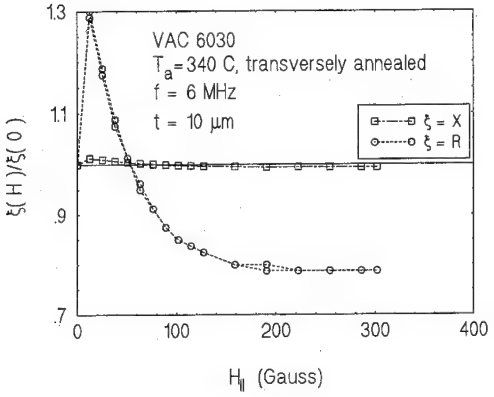

FIG. 1. A typical field dependence of MI in a thinned and field-annealed VAC6030 ribbon. Frequency f of the ac probe current was fixed.

 0021-8979/96/79(8)/6552/3/$10.00

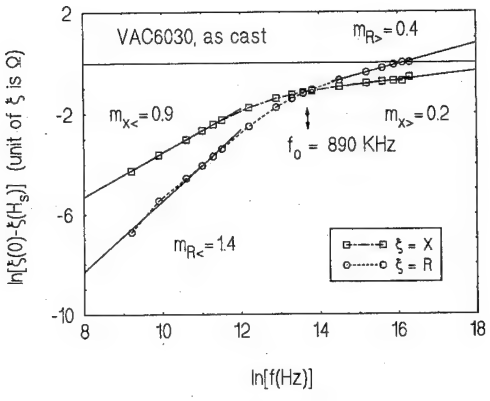

FIG. 2. $\Delta R=R(0)-R(H_s)$ and $\Delta X=X(0)-X(H_s)$, where H_s is the saturation field. $\ln(\Delta R)$ and $\ln(\Delta X)$ are plotted as a function of $\ln f$, respectively, for the as-cast VAC6030. f is the frequency of the probe current. f_0 is the characteristic frequency which shows the crossover from a inductive to a resistive MI.

limited to inductance-limited MI region, or vice versa. These features are evident in Fig. 2 and Table I. f_0 is equal to 890 kHz, 30 kHz, 8 MHz, and 400 kHz in the as-cast, $\perp$ annealed, $\parallel$ annealed, and $\perp$ annealed plus thinned VAC6030, respectively.

As is well known, MI effect is closely associated with the domain structures in the sample.[4,5] Meanwhile, the field anneal is the most common method used to orient stripe domains either perpendicular ($\perp$ anneal) or parallel ($\parallel$ anneal) to sample length.[6,7] In the $\perp$ annealed case, the circumferential field, generated by I, causes an S-shaped distortion for each domain wall.[5] The removal of quenched-in stresses and wall translations (at least the upper or lower part of a wall) would enhance the local μ value greatly.[8] As a result, δ is reduced more in $\perp$ annealed sample than in as-cast one for a fixed frequency (note, the small decrease of ρ due to annealing is negligible). This explains why f_0 is shifted downward (from 890 to 30 kHz), when the as-cast case is compared with the $\perp$ annealed case; however, for the $\parallel$ annealed sample, the circumferential field acts in a hard-axis direction. The rotational permeability at high f must be the smallest among the three cases (as cast, $\perp$, and $\parallel$).[7] Therefore, f_0 of $\parallel$ annealed sample is shifted upward from 890 kHz to 8 MHz. Furthermore, from the criterion $(t/2)=\delta=(2\rho/\omega_0\mu)^{1/2}$, it is easy to find the characteristic frequency $\omega_0=2\pi f_0=(8\rho/t^2\mu)$. Then, the shiftings of f_0 stated above are all in agreement with the predictions from the formula of ω_0, and may be estimated quantitatively, if μ is known exactly. Similarly, in Table I we see that if a sample has been thinned from $t=23$ to 10 μm, and $\perp$ annealed, f_0 could be shifted back from 30 to 400 kHz as expected.

TABLE I. f_0 is the characteristic frequency, which separates the resistance-limited from the inductance-limited MI regions. $m_{X<}$, $m_{R<}$, $m_{X>}$, and $m_{R>}$ are the slopes from the fittings of the $\ln\Delta R$ (or $\ln\Delta X$) vs $\ln f$ plot. $<$indicates $t/2<\delta$, and $>$ indicates the opposite.

VAC6030	f_0(Hz)	$m_{X<}$	$m_{R<}$	$m_{X>}$	$m_{R>}$
$t=23$ μm as cast	890 k	0.9	1.4	0.2	0.4
$t=23$ μm $\perp$ annealed	30 k	...	...	0.3	0.4
$t=23$ μm $\parallel$ annealed	8 M	1.0	1.4	...	...
$t=10$ μm $\perp$ annealed	400 k	0.8	1.8	0.5	0.6

In regard to the f dependence of ΔR and ΔX in the $\delta>t/2$ region, Ref. 5 has shown that if walls are perpendicular to the current, $\Delta R\propto f^2$ and $\Delta X\propto f$. By a similar argument, ac domain rotations (in the $\parallel$ case) would also lead to a result that ΔR and ΔX are proportional to ω^2 and ω, respectively. From Fig. 2 and Table I, the slopes $m_{X<}$ and $m_{R<}$ are defined from the $\ln\Delta X$ vs $\ln f$ and $\ln\Delta R$ vs $\ln f$ plots for the as-cast sample. $<$ sign indicates the low-f region to satisfy $t/2<\delta$. Conversely, $m_{X>}$ and $m_{R>}$ could also be found. The ellipses in Table I indicate that the corresponding f_0 has been shifted too close to either bound of the frequency measurement and that causes insufficient data for the fitting. For the as-cast sample, although $m_{X<}=0.9$ is close to 1, $m_{R<}=1.4$ is below the value 2, perhaps because the domain structures in the as-cast sample[9] are not all in agreement with the stripe domains assumed in the model. Nevertheless, for the $t=10$ μm and $\perp$ annealed sample, both the values of $m_{X<}$ and $m_{R<}$ agree with the predicted values respectively. The reasons are threefold:

(i) after $\perp$ anneal stripe domains are oriented properly;
(ii) since the circumferential field is proportional to sample thickness t, by thinning t (and/or widening w) the wall displacement Δx is further reduced for the same magnitude of the probe current; and
(iii) the model calculation in Ref. 5 is valid for small Δx, i.e., $|I|\ll I_{\text{sat}}=(4\sigma w)/(M_s t)$.

To discuss the skin-depth effect dominant region ($t/2>\delta$), a simple calculation shows that

$$R(f,H)\equiv R_{\text{dc}}(\mathscr{y}/2)[(\sinh\mathscr{y}+\sin\mathscr{y})/(\cosh\mathscr{y}-\cos\mathscr{y})]$$

and

$$X(f,H)=R_{\text{dc}}(\mathscr{y}/2)[(\sinh\mathscr{y}-\sin\mathscr{y})/(\cosh\mathscr{y}-\cos\mathscr{y})]+\omega L_e,$$

where $\mathscr{y}=t/(2\delta)$, $R_{\text{dc}}=\rho/t$, and L_e is the external part of self-inductance of the sample. When $H\geqslant H_s$, the sample behaves like a nonmagnetic conductor; the domain effect has been eliminated. Therefore, no matter if the sample has been field annealed, $R(f,H_s)\simeq$const and $X(f,H_s)\propto\omega L_e$ as shown in Fig. 3. This is true as long as $t\leqslant 4\delta$. However, in the high-f limit, we have

$$R(f,H)=R_{\text{dc}}(kf^{1/2})$$

and

$$X(f,H)=R_{\text{dc}}(k'f^{1/2})+2\pi fL_e,$$

where both k and k' are functions of t, ρ, and μ, respectively. Since only μ or δ is a function of H, but L_e is not, we find that in the high-f region

$$\Delta R(f)\equiv R(f,0)-R(f,H_s)\propto f^{1/2}$$

and

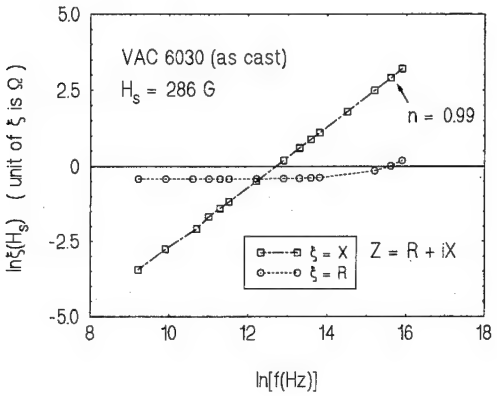

FIG. 3. The frequency dependence of $R(H_s)$ and $X(H_s)$ in an as-cast VAC6030 sample. n is the slope of the $\ln[X(H_s)]$ vs $\ln f$ curve. $R(H_s)$ is almost independent of f.

$$\Delta X(f) \propto f^{1/2},$$

also. Hence, in the inductance-limited case, both $m_{X>}$ and $m_{R>}$ approach the same value 1/2. Table I has summarized all $m_{X>}$ and $m_{R>}$. Once again, for the thinner sample (t=10 μm), the agreement between experiment and theory is better.

Finally, Figs. 4 and 5 show the MI effect, $\Delta R/R$ and $\Delta X/X$, plotted as a function of f. Here, it is noted that since l and w of each sample were deliberately kept the same sizes, the absolute value of R or X does not vary more than 2% from one sample to another at a fixed f. On the other hand, the change of ΔR or ΔX due to field annealing is often more than 40%. Therefore, the trends observed in Fig. 2 for ΔR and ΔX agree with that in Figs. 4 and 5 for $\Delta R/R$ and $\Delta X/X$ in that a low-f MI is inductive and at high-f MI is resistive. Also, the variations of $\Delta R/R$ and $\Delta X/X$ because of thinning or field-annealing are in proportion to that of ΔR and ΔX for each f. The explanations have been given in Ref. 2. Since the

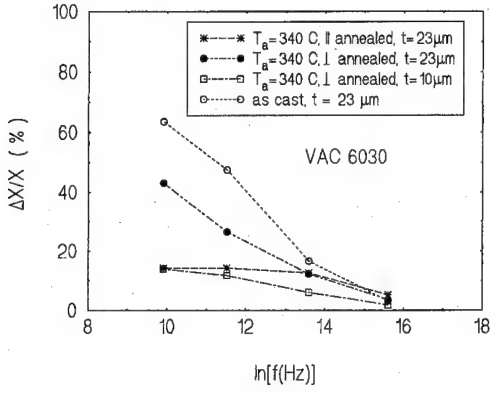

FIG. 4. Field-annealing effects on $\Delta X/X$ at various frequencies f. T_a is the annealing temperature. A longitudinal (∥) or transverse (⊥) field was applied with respect to sample's length during annealings. t is the thickness of the sample.

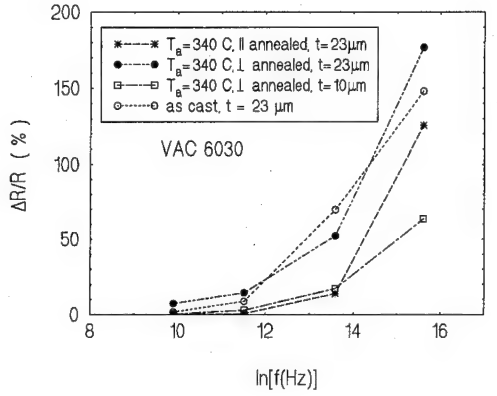

FIG. 5. Field-annealing effects on $\Delta R/R$ at various frequencies f. The rest of the notations are the same as in Fig. 4.

precautions have been taken, even if $\Delta R/R$ and $\Delta X/X$ may be a function (l/w) or (w/l), we think Figs. 4 and 5 do reflect the field-annealing effect, rather than other uncertainties from the variations of l or w among different samples.

IV. CONCLUSION

Zero magnetostrictive VAC6030 samples have been field-annealed at T=340 °C. MI measurements were performed for each sample. The field-annealing effects on MI were studied. Those include

(i) how the characteristic frequency f_0 is shifted by various field annealings,
(ii) the f dependence of ΔR and ΔX in the corresponding two frequency regions ($t/2 < \delta$ and $t/2 > \delta$), and
(iii) the changes of $\Delta R/R$ and $\Delta X/X$ due to different field annealings.

The existing models could partially explain the phenomena observed.

We report room-temperature transversal magnetoimpedance (TMI) and Hall-effect measurements performed in ribbons of the zero-magnetostriction soft-ferromagnet $Co_{70.4}Fe_{4.6}Si_{15}B_{10}$ alloy annealed at 587 K for 15 min at a dc magnetic field of 2 kOe. The annealing showed little effect on the magnetostriction of the samples. The frequency f and the amplitude I_{ac} of the current used in the measurements, and the measuring magnetic field H were varied in the intervals $10 \leqslant f \leqslant 10^5$ Hz, $2.5 \leqslant I_{ac} \leqslant 25$ mA, and $-15 \leqslant H \leqslant 15$ kOe, respectively. The magnetic field dependence of the TMI shows a peak which is strongly dependent on f and on I_{ac}. It reaches the giant value of 28% at $H=350$ Oe for $f=100$ kHz and $I_{ac}=25$ mA. This TMI giant value is of the same order of the giant longitudinal magnetoimpedance (GLMI) but its peak is positioned in a magnetic field two orders of magnitude larger than the value obtained for the GLMI. The Hall effect yielded a value of $R_S=0.43$ $\mu\Omega$ cm kOe^{-1}. Peaks which are also frequency dependent were observed at the Hall voltage. © *1996 American Institute of Physics.* [S0021-8979(96)58408-0]

I. INTRODUCTION

Recently we showed that annealed amorphous $Co_{70.4}Fe_{4.6}Si_{15}B_{10}$ in an applied magnetic field H exhibits sharp peaks in the longitudinal magnetoresistance.[1] The annealing plays a major role in the shape and size of the magnetoimpedance.[2] The magnitude of these peaks varies strongly with the frequency f and with the amplitude of the ac current I_{ac} used to measure the magnetoresistance. They have their magnitude increased either by increasing f or I_{ac}, and reach giant values at low magnetic fields.[3,4] A f and I_{ac} dependence was also observed in the signal phase and the effect was later called giant magnetoimpedance (GLMI). More recently, GLMI was also observed in wires made of amorphous[5–9] and nanocrystalline[10] materials. These phenomena opened interesting questions on electronic transport and its interrelation to magnetic properties and made amorphous materials as strong candidates for applications in magnetic sensor technology.

The transverse field annealing induces an anisotropy which results in a regular pattern of domains aligned antiparallel to each other. This pattern can be seen by, e.g., Kerr-effect spectroscopy.[11] The GLMI in amorphous ribbons has its origin on the combined effect of domain rotation and domain-wall oscillations and the high permeability of this material. These effects are equally important to determine the frequency and magnetic-field dependences of the magnetoimpedance of samples with induced anisotropy. The oscillations are due to the coupling of the domains with the transverse in-plane ac magnetic field h generated by the electrical current. The high permeability leads to a small skin depth even at low frequencies and the experiments essentially measure the surface impedance of the samples. A theoretical model based on this assumption allows one to calculate the magnetoimpedance with a good agreement with the experimental results.[12] Depending on the annealing and measuring conditions one can obtain a regular circular pattern of domain in wires with negative magnetostriction and the skin depth plays also an essential rule in determining the size and shape of the magnetoimpedance in these systems.[5–10]

As far as we know, up to now the giant magnetoimpedance effect has only been observed with the applied magnetic field H parallel to the ac current (longitudinal magnetoimpedance). However, some technological applications require H being applied perpendicularly to the plane of the ribbon. In this article we demonstrate the existence of a transverse magnetoimpedance effect in pieces of ribbons of $Co_{70.4}Fe_{4.6}Si_{15}B_{10}$. The effect of an ac current on the Hall effect and the changes in the magnetostriction due to annealing in samples under an applied magnetic field are also reported. Results for the I_{ac} and f dependencies of the peaks of the GLMI in magnetic field are included for comparison.

II. SAMPLES AND TECHNIQUES

The samples were prepared by a melt-spinning technique in a He atmosphere. Pieces of a ribbon of $Co_{70.4}Fe_{4.6}Si_{15}B_{10}$ 11 mm long, 1 mm wide, and 40 μm thick were used throughout the experiments. The samples were annealed in a He atmosphere for 15 min at 587 K in a magnetic field of 2 kOe applied transverse to the length of the samples in the plane of the ribbon.

A modified small angle magnetization rotation technique[13,14] (SAMR) was employed to measure the magnetostriction of samples annealed in the same manner like those used in the magnetoimpedance and Hall-effect measurements.

The magnetoimpedance was measured using an ac four-probe technique. The four leads were attached to samples

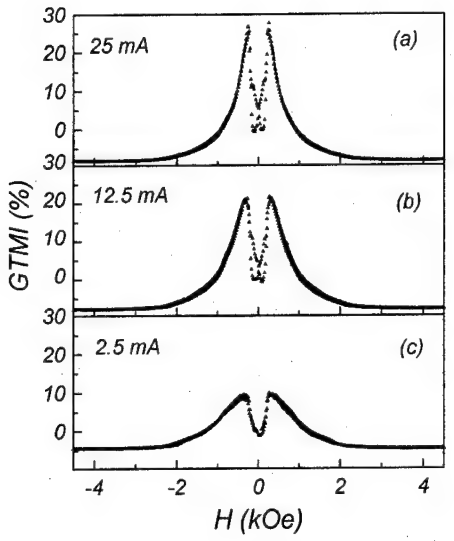

FIG. 1. Transversal giant magnetoimpedance (GTMI) vs applied magnetic field H for three values of I_{ac} and for $f=100$ kHz. The values of the GTMI are given in percent relative to the resistivity at zero applied magnetic field.

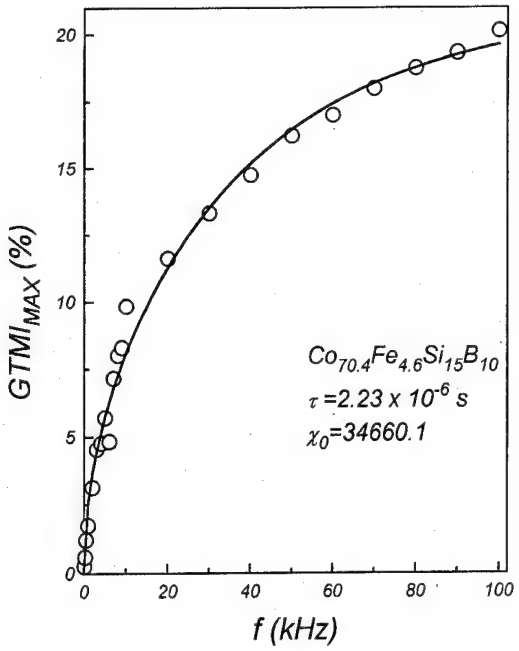

FIG. 2. Frequency dependence of the maximum value of the GTMI vs frequency for $I_{ac}=12.5$ mA. The solid line is a fit to a theoretical model.

cleaned with $HNO_3(10\%)$ using silver paint. Contacts with less than 1 Ω were obtained with this process. The magnitude and the phase of the magnetoimpedance were detected with a lock-in amplifier operating in the Z-Θ mode. A pair of Helmholtz coils generated the magnetic field used to measure the GLMI while the giant transversal magnetoimpedance (GTMI) was measured in a conventional magnet.

The Hall effect was measured with the four leads glued directly to the sample using silver paint. The measurements were made using ac current and the Hall voltage was also detected by a lock-in amplifier. The amplitude of the current was kept at 12.5 mA while its frequency was varied from 10 to 10^5 Hz. The magnetic field was applied perpendicularly to the plane of the ribbon and its amplitude was swept in the interval $-15<H<15$ kOe.

III. EXPERIMENTAL RESULTS

Figure 1 shows the transversal magnetoimpedance measured as function of the applied dc magnetic field H for three values of current, namely, (a) 25, (b) 12.5, and (c) 2.5 mA, and for $f=100$ kHz. The GTMI is increased by increasing I_{ac}. The maximum value of the GTMI as a function of the frequency is plotted in Fig. 2. The solid line is a fit to Eq. (14) reported in Ref. 12,

$$Z=\frac{L}{2lc}\left(\frac{4\pi\rho\omega}{1+\omega^2\tau^2}\right)^{1/2}$$
$$\times[(1+\omega^2\tau^2+4\pi\chi_0)^2+(4\pi\chi_0\omega\tau)^2]^{1/4},$$

where Z is the magnetoimpedance, χ_0 is the static susceptibility, τ is the dynamical susceptibility relaxation time, ρ is the resistivity, L and l are ribbon length and width, respectively, c is the speed of the light, and ω is the angular frequency $(=2\pi f)$. The maximum of the GTMI measured as function of I_{ac} for $f=100$ kHz is shown in Fig. 3. The value of the magnetic field where the GTMI reaches it maximum (H_T) also depends on I_{ac}. This result is shown in the upper inset of Fig. 3. For small current values $H_T=500$ Oe while for higher currents it is about 350 Oe. The lower inset in Fig. 3 shows the I_{ac} dependence of H_L for the GLMI for three values of f. For lower frequencies the dependence on I_{ac} is more pronounced for the GLMI.

Figure 4 shows the Hall resistivity measured for $-15<H<15$ kOe, $f=1$ kHz, and $I_{ac}=12.5$ mA. The lower and

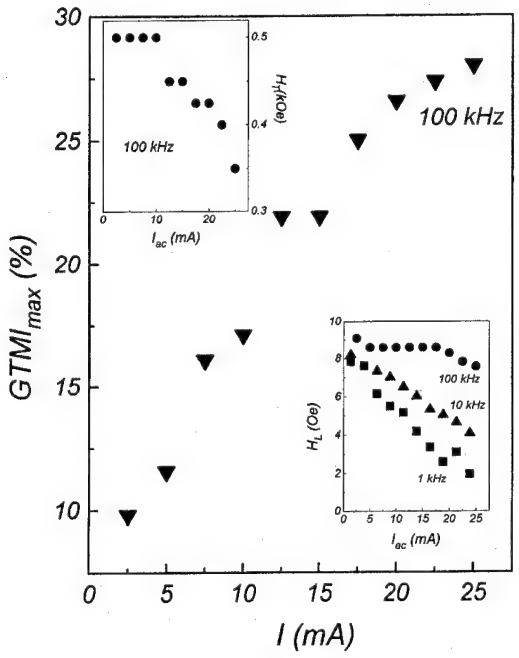

FIG. 3. Maximum value of the GTMI vs I_{ac} for $f=100$ kHz. The values of the GTMI are given in percent relative to the resistivity at zero applied magnetic field. The upper inset shows the I_{ac} dependence of H_T (magnetic field corresponding to the maximum value of the GTMI) while the lower one shows the same dependence for H_L for three values of f.

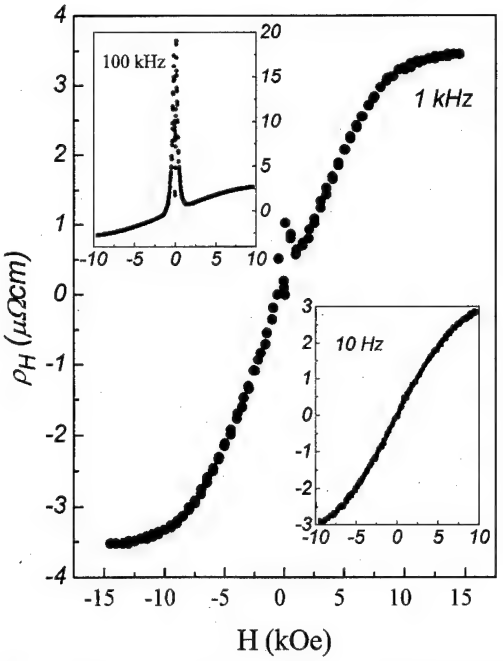

FIG. 4. Magnetic-field dependence of the Hall resistivity for $I_{ac}=12$ mA and $f=1$ kHz. Upper and lower insets show the results for $f=100$ kHz and 10 Hz, respectively. Peaks at the center of the curves are observed for $f=1$ and 100 kHz.

upper insets show the Hall resistivity for $f=10$ and 10^5 Hz, respectively. Very large peaks which depend on the frequency of the current are also observed in the Hall effect. The Hall resistivity data yields $R_0=-0.02\ \mu\Omega\,\mathrm{cm\,kOe^{-1}}$ and $R_S=0.43\ \mu\Omega\,\mathrm{cm\,kOe^{-1}}$ for the ordinary and spontaneous Hall coefficients, respectively, obtained from the 1 kHz curve.

We also measured the magnetostriction of $Co_{75-x}Fe_xSi_{15}B_{10}$ for samples annealed in a magnetic field and as quenched for $2<x<6$. We found that annealing changes significantly the magnetostriction of the samples with positive or negative values. However, within the experimental resolution (2×10^{-8}) we found no change in the magnetostriction of samples with zero magnetostriction ($x=4.6$).

IV. DISCUSSION AND CONCLUSIONS

The overall shape and size of the GTMI peaks are quite similar to those observed for the longitudinal magnetoimpedance. Indeed, the f and I_{ac} dependencies for the GTMI maximum and the I_{ac} dependence for H_T show that the same physics is behind both cases. The results do also show that the model proposed in Ref. 12 is also valid for the transverse effect. In the model, the magnetoimpedance increases roughly with the square root of f and the peaks shifts to lower H by increasing I_{ac}. The deviation of the fit from the data observed in Fig. 2 for intermediate and high frequencies may be in part due to frequency-dependent contributions not taken into consideration in our model.[15] The main difference among the GTMI and the GLMI is the value of H for which they attain their maximum values. $H_T=500$ Oe for the GTMI while $H_L=10$ Oe for the GLMI. This difference is mainly due to the demagnetizing field which is larger for H applied perpendicular to the plane of the ribbon. These results were confirmed by measuring the magnetization versus H curve in both cases.

Skew scattering and side-jump mechanisms yield a resistivity dependence on the anomalous Hall coefficient ($R_S=a\rho+b\rho^2$). This ρ dependence was investigated in detail in magnetic multilayer systems which show giant magnetoresistance behavior.[16] The anomalous Hall effect in multilayers showed a strong correlation among R_S and ρ as expected from these two scattering processes. In our Hall resistivity results we also observed peaks quite similar to the ones present in the resistivity data. However, from these preliminary results it is quite difficult to distinguish, e.g., if its origin is on a pseudo-Hall effect from a small component of H in the plane of the sample or if it is due to the ρ dependence in R_S. In fact, from R_S one would probably expect nonsymmetric peaks around $H=0$ since the magnetization changes sign when $H<0$ and ρ is always positive. More experiments are underway to better clarify these points.

In short, we showed that giant magnetoimpedance can also be observed with H applied perpendicularly to the plane of the ribbon (transverse magnetoimpedance). The H, f, and I_{ac} dependencies for the GTMI are very similar to those observed for the longitudinal magnetoimpedance reported earlier. These results are somewhat important for magnetic sensor technology.

A theoretical model for the giant magnetoimpedance in ribbons of amorphous soft-ferromagnetic alloys

F. L. A. Machado and S. M. Rezende
Departamento de Física, Universidade Federal de Pernambuco, 50670-901 Recife-PE, Brazil

Giant magnetoimpedance (GMI) measured in ribbons of the soft ferromagnet $Co_{75-x}Fe_xSi_{15}B_{10}$ annealed in the presence of a transverse magnetic field exhibits peaks in its field dependence. The GMI is strongly dependent on the magnitude of the longitudinal field and on the frequency of the applied current. We present a theoretical model which explains the existence of the peaks and its frequency dependence. The model is based on the skin depth effect and on the domain-wall motion due to the magnetic field and the ac current. © *1996 American Institute of Physics.* [S0021-8979(96)58508-9]

Amorphous ribbons and wires of soft ferromagnetic alloys have attracted considerable attention in recent years due to their unique physical properties and potential technological applications. One of the most interesting phenomena observed in these materials, is the frequency-dependent giant magnetoimpedance (GMI) exhibited by the low-magnetostriction alloy $Co_{75-x}Fe_xSi_{15}B_{10}$.[1–6] Particularly interesting is the sharp peak in the field dependence of the GMI in transversely annealed ribbons with concentration $x=4.6$.[1,2,6] In this article we present a model which explains the peak in magnetic field and its frequency dependence.

Figure 1 illustrates the experimental geometry used to observe the GMI effect in amorphous ribbons of CoFeSiB prepared by melt spinning techniques. The sample is previously annealed in a field applied in the ribbon plane, perpendicularly to the long direction. This is known to introduce a transverse anisotropy,[7–9] which results in a domain structure consisting of transverse stripe domains. The impedance $\mathbf{Z}=Z\exp(i\theta)$ is measured through an alternating current $I=I_0\exp(i\omega t)$ in the presence of a longitudinal magnetic field H. In alloys with composition $Co_{70.4}Fe_{4.6}Si_{15}B_{10}$, which have nearly zero magnetostriction, the variation of Z with H has a pronounced peak at fields of a few Oe. As a result, the magnetoimpedance ratio $\mathrm{MIR}=10^2[Z(H)-Z(0)]/Z(0)$, has a double peak structure. Figure 2(a) shows the peak on the positive H part only. Furthermore, the MIR is a strong function of frequency $f=\omega/2\pi$, increasing continuously with f up to around 100% at about 1 MHz.[6] Notice that in samples with concentration different than $x=4.6$, the MIR is also frequency dependent, but it does not have the double peak structure in field and has a much smaller maximum value.

Since the frequency dependence of the impedance in CoFeSiB with $x\neq 4.6$ has been previously explained by classical electrodynamics,[4] we use here a similar concept. The basic idea is that in a metal with very large initial transverse magnetic permeability μ_t, the ac current is essentially confined to surface layers with thickness given by the skin depth,[10]

$$\delta=c\left(\frac{\rho}{2\pi\omega\mu_t}\right)^{1/2}, \tag{1}$$

where c is the speed of light and ρ the dc resistivity. For typical values $\rho=130\ \mu\Omega$ cm and $\mu_t=10^5$, the skin depth is $10<\delta<2000$ Å for $10^2<f<10^7$ Hz. These values are much smaller than typical ribbon thickness (50 μm), so that the current flows very near the upper and lower surfaces of the sample. Thus, the impedance of the sample is approximately[10]

$$\mathbf{Z}=(1-i)\frac{\rho L}{2l\delta}=\frac{(1-i)L}{2lc}(2\pi\rho\omega\mu_t)^{1/2}, \tag{2}$$

where l and L are the ribbon width and length, respectively. Equation (2) shows that the behavior of Z with field and frequency is determined by the factor $\sqrt{\omega\mu_t}$, hence, it is dictated by the response of the domains to the longitudinal field H and the ac current I.

Field dependence: The motion of the domain walls results from the combined effect of the external longitudinal field H and the transverse field h created by the current, $h=I/2t$, where t is the ribbon thickness.[11] Since the current flows along the two surfaces, we analyze only the behavior of the domains on one surface. Assuming initially quasistatic conditions, the domain-wall displacement x from the equilibrium configuration ($H=h=0$) and the directions of the domain magnetizations are obtained by minimizing the free energy density. This is the sum of the following terms:[12]

$$U_z=M_sH[(\alpha-1)\sin\phi_2-\alpha\sin\phi_1], \tag{3}$$

$$U_A=K[\alpha\sin^2\phi_1+(1-\alpha)\sin^2\phi_2], \tag{4}$$

$$U_{zt}=M_sh[(1-\alpha)\cos\phi_2-\alpha\cos\phi_1], \tag{5}$$

$$U_W=\tfrac{1}{2}kAx^2, \tag{6}$$

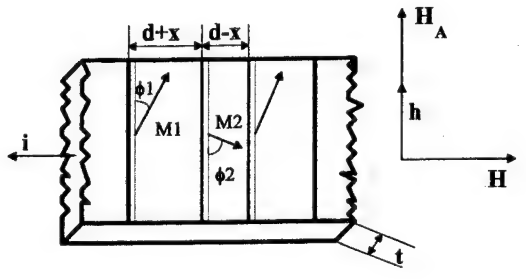

FIG. 1. Illustration of a piece of an amorphous ferromagnetic ribbon used for measuring magnetoimpedance. The magnetizations of the stripe domains, the relevant fields, and the probe current are also shown.

 0021-8979/96/79(8)/6558/3/$10.00

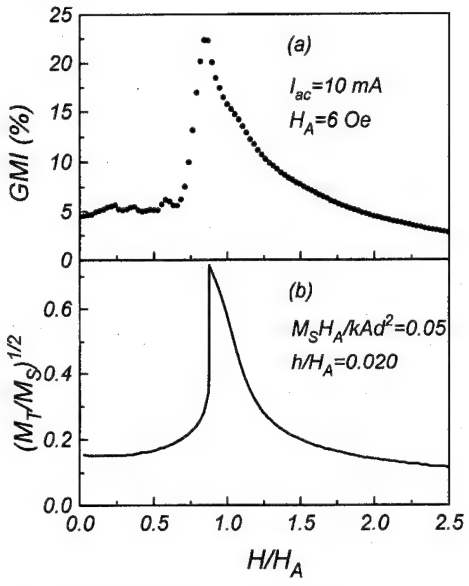

FIG. 2. Comparison between the giant magnetoimpedance ratio measured in Ref. 6 [Fig. 3(c)] in $Co_{70.4}Fe_{4.6}Si_{15}B_{10}$ and the relative impedance calculated with the theoretical model.

where U_z, U_A, U_{zt}, and U_W are, respectively, the Zeeman, anisotropy, transverse Zeeman, and wall energy contributions; ϕ_1 and ϕ_2 are the angles between the two domain magnetizations and the easy axis direction induced by the transverse annealing, shown in Fig. 1; $\alpha=1/2+x/d$ is the fraction of the volume occupied by the domains at angle ϕ_1; M_s is the saturation magnetization; K is the anisotropy constant; A is the wall area per unit volume; and k denotes the mean wall stiffness in a model in which the domain-wall energy is represented by a single parabolic potential. Note that the magnetoelastic energy has been neglected because we are mainly concerned with a nearly zero magnetostriction alloy.

The angles ϕ_1 and ϕ_2 and the wall displacement x can be obtained by $\partial U/\partial\phi_1=\partial U/\partial\phi_2=\partial U/\partial x=0$. These equations yield analytical solutions in terms of the variables H and h and the material parameters K, M_s, k, d, and A. These solutions are

$$\cos^4\phi_1+2b\cos^3\phi_1-(1-g^2)\cos^2\phi_1 -2b\cos\phi_1-b^2=0, \tag{7}$$

$$\cos^4\phi_2-2b\cos^3\phi_2-(1-g^2)\cos^2\phi_2 +2b\cos\phi_2-b^2=0, \tag{8}$$

$$x=\frac{M_s}{kAd}\left(H(\sin\phi_1-\sin\phi_2)-\frac{H_A}{2}(\sin^2\phi_1-\sin^2\phi_2) +h(\cos\phi_2+\cos\phi_1)\right), \tag{9}$$

where $H_A\equiv 2K/M_s$ is the anisotropy field, $b\equiv h/H_A$, and $g\equiv H/H_A$. Solving Eqs. (7)–(9) we obtain ϕ_1, ϕ_2, and x which are used to calculate the transverse susceptibility,

$$\chi_t=\frac{M_t}{h}=\frac{M_s}{h}\left(\frac{1}{2}(\cos\phi_1-\cos\phi_2) +\frac{x}{d}(\cos\phi_1+\cos\phi_2)\right). \tag{10}$$

Physically what happens is this: For zero current, $h=0$ and then $\phi_1=\phi_2$. In this case, as the longitudinal field increases, the two domains rotate with the same angle until $\phi_1=\phi_2=90°$ for $H=H_A$. The longitudinal magnetization increases linearly as H varies from 0 to H_A, where saturation is reached, whereas the domain displacement and the transverse magnetization are always zero. However, for $h\neq 0$, ϕ_2 increases more rapidly than ϕ_1, resulting in $x\neq 0$ and a nonzero transverse magnetization. Figure 2(b) shows the square root of the transverse magnetization versus H/H_A for $h/H_A=0.02$ (which corresponds to a current of 10 mA) and $M_sH_A/kAd^2=0.05$. The jump observed at a field value near H_A is due a flipping of the domains pointing opposite to h, made possible by the fact that the anisotropy energy curve is almost flat at $\phi_2\simeq 90°$. Comparing (a) and (b) in Fig. 2 we see that the qualitative agreement between the results of the model and the data is quite good.

Frequency dependence: The frequency dependence of the transverse susceptibility can be obtained from the analysis of the domain dynamics. In a first approximation we assume that the domain dynamics is limited by the wall motion and not by the magnetization rotation. In this approximation the dynamics is not expected to vary with H. So we consider $H\ll H_A$, so that $\phi_1\simeq\phi_2\ll 90°$. In this case the force per unit volume acting on the domain walls is $-\partial U/\partial x\simeq 2hM_s/d - kAx$. Thus, the equation of motion for the domain walls is

$$m\frac{d^2x}{dt^2}=\frac{2hM_s}{d}-kAx+\gamma\frac{dx}{dt}, \tag{11}$$

where m is the wall mass per unit volume and the last term is a domain-wall drag force introduced phenomenologically. Assuming an alternating transverse field $h\exp(i\omega t)$ generated by the ac current and neglecting the wall mass we obtain for the displacement

$$x=\frac{2M_s/d}{kA-i\omega\gamma}he^{i\omega t}. \tag{12}$$

Using Eq. (12) in Eq. (10) we obtain the transverse susceptibility

$$\chi_t=\frac{\chi_0}{1-i\omega\tau}, \tag{13}$$

where $\chi_0=4M_s^2/kAd^2$ is the static susceptibility and $\tau=\gamma/kA$ is the relaxation time. Similar expression for the dynamical susceptibility is being used[4,11] for different magnetic field and frequency regimes by choosing the appropriate τ. With this result, the magnitude of the impedance in Eq. (2) becomes

$$Z=\frac{L}{2lc}\left(\frac{4\pi\rho\omega}{1+\omega^2\tau^2}\right)^{1/2}[(1+\omega^2\tau^2+4\pi\chi_0)^2 +(4\pi\chi_0\omega\tau)^2]^{1/4}. \tag{14}$$

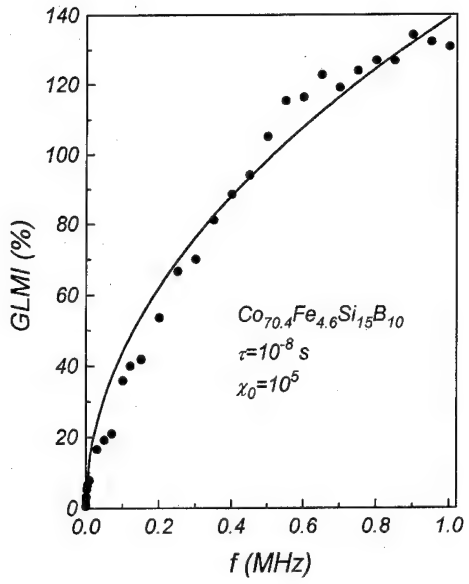

FIG. 3. Fit of the theoretical frequency dependence of the giant magnetoimpedance to the data of Ref. 6.

Figure 3 shows the fit of Eq. (14) to the data obtained for $Co_{70.4}Fe_{4.6}Si_{15}B_{10}$ at the peak of the MIR with the parameters $\chi_0=10^5$ and $\tau=10^{-8}$ s. Thus, the model also accounts very well for the frequency dependence of the GMI observed in this alloy.

Superconducting properties of Fe-doped YNi_2B_2C

X. Z. Zhou, H. P. Kunkel, P. A. Stampe, and Gwyn Williams
Department of Physics, University of Manitoba, Winnipeg, MB R3T 2N2, Canada

The effects of Fe substitution for Ni in the intermetallic superconductor YNi_2B_2C are reported. Samples of nominal composition $Y(Ni_{1-x}Fe_x)_2B_2C$ with $x=0.01$, 0.02, 0.05, and 0.1 have been prepared and subsequently characterized by x-ray diffraction, ac susceptibility, and resistivity/magnetoresistance measurements. A summary of these data is presented, and these are compared and contrasted with both the behavior previously reported for and the conclusions drawn from Fe and Co doping in this system. © *1996 American Institute of Physics.* [S0021-8979(96)41108-7]

Over the past year there have been several studies of the influence of substitutional transition metal replacement of Ni in the quaternary YNi_2B_2C system, in particular by Fe[1] and Co.[1,2] One of the more interesting conclusions drawn from such studies is that Fe carries no moment in this host. Such a conclusion would not be unusual for the Ni sites prior to doping as Ni is unique amongst the $3d$ transition metals in that it never displays a stable moment in the single impurity limit when introduced into nonmagnetic metals.[3] Both Fe and Co are different; they frequently exhibit a long-lived local moment and ordering effects can be important at or below the 1 at. % level.[3]

Samples of nominal composition $Y(Ni_{1-x}Fe_x)_2B_2C$ with $x=0.01$, 0.02, 0.05, and 0.1 were prepared by arc melting appropriate quantities of starting materials [Y (99.9%), Ni (99.95%), Fe (99.98%), B (99%), and C (spec pure)], and the resulting buttons were homogenized by inverting and remelting them several times. Specimens of dimensions $(5\times1\times1)$ mm^3 (~30 mg) were cut from these buttons and subsequently annealed *in vacuo* at 1000 °C for 24 h followed by furnace cooling. Powder diffraction measurements on the $x=0.05$ sample confirm that its structure is the same as that of the undoped parent compound, in agreement with Ref. 1. ac susceptibility and (longitudinal) magnetoresistance data were acquired using previously described techniques.[4]

Figure 1 reproduces the ac susceptibility (measured at 2.4 kHz with an ac driving field of 50 mOe rms applied along the largest sample dimension) taken in zero static biasing field; here it can be seen that as the Fe concentration is increased so the superconducting transition temperature T_c is progressively depressed and the width of the transition to the superconducting state broadens. These data—corrected for background and demagnetizing effects[4]—also indicate that these doped samples exhibit no more than about 90% shielding in contrast to the full shielding reported in the parent compound. Furthermore, this shielding decreases as the Fe doping increases, in contrast to the behavior reported[1] for Co doping. The zero-field resistivity data confirm both the depression of T_c and the escalating transition width as the Fe content increases. These data also indicate that Fe substitution increases the residual resistivity (above T_c) at a rate of 3–4 $\mu\Omega$ cm/at. % Fe, an estimate that should, however, be regarded with some reservation as it is based on the subtraction of a substantial residual term (~16 $\mu\Omega$ cm) associated with the parent compound; the latter value cannot be attributed to either form factor uncertainties (since these have been calculated from measured lattice parameters)[1] or voids (not detected when cuts on arc-melted buttons were examined with an optical microscope), and while significant strains in polycrystalline specimens appear as a possible source, they do not result in noticeable x-ray line broadening. The residual resistivity quoted above is considerably larger than that (~3 $\mu\Omega$ cm) previously reported[5] for similarly prepared YNi_2B_2C polycrystals; it is, however, comparable with that deduced[6] for $HoNi_2B_2C$ and much smaller than values quoted[6] for $TbNi_2B_2C$, $DyNi_2B_2C$, and[7] $LaRh_2B_2C$. Interestingly, in YPdBC higher residual resistivities have been associated with higher T_c values. The longitudinal magnetoresistance is presented in Figs. 2 ($x=0.02$) and 3 ($x=0.05$); although *initially* not as sharp as the transition in the parent compound (ΔH for the 10%–90% width is 0.5 T at 10.7 K in the $x=0.02$ specimen, increasing to 0.85 T at 6.1 K in the

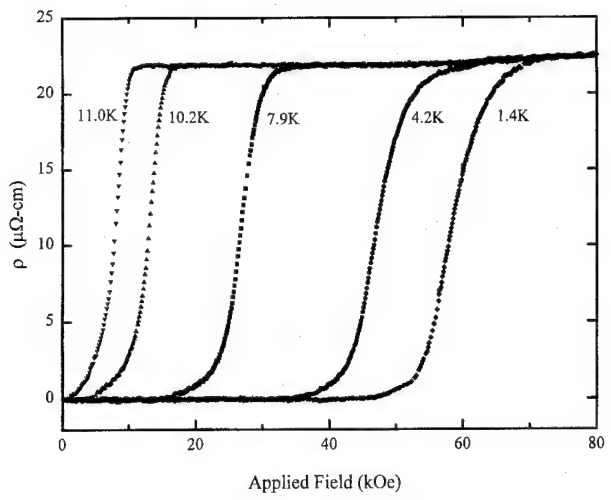

FIG. 2. The longitudinal magnetoresistance of the $x=0.02$ sample at various fixed temperatures.

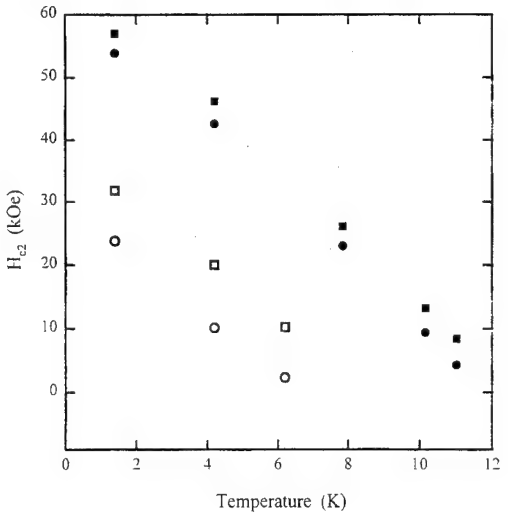

FIG. 4. The temperature dependence of H_{c2} for the $x=0.02$ samples (solid symbols) and $x=0.05$ sample (open symbols) from point of maximum slope of the data in Figs. 2 and 3, respectively (squares) and the field for restoration of 10% of the normal state resistivity (circles).

$x=0.05$ sample, cf. 0.2 T at 13 K in the undoped system[4]), these transitions are sharper at the lowest measuring temperature in the doped specimens (at 1.5 K $\Delta H\sim 1$ T in both doped samples compared with some 2.2 T in the parent)[4]. However, the principal effect of these applied fields is to shift the transition. From these magnetoresistance data it is also possible to estimate the upper (resistive) critical field H_{c2} (here, taken either as the field that restores 10% of the normal state resistivity or as the field at which $d\rho/dH$ is a maximum). Figure 4 summarizes the temperature dependence of these two estimates for the $x=0.02$ and 0.05 samples, respectively; as in the parent compound[4] the unusual feature in this figure is that there is little evidence of a saturation in $H_{c2}(T)$ even at the lowest measuring temperature, a feature that does not depend on the specific criterion used to estimate $H_{c2}(T)$. This behavior resembles that of nonoptimally doped cuprate superconductors.[8] A summary of the dependence of the superconducting transition temperature T_c on Fe concentration from previous[1] and current work is presented in Fig. 5. The present data show less scatter than those of Bud'ko *et al.*,[1] although there is generally good agreement between the estimates for T_c from susceptibility data in Ref. 1 and the present measurements; current data also extend to higher Fe concentration, a point returned to below. The dashed and solid lines in this figure are, respectively, fits to the depression of T_c induced by spin fluctuations[9] and by a stable local moment[10] at the Fe site. The first model, also used to fit the suppression of T_c below that of the host (T_{c0}) by Co substitution,[2] predicts that

$$\ln\left(\frac{T_c}{T_{c0}}\right)=-\frac{(\alpha+\beta)c}{g(1-\beta c)}, \tag{1}$$

where c is the Fe concentration, $\alpha=N_i(E_F)/N(E_F)$ is the ratio of the impurity to the host density of states, while

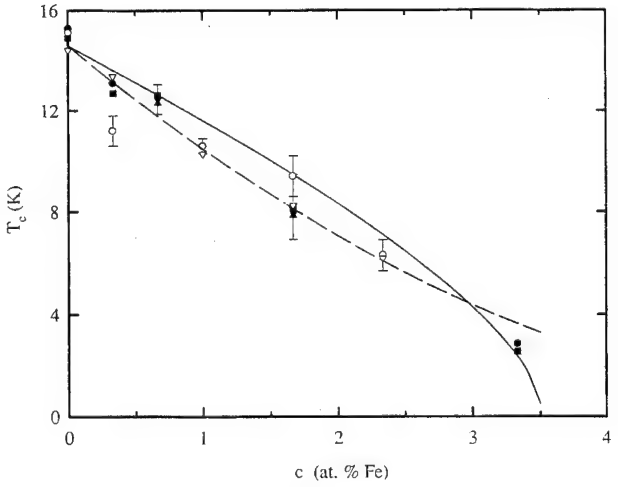

FIG. 5. The superconducting transition temperature [present data estimated from (■) susceptibility onset, (●) maximum in $d\chi/dT$, (▲) resistivity onset, (▼) maximum in $d\rho/dT$, open symbols, Ref. 1] plotted against Fe concentration. The lines are explained in the text.

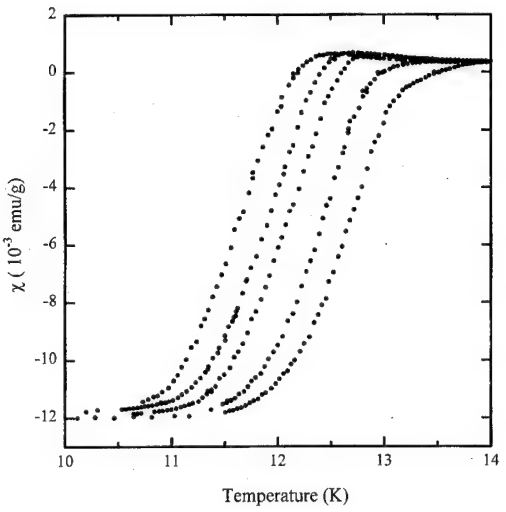

FIG. 6. The ac susceptibility of the $x=0.01$ specimen; the static biasing fields of 0, 100, 500, 750, and 1000 Oe increase from right to left.

$$\beta=\frac{N_i(E_F)^2 U_{\text{eff}}}{N(E_F)(2l+1)g}, \tag{2}$$

in which U_{eff} is the intra-atomic Coulomb repulsion, g the BCS coupling constant, and $(2l+1)$ accounts for orbital degeneracy. In the second approach

$$\ln\left(\frac{T_c}{T_{c0}}\right)=\Psi\left(\frac{1}{2}\right)-\Psi\left(\frac{1}{2}+\frac{0.14cT_{c0}}{c_0T_c}\right)\cdots, \tag{3}$$

in which c_0 is the critical Fe concentration for the complete suppression of superconductivity. Ψ is the digamma function. While neither curve produces a completely convincing fit to these data, the dashed curve displays the opposite curvature to these data at the highest Fe concentration (the latter being associated with data acquired in the present study); this results in the spin-fluctuation model utilizing questionable parameter values of $U_{\text{eff}}\sim 2\times 10^6$ eV and $N_i(E_f)\sim 0.6\times 10^{-5}$ states/eV atom spin [based[11] on $N(E_f)=0.34$ states/eV atom spin and $g=0.27$]; nevertheless $N_i(E_f)\cdot U_{\text{eff}}>1$, so that the static Hartree–Fock criterion for a stable moment *is* satisfied at the Fe site. Recall that the suppression of T_c with Co substitution[2] *is* consistent with the presence of spin fluctuations at the Co site, with $N_i(E_F)\cdot U_{\text{eff}}\simeq 1.06$. The solid line in this figure represents a fit based upon the stable moment model with $c_0=3.5$ at. % Fe ($x=0.105$) and appears to reproduce the curvature evident in the higher concentration data. While these indications that the Fe site supports either persistent spin fluctuations or a stable moment in this environment are admittedly indirect, there is some direct evidence supporting this suggestion; from Fig. 6—a plot of the field dependent ac susceptibility $\chi(H,T)$ in the $x=0.01$ sample—the presence of a small, temperature dependent paramagnetic signal can be seen in the region immediately above T_c. As the current indications run counter to those drawn by Bud'ko *et al.*[1] (based primarily on unpublished Mössbauer data), we suggest that there are still unresolved questions concerning the appropriate description of the effects of Fe doping in this host. An investigation of this problem using more sensitive probes is currently under way.

We have performed measurements of ac magnetic susceptibility χ_{ac} as a function of temperature and magnetic field on polycrystalline specimens of $Sm_{2-x}Ce_xCuO_{4-y}$ ($0.15 \leqslant x \leqslant 0.18$) prepared from a sol-gel precursor. All the samples studied show a striking double resistive superconducting transition. One of the resistive transitions occurs at a higher temperature T_{ci} and the other one at a lower Josephson-coupling temperature T_{cj}. Magnetic measurements reveal the appearance of superconductivity below T_{cj} which is evident from the resistive component χ'' which peaks only at T_{cj}. Measurements made on pellets and crushed samples with average grain size ~ 1 μm show essentially the same features. This suggests that Josephson coupling occurs inside physical grains with dimensions close to 5 μm. We have also utilized the behavior of the peak in the χ'' component as a function of applied magnetic fields to build a H vs T phase diagram for these compounds. Some interesting features were observed in this H vs T phase diagram: (1) a H^{α}, $\alpha=2/3$, dependence at low applied magnetic fields ($H \leqslant 2$ kOe) and high temperatures, and (2) an abrupt increase in the magnitude of the exponent at high fields and low temperatures. The behavior at low fields and high temperatures suggests that the magnetic response of the system is mainly controlled by a disordered Josephson network. Possible connections between these two different behaviors are discussed.
 [S0021-8979(96)01008-6]

The magnetic response of high-T_c cuprates under applied magnetic fields is still object of some controversy. This seems to be also interesting when the compounds analyzed display the so-called double resistive superconducting transition. This unusual feature has been frequently observed in electrical resistivity $\rho(T)$ measurements carried out on polycrystalline samples of electron-doped superconductors with stoichiometries $Ln_{2-x}Ce_xCuO_{4-y}$; Ln=Nd, Pr, Sm; $0.13 \leqslant x \leqslant 0.20$.[1–6] Such a property is mainly observed when the zero resistance state is attained through two well-defined drops in the magnitude of $\rho(T)$.[1] The first drop, which occurs at an upper transition temperature T_{ci}, is attributed to a genuine superconducting phase,[1–6] and usually corresponds to an $\sim$25% fall in the magnitude of $\rho(T)$. Below this temperature, it is believed that the sample is comprised of small superconducting islands embedded in a nonsuperconducting host and $\rho(T)$ exhibits a well-defined plateau until reaching a lower transition temperature T_{cj}.[1,2] At this lower temperature, Josephson coupling develops between superconducting islands and a second $\sim$75% sharp drop in $\rho(T)$ is frequently observed. Such a drop ultimately leads the system to a zero resistance state. These features show certain similarities when compared with a disordered network of Josephson junctions.[1–6]

Such an explanation involving superconducting islands embedded in a nonsuperconducting host seems to be a useful tool in separating contributions from inter-and-intragrain properties. In addition, such a separation in these systems can be made by controlling both T_{ci} and T_{cj} by means of Ce doping[1,3,4,6] or oxygen removal.[7]

In this work, we will focus on additional properties of the disordered Josephson-coupled network shown in polycrystalline samples of $Sm_{2-x}Ce_xCuO_{4-y}$ ($0.15 \leqslant x \leqslant 0.18$)[4] obtained from a sol-gel precursor. We have performed measurements of ac magnetic susceptibility χ_{ac} as a function of temperature and applied magnetic fields in crushed samples, with average grain size ~ 1 μm, and pellets. We found that the resistive χ'' component peaks only at the Josephson-coupling temperature T_{cj} in both crushed and pellets samples, giving further evidence that superconductivity is mostly confined to small islands within grains. In addition, a field dependence of the χ'' peak provided the behavior of the so-called irreversibility line in these compounds. We have found that the irreversibility line inferred from these experiments is characterized by an $\alpha=3/2$ power law near T_{cj}, but shows a crossover to a more rapid temperature dependence at low temperatures.

Polycrystalline samples of $Sm_{2-x}Ce_xCuO_{4-y}$ ($0.15 \leqslant x \leqslant 0.18$) were prepared using the sol-gel route. Further details of this chemical route and the reduction processes employed for these samples are given elsewhere.[2,8] All samples were characterized by x-ray diffraction using Cu K_{α} radiation on a Rigaku RU-200B diffractometer and had no additional phases except for the $x=0.18$ sample, which had small amounts of a $Sm_{1-x}Ce_xO_y$ spurious phase.[9]

Alternating current magnetic susceptibility χ_{ac} measurements, made on both crushed and bar-shaped samples, were performed with a mutual-inductance bridge operating at fre-

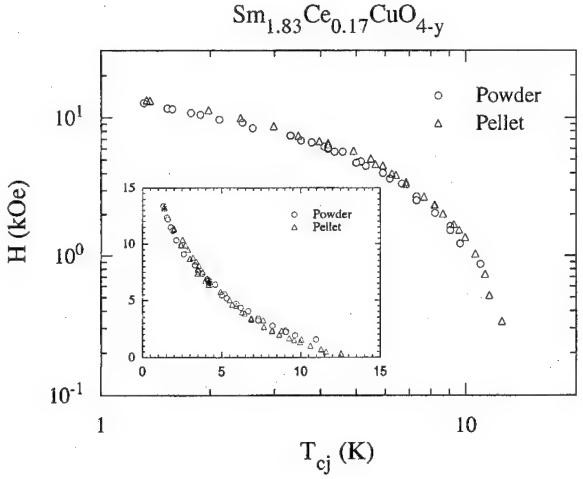

FIG. 1. A log-log plot of magnetic field H vs T_{cj} of a crushed sample and a pellet of polycrystalline $Sm_{1.83}Ce_{0.17}CuO_{4-y}$. The inset shows a H vs T_{cj} plot of the same data.

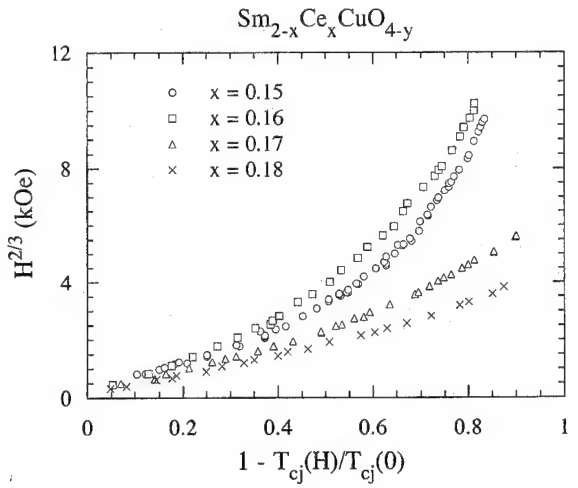

FIG. 2. Magnetic field $H^{2/3}$ dependence of the reduced Josephson-coupling temperature $[1-T_{cj}(H)/T_{cj}(0)]$. We have defined $T_{cj}(0)$ as the temperature at which χ'' peaks in zero applied magnetic field. These measured values of $T_{cj}(0)$ are 17.5, 19.3, 13.5, and 10.6 K for samples of $Sm_{2-x}Ce_xCuO_{4-y}$ with $x=0.15$, 0.16, 0.17, and 0.18, respectively. A change of the exponent at low temperatures and high fields is observed and discussed in the text.

quencies f in the range 17 Hz$\leq f\leq$5555 Hz and modulation fields H_m in the range 0.01 Oe$\leq H_m\leq$17 Oe. External dc magnetic fields were produced with a NbTi superconducting magnet up to 35 kOe. We have defined the Josephson-coupling temperature T_{cj} as the temperature where a peak in the χ'' component is observed. The average grain size of both crushed samples and pellets were $\leq$1 and $\sim$5 μm, respectively.

It is useful to begin this discussion with the results of Fig. 1 which shows a log-log plot of H vs T_{cj} obtained on both crushed sample and pellet of a polycrystalline sample of $Sm_{1.83}Ce_{0.17}CuO_{4-y}$. As we have discussed previously,[10] the $\chi_{ac}(T)$ data of polycrystalline samples of electron-doped superconductors reveal the total absence of a peak in the χ'' component at T_{ci}. Indeed, a well-defined peak in χ'' has been only observed at the Josephson-coupling temperature T_{cj}.[10] Such a peak has been widely attributed to the so-called irreversibility line in these cuprates and often used for constructing H vs T phase diagrams. The first interesting feature of these curves is associated with the temperature dependence of the so-called irreversibility line in these compounds. It seems that, within the precision of our measurements, the behavior of the irreversibility line is coincident for both crushed samples and pellets. Such an experimental result has been observed in all samples studied and claims for an additional discussion.

Usually, the ac magnetic response χ_{ac} of polycrystalline samples of high-T_c superconductors shows two well-defined peaks in the χ'' component.[11] One of these peaks occurs at the temperature where the superconducting order parameter develops, i.e., at the mean-field critical temperature T_c (or more appropriately T_{ci} in samples with the double resistive superconducting transition). The second peak is believed to occur at a lower temperature T_{cj}, where the grains become coupled together through Josephson-coupling or proximity effect. Since the average grain size ($\sim$1 μm) of the crushed samples is significantly smaller than the physical grains ($\sim$5 μm), the peak in the χ'' component would be mostly associated with Josephson coupling within physical grains. Such an experimental result is also important because it suggests that superconductivity in these polycrystalline samples would occur in small island and that the entire physical grains are not fully superconducting.

The presence of small superconducting islands with average size ranging between 10 and 300 Å in polycrystalline samples of electron-doped superconductors has been proposed recently.[3,4,6] According to Ref. 6, small superconducting islands, closely spaced, are interspersed with occasional large regions resulting in a morphology that accounts for the observed absence of a peak of the χ'' component at T_{ci},[10] and the observed absence of a significant diamagnetism above T_{cj} in these compounds.[1–6] Also, at very low applied magnetic fields, there is no evidence of detectable differences between data taken on the crushed sample and pellet. Such a behavior suggests that, even at very low applied magnetic field, the "irreversibility line" of these compounds should be mainly governed by the intragrain Josephson coupling.

Values of $T_{cj}(H)$ were extracted from curves of $\chi''(T,H)$ and used to construct the $H^{2/3}$ vs $[1-T_{cj}(H)/T_{cj}(0)]$ plots shown in Fig. 2. In the low-field regime ($H\leq$2 kOe) and high temperatures, all the curves display the expected behavior of a disordered Josephson network, i.e., a quasi de Almeida–Thouless boundary line, where $H(T_{cj})=H_0[1-T_{cj}(H)/T_{cj}(0)]^{\alpha}$, $\alpha=1.5$, as discussed in Ref. 10. Careful analysis of the curves also reveals that the data are described well by this general relation. However, a change of exponent is easily observed in all samples studied. Such a change usually takes place at low temperatures and applied magnetic fields higher than $\approx$3 kOe. Fits of the data show that the exponent changes from $\alpha=1.5$ in the low-field regime to 3.5–1.8 in high fields. Indeed, the high-field exponent decreases monotonically with increasing Ce content. We found $\alpha=3.5$, 3.1, 2.4, and 1.8 for samples with Ce concen-

tration $x=0.15$, 0.16, 0.17, and 0.18, respectively. Indeed, no definite correlation between H_0 and the concentration of Ce in this series has been found.

Similar crossover or change in the exponent of the irreversibility line has been observed in polycrystalline and single-crystals samples of electron-doped superconductors.[12,13] It was found that such a change in the exponent of the irreversibility line is not only observed in the electron-doped superconductor $Sm_{1.85}Ce_{0.15}CuO_{4-y}$, but also in $Y_{1-x}Pr_xBa_2Cu_3O_{7-\delta}$, oxygen deficient $YBa_2Cu_3O_{7-\delta}$, and $Bi_2Sr_2CaCu_2O_{8+\delta}$.[12] Such an effect has been attributed to the onset of strong correlations in the flux line lattice at high magnetic fields, a universal feature of the irreversibility line of high-temperature superconductors.[12] Similar crossover has been also observed in single crystals of $Nd_{2-x}Ce_xCuO_{4-y}$ with T_c varying from 7 to 19 K.[13]

The results shown in Fig. 2 show different features when compared with the ones described above. While the data seem to be similar to those observed in other high-T_c cuprates, it is important to notice that our results were obtained on samples which exhibit the double resistive superconducting transition.[4] This suggests that, at least for low applied magnetic fields, the macroscopic response of the system would be mainly associated with the response of a disordered array of a Josephson network. The expected irreversibility line of such a system would show a de Almeida–Thouless behavior which is controlled by the intrinsic properties of the junctions, as observed in the experiments.[10]

A reasonable explanation for such a crossover would invoke a competition between inter-and-intragrain properties of these compounds. At low fields all the macroscopic response of these samples are controlled by the disordered array of Josephson junctions. Increasing magnetic field modifies all the properties of the superconducting islands and a crossover of the irreversibility line would be expected.

However, if this were the case, there are few points to be addressed. First of all, there is a change in the exponent of the irreversibility line as a function of Ce content in this series. It decreases from ~3.5 for the sample with $x=0.15$ to ~1.8 for the sample with $x=0.18$. This seems to be in complete agreement with the results obtained in single crystals of $Nd_{2-x}Ce_xCuO_{4-y}$ (Ref. 13) which showed a sample-dependent exponent of the irreversibility line at high magnetic fields. In our case, it seems that a sample dependent exponent would be associated with a different Josephson-coupling temperature. Furthermore, we have not found any systematic correlation between the exponent of the irreversibility line and the Ce content in this series. We plan to explore this point further.

In summary, from the temperature and field dependence of the χ'' peak in pellets and crushed samples of $Sm_{2-x}Ce_xCuO_{4-y}$ ($0.15 \leqslant x \leqslant 0.18$), we found evidence that these systems are comprised of small superconducting islands coupled by Josephson junctions. An appropriate H vs T phase diagram reveals that the irreversibility line of these samples, at low fields and high temperatures, shows the expected exponent ($\alpha=1.5$) of a disordered Josephson junction array. Also, we have found a crossover to a more rapid temperature dependence at low temperatures and high magnetic fields. A detailed analysis of the irreversibility line shows no correlation between the exponent at high fields and the Ce concentration of these samples. It has been argued that such a crossover of the irreversibility line would be associated with inter-and-intragrain properties of these polycrystalline samples of electron-doped superconductors.

Thermal conductivity of $Bi_2Sr_2Ca_nCu_{n+1}O_x$ bulk superconductors in high magnetic fields (abstract)

S. C. Nakamae[a] and J. Schwartz[b]
National High Magnetic Field Laboratory, Tallahassee, Florida 32306-4005

The study of the thermal conductivity of high temperature superconductors can provide a theoretical understanding of the nature of the charge carriers, phonons, and scattering processes between them. From the technological point of view, thermal conductivity influences the growth rate of a local hot spot in a superconductor and therefore it is an important parameter in thermal stability analysis. Recently, the magnetothermal conductivity has been considered to be a key factor in the understanding of the vortex mechanisms. Here we report thermal conductivity measurements of bulk $Bi_2Sr_2Ca_nCu_{n+1}O_x$ superconductors in an applied magnetic field up to 20 T. The measurements are taken with field directions both parallel and perpendicular to the *a-b* plane of the samples for a wide range of temperatures. The phonon scattering mechanism at vortex sites, thermal transport mechanism in both *a-b* and *c* directions, as well as across grain boundaries will be discussed. [S0021-8979(96)63508-0]

Cu spin reorientation in $Tl(BaSr)PrCu_2O_7$

The Cu spins in $TlBa_2PrCu_2O_7$ order at $T_N \approx 370$ K with a spin structure that is collinear and is characterized by the $\{\frac{1}{2}\frac{1}{2}1\}$ wave vector, where the nearest neighbor spins are aligned antiparallel along all three crystallographic directions. If 50% of the Ba atoms are randomly replaced by the smaller Sr atoms to form $Tl(BaSr)PrCu_2O_7$, the T_N of the Cu spins reduces to 350 K but the magnetic structure that forms below T_N is the same. However, at $T \approx 20$ K the Cu spins undergo a change in structure, and the spin arrangement is then characterized by the $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ wave vector below $T \approx 12$ K. The ground state spin structure of the Cu ions in $Tl(BaSr)PrCu_2O_7$ is hence noncollinear, where the spin directions of the nearest neighbor Cu ions in the ab plane remain collinear and antiparallel while along the c axis they are orthogonal. These results demonstrate that the atoms in the BaO layers are also actively participating in the coupling between the Cu ions. © *1996 American Institute of Physics.* [S0021-8979(96)02808-9]

There are two copper–oxygen layers per unit cell in $TlBa_2PrCu_2O_7$, and both of them are the so-called "CuO_2-plane" layers in which O atoms are present between the Cu atoms along both the a and b axes.[1] Neutron diffraction measurements[2] have shown that the magnetic coupling between the Cu spins is antiferromagnetic in nature, and they order at $T_N \approx 370$ K with a spin structure that is identical to the "plane ordering" observed[3] in the 1:2:3 system where the nearest neighbor Cu spins are aligned antiparallel along all three crystallographic directions. The moment direction is in the tetragonal ab plane with a saturated ordered moment $\langle \mu_z \rangle = 0.59\ \mu_B$, and this spin structure of Cu remains unchanged down to $T = 1.36$ K. Specific heat data[4] also show a sizable linear term that is comparable to that found in heavy fermion systems.

To study the role that the atoms in the BaO layers play in the Cu magnetism, neutron diffraction and ac susceptibility measurements have been performed on the $Tl(BaSr)PrCu_2O_7$ compound, where 50% of the Ba atoms in $TlBa_2PrCu_2O_7$ have been replaced by Sr atoms. Structural analysis via high-resolution neutron diffraction has shown that the Ba and Sr atoms in $Tl(BaSr)PrCu_2O_7$ are randomly mixed in such a way that on average there are two $(Ba_{0.5}Sr_{0.5})O$ layers, rather than one BaO and one SrO layer, in a unit cell. The magnetic studies that we are reporting here show that the replacement of Ba atoms by Sr causes only a slight reduction in the ordering temperature of the Cu spins, but increases the saturated ordered moment by 50%, and alters the ground state spin structure of Cu ions.

A polycrystalline sample of $Tl(BaSr)PrCu_2O_7$ was prepared by the solid-state reaction from fine powders, and the details of the preparation procedure can be found elsewhere.[5] Neutron diffraction measurements on the combined powder samples were performed at the Research Reactor at the U.S. National Institute of Standards and Technology. The data were collected using the BT-9 triple-axis spectrometer operated in double-axis mode. A pyrolytic graphite PG(002) crystal was used to extract neutrons of energy 14.8 meV (2.351 Å). A PG filter was also employed to suppress higher order wavelength contaminations, and the angular collimations used were 40′-48′-48′. About a 10 g powder sample was mounted in a cylindrical aluminum can, and a pumped ^{4}He cryostat was used to cool the sample.

Neutron diffraction patterns were taken at several different temperatures to study the intensity variations with temperature. Similar to what has been observed[3] in $TlBa_2Cu_3O_7$, the $\{\frac{1}{2}\frac{1}{2}1\}$ magnetic reflection that characterizes the Cu spin ordering is observed below 350 K. However, below $T \approx 20$ K this intensity was found to decrease. Figure 1 shows the difference between the diffraction patterns taken at $T = 15$ K and $T = 50$ K. The solid curve is a fit of the observed Bragg peaks to the Gaussian instrumental resolution function, with the dashed line being the base line, and the indices shown are based on the chemical unit cell. A negative amplitude was obtained for the $\{\frac{1}{2}\frac{1}{2}1\}$ peak, clearly indicating a reduction in the $\{\frac{1}{2}\frac{1}{2}1\}$ intensity as the temperature is reduced from 50 to 15 K, while the intensities of both the $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ and $\{\frac{1}{2}\frac{1}{2}\frac{3}{2}\}$ reflections increase. Hence there is a change in the magnetic structure, with the magnetic unit cell doubling in size along the c axis.

A more complete temperature dependence of the magnetic intensities is shown in Fig. 2, where the peak intensities of the $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ and the $\{\frac{1}{2}\frac{1}{2}1\}$ reflections measured over a temperature range of 1.4 to 450 K are presented. Clearly, the $\{\frac{1}{2}\frac{1}{2}1\}$ intensity starts to develop at $T_N \approx 350$ K. This intensity increases on cooling in the usual way, and reaches saturation at $T \approx 220$ K. At $T \approx 20$ K, however, the $\{\frac{1}{2}\frac{1}{2}1\}$ intensity starts to decrease, and at low temperatures no significant magnetic intensity remains. This is accompanied by the development of the $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ types of peaks, demonstrating that the Cu spins undergo a change in structure.

A half-integer value for the c axis miller's index means that the magnetic unit cell is double the chemical one along that axis direction.[6] We note that in each chemical unit cell

 0021-8979/96/79(8)/6568/3/$10.00

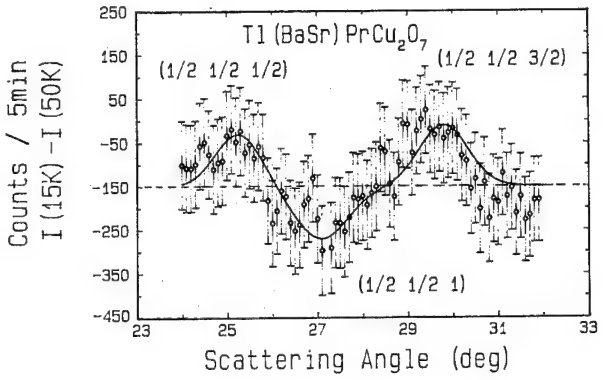

FIG. 1. The difference between the diffraction patterns taken at $T=15$ K and $T=50$ K. As temperature is reduced from 50 to 15 K, the $\{\frac{1}{2}\frac{1}{2}1\}$ intensity decreases while the intensities of the $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ and $\{\frac{1}{2}\frac{1}{2}\frac{3}{2}\}$ reflections increase. The solid line is a fit to the Gaussian instrumental resolution function with the dashed line indicating the base line.

there is one Cu ion along the a and b axes while there are two along the c axis.[1] The magnetic unit cell for the high-T phase, which is characterized by the $\{\frac{1}{2}\frac{1}{2}1\}$ wave vector, hence contains two Cu ions along each crystallographic direction. The proposed Cu spin structure for the high-T phase is a collinear one, where the nearest neighbor spins alternate in direction along all three crystallographic directions, as shown in Fig. 3(a). The moments lie in the ab plane; however, its specific direction with the ab plane cannot be determined from our powder measurements. In Fig. 3(a) we have simply chosen the moment direction of the Cu spins to be along the a axis for clarity. This is the same Cu spin structure as the one observed for $TlBa_2PrCu_2O_7$,[2] $TlBa_2YCu_2O_7$,[7] and $NbBa_2NdCu_2O_8$.[8] Furthermore, by comparing the $\{\frac{1}{2}\frac{1}{2}1\}$ intensity obtained at $T=50$ K to the {001} nuclear intensity, a saturated ordered moment of $\langle\mu_z\rangle=0.89\pm0.05\ \mu_B$ was obtained for the Cu ions. This value of the ordered moment is 50% larger than the 0.59 μ_B obtained for $TlBa_2PrCu_2O_7$.

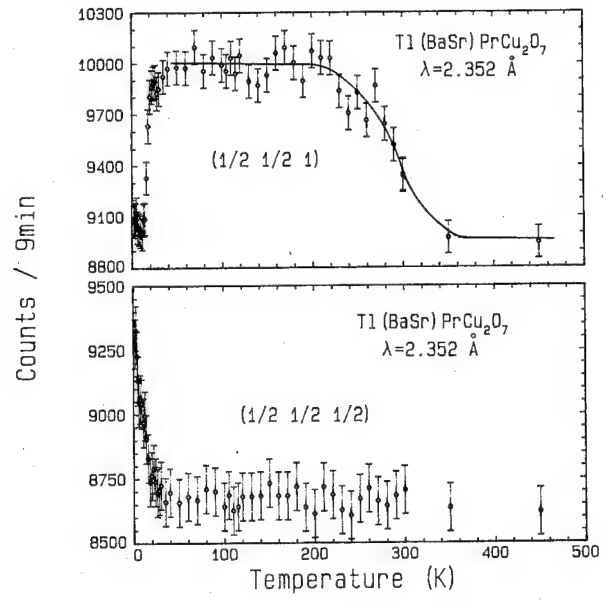

FIG. 2. Temperature dependence of the (a) $\{\frac{1}{2}\frac{1}{2}1\}$ and (b) $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ intensities observed in $Tl(BaSr)PrCu_2O_7$. The ordering temperature of the Cu spins is determined to be $T_N\sim350$ K, and the solid curve is a guide to the eye only. The downturn in the $\{\frac{1}{2}\frac{1}{2}1\}$ intensity at low temperature is accompanied by the development of the $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ intensity, and signifies a Cu spin reorientation to a new magnetic structure occurs in this temperature range.

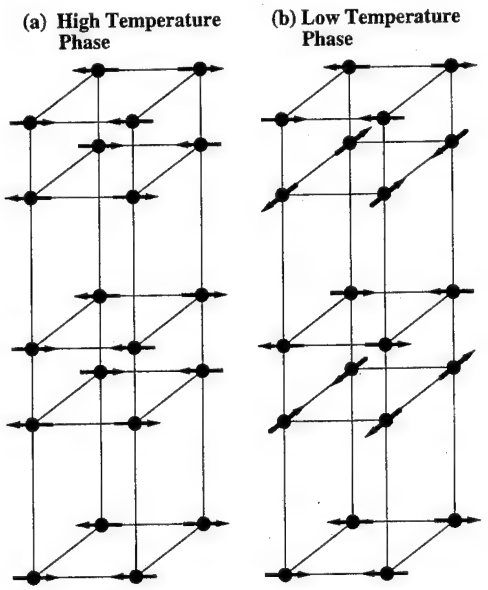

FIG. 3. The Cu spin configurations observed in $Tl(BaSr)PrCu_2O_7$ at (a) high and (b) low temperatures. At high temperatures the nearest neighbor Cu spins alternate along all three crystallographic directions, while at low temperatures the nearest neighbor Cu spins along the c axis are orthogonal.

Below the second magnetic transition at 20 K the magnetic unit cell along the c axis also becomes double the chemical one, which means there are four Cu ions along the c axis in the magnetic unit cell. The simplest Cu spin arrangement along the c axis is the one where the spin directions of the nearest neighbor Cu ions differ by 90°. The nearest neighbor spins along the a and b axes, on the other hand, remain antiparallel. This low-T phase for the Cu spin structure is noncollinear and is shown in Fig. 3(b). The proposed spin structure is supported by the observed relative intensity between the $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ and $\{\frac{1}{2}\frac{1}{2}\frac{3}{2}\}$ reflections, assuming the magnitude of the moments on the two CuO_2 layers are the same. Moreover, the value obtained for $\langle\mu_z\rangle$ using the $\{\frac{1}{2}\frac{1}{2}\frac{1}{2}\}$ intensity observed at $T=1.4$ K is the same value, within experimental accuracy, as the one obtained in the high-T phase. This result further supports the argument that the downturn in the $\{\frac{1}{2}\frac{1}{2}1\}$ intensity together with the development of the $\{\frac{1}{2}\frac{1}{2}\frac{3}{2}\}$ intensity are simply due to Cu spin reorientation.

At intermediate temperatures, i.e., below 20 K and above 12 K, the Cu spin structure may be obtained by superimposing the structures of the high-T and low-T phases, with a weighting which depends on temperature. A noncollinear Cu spin structure such as the one found for the low-T phase is still obtained in this temperature range, but the angle between nearest neighbor Cu spins along the c axis varies continuously with temperature.

The ac susceptibility was measured using a Lake Shore 7221 ac susceptometer. Polycrystalline samples of ~1g were loaded into a cylindrical plastic container which has a height

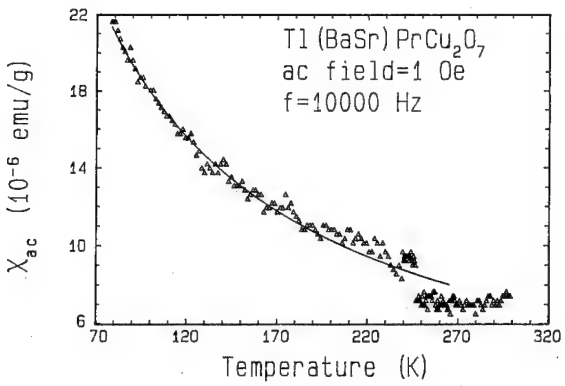

FIG. 4. Portion of the in-phase component of the ac susceptibility measured as a function of temperature. The solid line is a fitted Curie–Weiss curve using the data collected in the temperature range of 30–200 K. The susceptibility shows a sudden drop around 240 K, that signifies the Cu spin disordering.

much greater than its radius, and a conventional ^{4}He flow cryostat was used to cool the sample, with a lowest achievable temperature of 4.5 K. Figure 4 shows a portion of the in-phase component of the *ac* susceptibility measured with a driving magnetic field of 1 Oe and frequency 10^4 Hz. Measurements made using a different field strength or a different frequency generated the same results, indicating the Cu spin relaxation rate is far beyond the frequency used, as expected. The low-temperature portion of the data shown in Fig. 4 may be well described by the Curie–Weiss law, and the solid line shown is a fit of the data to $\chi_0+C/(T+\theta)$ for 30 K$<T<$200 K. This Curie–Weiss behavior signifies the paramagnetic state of the Pr spins, which order at $T\approx5$ K. Around 240 K, the susceptibility is seen to depart from the Curie–Weiss line shown, which is where significant Cu spin disorder begins to occur.

In summary, we have studied the Cu spin ordering in $Tl(BaSr)PrCu_2O_7$ by neutron diffraction and ac susceptibility measurements. By comparing the results obtained in the present study to that obtained previously[2] in $TlBa_2PrCu_2O_7$, it is clear that the atoms in the BaO layer are also actively participating in the magnetic coupling between the Cu ions, especially along the *c* axis. Although both the Ba and Sr ions have a valence state of 2+, replacing Ba^{2+} by the smaller Sr^{2+} should still lead to a modification of the hybridization among the atoms in the unit cell. The present studies show that the coupling between the Cu spins along the *c* axis is affected more strongly by the substitution than those in the *ab* plane. As 50% of the Ba atoms are replaced by Sr atoms, the T_N of the Cu spins is only slightly reduced, while the ground state spin structure is changed from a collinear spin state into a complicated noncollinear spin state. It would be interesting to see how the Cu spin structure is changed by different degrees of substitution.

The research at the NCU was supported by the National Science Council of the Republic of China under Grant No. NSC 84-2112-M-008-021.

T. H. Meen and H. D. Yang
Department of Physics, National Sun Yat-Sen University, Kaohsiung, Taiwan 80424, Republic of China

The magnetic response of the Tb spins in $Pb_2Sr_2TbCu_3O_7$ to the applied magnetic field have been studied by ac susceptibility measurements. Both the in-phase component χ' and the out-of-phase component χ'' of ac susceptibility are found to be sensitive to the frequency but not to the strength of the driving field. At high temperatures χ' exhibits Curie–Weiss behavior, it departs from this behavior as the magnetic correlations between the Tb spins develop, and a cusp which is typical of antiferromagnetic ordering is clearly revealed at lower temperatures. The correlated Tb spins respond "better" to a driving magnetic field which has a lower frequency. The relative maximum of the $d\chi'/dT$ versus T plot matches to the T_N determined using neutron diffraction measurements. This relative maximum continues to occur at the same temperature as the frequency of the driving field is varied. It, however, shifts to a lower temperature as a dc external field is applied, indicating the antiferromagnetic coupling between the Tb spins are weaken by the dc field. Moreover, the thermal behavior of χ'' exhibits a well-defined peak around the transition temperature, and a dc field of strength 5 kOe smears the peak. © *1996 American Institute of Physics.*
[S0021-8979(96)02908-5]

The magnetic interactions between the Tb spins in $Pb_2Sr_2TbCu_3O_8$ are two-dimensional (2D) and antiferromagnetic (AF) in nature. The 2D magnetic correlations between the Tb spins develop below $T\approx 9$ K, and they order two dimensionally at $T_N\approx 5.3$ K. Even at $T=1.36$ K the magnetic correlations are still mainly 2D, with nearest neighbor spins within the ab plane aligned antiparallel.[1] The 2D nature of the Tb spins mainly originates from the crystallographic structure, where the Tb atoms form an orthorhombic sublattice with $a\approx b$ and $c\approx 4a$.[2,3] Highly anisotropic magnetic interactions between the Tb ions are hence anticipated, and 2D magnetic behavior is expected. In comparison to its isostructural compounds $Pb_2Sr_2RECu_3O_8$ (RE=rare earth), the $T_N\approx 5.3$ K for the Tb spins is lower than the $T_N\approx 8$ K for Pr,[4] but is much higher than $T_N\approx 2.4$ K for Gd.[3] It is clear that the T_N for Tb is much higher than expected based on purely dipolar interactions, and likely exchange interactions are responsible for the Tb ordering.

The measurement of ac susceptibility remains one of the most powerful methods in studying the response of spin systems to an applied magnetic field.[5] Both the in-phase component χ' and the out-of-phase component χ'' of the ac susceptibility characterize the energy exchange between the spin system and the ac field. The in-phase component reflects the response of the system to the ac field, while the out-of-phase component corresponds to the dissipation signal.[6] In this article we present the results of the ac susceptibility measurements performed on polycrystalline $Pb_2Sr_2TbCu_3O_8$ compound with and without an applied external dc field. Our aim is to study the response of the Tb spins to different driving frequencies.

Polycrystalline samples of $Pb_2Sr_2TbCu_3O_8$ were prepared by solid-state reaction from fine powders. The details of the preparation procedure can be found elsewhere.[3] The samples were characterized using x-ray diffraction and the diffraction pattern taken at room temperature is well described by the orthorhombic $Pb_2Sr_2YCu_3O_8$ structure.[2] The ac susceptibilities were measured using a Lake Shore 7221 ac susceptometer, which is capable of measuring both the in-phase and out-of-phase components of the susceptibility driving by ac fields ranging from 0.1 to 25 Oe rms with frequencies from 1 to 10^4 Hz. A dc magnetic field with strength up to 1 T may also be applied. Powder samples of ~1 g were loaded into a cylindrical plastic container which has a height much greater than its radius, and a conventional ^{4}He flow cryostat was used to cool the sample, with a lowest achievable temperature of 4.5 K.

The ac susceptibility was measured over a temperature range of 4.3–320 K using driving fields of strength 1 Oe at various frequencies. Measurements made using a different strength for the driving field generated essentially the same results. At high temperatures, the thermal behavior of χ' is well described by the Curie–Weiss law $C/(T+\theta)$ that signifies the paramagnetic state of the Tb spins. A small temperature independent term χ_0', however, is also needed in describing the data, and this term is found to depend weakly on the frequency of the driving field.[7] At low temperatures, on the other hand, a cusp which characterizes the antiferromagnetic ordering[1] of the Tb spins is clearly revealed. A comparison of the response of the Tb spins to different driving frequencies is shown in Fig. 1, where the χ' measured at three different frequencies with χ_0' has been subtracted from the data were plotted against temperature.

Above ~16 K, $\chi'-\chi_0'$ obtained at different frequencies agree very well, and this agreement holds up to the highest temperature studied of $T=320$ K. The solid line shown in Fig. 1 is the fitted Curie–Weiss curve using the data obtained at 30 K$\leqslant T\leqslant$320 K (not shown). The effective moment μ_{eff} that we obtained using the fitted value for the Curie–Weiss constant C is 8.64(3) μ_B, which is about 10% smaller than the value of 9.72 μ_B expected for Tb^{3+} free ions. This discrepancy likely originates from crystal field effects. More-

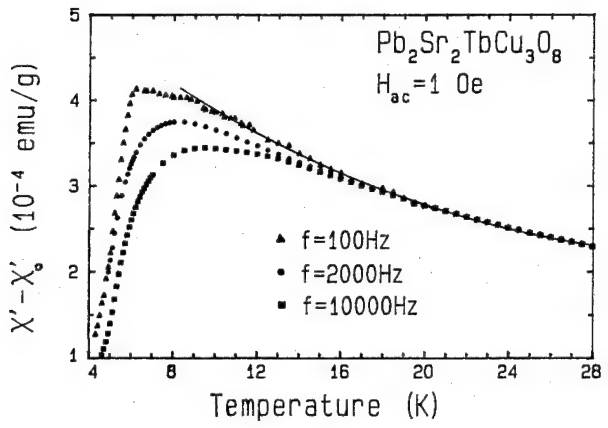

FIG. 1. Frequency dependence of the thermal behavior of χ' measured at zero dc field. The data were plotted with the temperature-independent term subtracted. The solid line is the fitted Curie–Weiss curve using the data obtained at 30 K$<T<$320 K.

over, a value of θ=21 K was obtained from the fit for Curie–Weiss temperature. This is the temperature at which χ' departs from the Curie–Weiss behavior, and below which $\chi'-\chi'_0$ measured at different frequencies begin to show discrepancies. The observed frequency-independent character of the Curie–Weiss behavior indicating that the relaxation rate of the paramagnetic Tb spins is far beyond the driving frequency used, as expected. The correlated Tb spins, on the other hand, respond differently to different driving frequency. They respond "better" to a lower frequency, as the cusp goes higher when lower driving frequency was used. This frequency-dependent behavior indicates that the relaxation rate of the correlated Tb spins is somehow far below that of the paramagnetic Tb spins.

Figure 2 shows the effect of dc field on χ', where the data were taken using a driving field of 1 Oe rms and frequency 100 Hz. At high temperatures, no obvious change on χ' was found due to the present of dc fields with strength up to 1 T, that indicating 1 T may not be strong enough to alter the paramagnetic Tb spins. At low temperatures, however, the cusp which characterizes the Tb spins ordering is affected by the dc field. Figure 1(a) clearly shows that the cusp shifts slightly upward, its maximum moves to a lower temperature as a dc field was applied. We note that the temperature at which χ' shows a maximum is not the ordering temperature of the Tb spins, rather it is the temperature at which $d\chi'/dT$ shows a maximum that matches to the ordering temperature determined from neutron diffraction measurements.[8] Figure 2(b) shows the temperature dependence of $d\chi'/dT$ obtained at various dc field, where well-defined peaks are clearly seen. As dc field was increased, however, the peak broadens and its maximum shifts to a lower temperature. The maximum of $d\chi'/dT$ at a zero dc field occurs at T=5.3 K, which is consistent with the ordering temperature measured by neutron diffraction.[1] This maximum shifts to 4.8 K as a dc field of 1 T was applied. These behavior suggests that the antiferromagnetic coupling between the Tb spins have been weakened by the dc field.

Portions of the temperature behavior of χ'' measured at different dc fields are shown in Fig. 3, where the data were

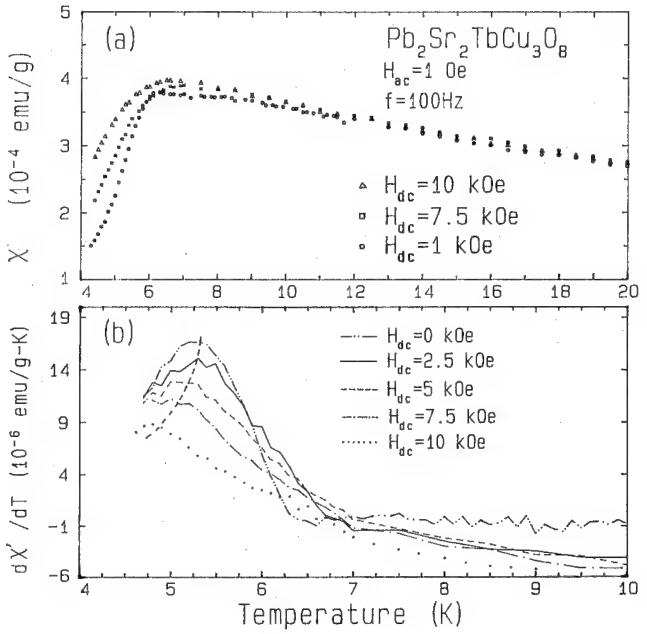

FIG. 2. The low-temperature portion of the thermal behavior of (a) χ' and (b) its temperature derivative $d\chi'/dT$ measured with dc fields applied. The relative maximum of $d\chi'/dT$ shifts to a slightly lower temperature as dc field was increased.

taken using a driving field of 1 Oe rms and frequency 100 Hz. At high temperatures, where Tb spins are completely disordered, and at low temperatures, where the Tb spin order, χ'' almost remains at constant. Only in the temperature range where transition occurs χ'' departs from the constant value and exhibits a peak in its thermal dependence. The peaks shown in Fig. 3 may be described by Lorentzian functions. At zero dc field, the maximum of χ' occurs at a temperature slightly above the ordering temperature. As dc field is applied the peak shifts to a slightly higher temperature, the width increases, and the amplitude decreases. A dc field of strength 0.5 T almost washes out the peak. Figure 4 shows the integrated dissipation signal as a function of the applied dc field, where the data were obtained by integrating over the peaks shown in Fig. 3. Clearly, the ac loss over the transition

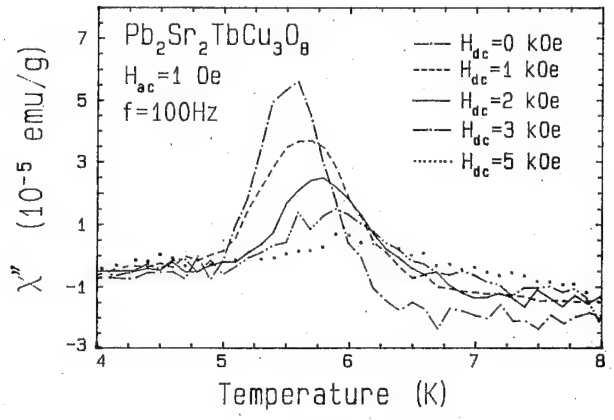

FIG. 3. Temperature dependence of the dissipation signal χ'' measured at different dc fields. At zero dc field, the thermal behavior of χ'' exhibits a well-defined peak; a dc field of 0.5 T then smears the peak.

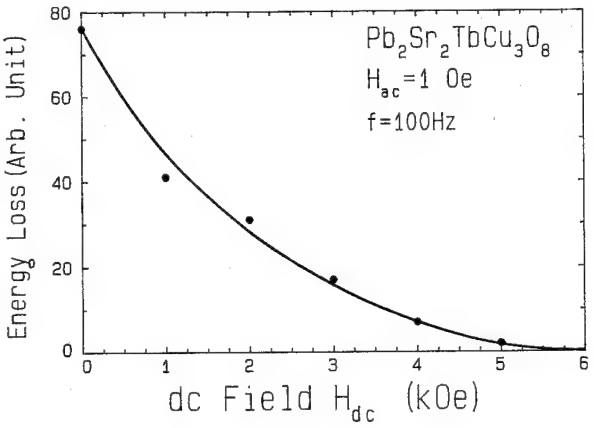

FIG. 4. The integrated ac losses plotted as a function of temperature. The solid curve is a fit to the exponentially decaying function.

decreases with an increasing dc field, and the rate of decrease may be described by an exponentially decaying function. The solid curve shown in Fig. 4 is a fit to $A_0 \exp(-\alpha H_{dc})$.

In summary, we have studied the response of Tb spins in $Pb_2Sr_2TbCu_3O_8$ to a weak ac magnetic field, with and without an additional dc field was applied. The ordered Tb spins are found to be sensitive to the frequency but not to the strength of the driving field, while the paramagnetic Tb spins are not sensitive to the frequency nor to the strength. These results suggesting that the relaxation time of the correlated Tb spins are relatively long in comparison with the uncorrelated Tb spins. The relative maximum of $d\chi'/dT$, which matches to the ordering temperature determined by neutron diffraction, shifts to a slightly lower temperature as a dc field is applied, indicating the antiferromagnetic coupling between the Tb spins has been weakened by the dc field. It would be interesting to see how strong a dc field is needed to flip the correlated Tb spins over to a direction perpendicular to the field.

Field dependence of magnetic relaxation in BiPbSrCaCuO superconductors

V. Raposo, A. G. Flores, M. Zazo, L. Torres, and J. Iñiguez
Departamento de Física Aplicada, Universidad de Salamanca, E-37071 Salamanca, Spain

Magnetic relaxation in ceramic cylindrical samples of BiPbSrCaCuO high T_c superconductors has been studied as a function of applied magnetic field for a constant decay rate of that field strength. We have analyzed the variation of the ac susceptibility versus time just after removing the magnetic field. Data have been obtained by means of an inductive technique from 1 to 3600 s, with magnetic fields that range from 10 to 100 Oe, and by switching off the field at a constant rate of 25 Oe/s. The field dependence of the thermally activated parameters has been obtained within the framework of the Anderson–Kim theory and using the so-called box distribution of energies. Anderson–Kim considered a logarithmic decay of the magnetic flux governed by an effective energy $U=U_0-FVX$, where U_0 is the pinning energy, V is the activation volume, X the pinning length, and F the driving force density. In this case we have found a field dependence of the form H^{-n} for the pinning energy, with n close to 2 and temperature dependent. However, we have observed that the box distribution, which assumes the existence of a continuous energy spectrum, shows no field dependence for the effective energy. © *1996 American Institute of Physics.* [S0021-8979(96)41208-3]

I. INTRODUCTION

Magnetic relaxation studies in high T_c superconductors (HTSCs) have received considerable attention from many researchers.[1–6] These studies help us to understand the bulk properties of superconductors and also reveal information about vortex dynamics and flux distribution within these materials. Magnetic relaxation can be studied by analyzing the time evolution of magnetic susceptibility.

The Anderson and Kim theory,[7,8] developed by Beasley *et al.*,[9] shows that the time evolution of the magnetization is logarithmic following a change in the external magnetic field. In conventional type-II superconductors this evolution is related to the decay of persistent currents, caused by the thermally activated jumps of vortices over their pinning barriers.[7] This effect is thought to be small in conventional superconductors, but in HTSCs with higher critical temperatures it can be important. However, initial nonlogarithmic behavior has been found in HTSCs, which is assumed to be caused by the transient diffusion redistribution of the magnetic flux over the sample after the change in the applied magnetic field.[10] This kind of dependence can be represented by introducing a time constant τ to describe the initial stage.[10] The value of τ depends on the macroscopic parameters such as geometry and also on the decay rate of the applied magnetic field.

Another way to explain thermally activated processes is to suppose the existence of an exponential decay obeying Debye kinetics. In HTSCs this model is introduced using distributions of activation energies because the theory assumes that a single process is too simple for these kinds of materials.[3] There are several distributions to be used, but a box distribution has proved to give similar results to that of a gaussian distribution and is far simpler.

In this work, we have studied the time evolution of the ac susceptibility in polycrystalline samples of BiPbSrCaCuO HTSCs cooled in different magnetic fields, just after removing the field. We have analyzed the field dependence of the energies involved in relaxation processes for both models. We have fitted our relaxation data to Anderson–Kim's model and we have found a field dependence of the pinning energy U_0 of the form H^{-n}. In the case of a box distribution, no field dependence for the effective activation energy box has been found.

II. EXPERIMENT

The ceramic samples of $Bi_{1.7}Pb_{0.3}SrCa_{1.8}CuO_x$ were prepared from the appropriate mixtures of high purity BiO, PbO, SrCO, CaCO, and CuO. The powders were milled and prefired for 14 h in air at 800 °C. The mixture was dry pressed in a cylindrical die, preheated at 845 °C for 72 h and then sintered at 850 °C for 200 h in air. The data reported here were obtained using samples of cylindrical shape, 10 mm in length and 5 mm in diameter.

Susceptibility measurements were performed with the help of a computer-aided system based on the use of an automatic bridge that registers the complex mutual inductance of two coils wound around the specimen under test.[4] The real (χ') and imaginary (χ'') parts of the complex magnetic susceptibility can be determined from the mutual inductance.[5] The magnetic field is controlled with a programmable dc power supply connected to the computer which allows us to change the field and the decay rate. Although the real and imaginary parts are easily obtained, we have only used the data from the real part for the fits because the signal to noise ratio is better.

Magnetic relaxation takes place when there is a change in the external magnetic field. It can be studied by cooling the sample in a magnetic field and then switching off the field, or cooling without a field and then applying it. In the first case we talk about flux expulsion while in the second case we study flux penetration.[1] Relaxation depends on the magnitude of the magnetic field and the decay rate, and consequently these parameters must be carefully controlled during the experiment. In our measurements the sample was cooled from the normal state under a longitudinal dc field to the chosen temperature, and when the required stability is attained [better than 0.03 K (Ref. 4)], the magnetic field is switched off with a constant decay rate of 25 Oe/s which can

be considered an average value in the literature.[10] The first measurement is taken 1 s after the field reaches 0 and data are recorded up to 3600 s. We have measured the relaxation for different temperatures by cooling the samples under magnetic dc fields of 10, 15, 25, 50, and 100 Oe.

III. RESULTS AND DISCUSSION

The relaxation study in our samples has been carried out by analyzing the time evolution of the ac susceptibility. Figure 1 shows a typical result of the real part of ac susceptibility normalized to the first datum point, versus time when the sample is cooled in different magnetic fields. The variation of the ac susceptibility with time has been analyzed using the Anderson–Kim theory[7,8] that predicts a logarithmic time dependence for the relaxation of the magnetic susceptibility which can be written in the form:

$$\chi(t)=\chi_0\left[1-\frac{kT}{U_0}\ln\left(1+\frac{t}{\tau}\right)\right], \tag{1}$$

where χ_0 is the real part of the magnetic susceptibility at time $t=0$, and τ is a macroscopic time constant that depends on the sample geometry and the decay rate of the applied magnetic field.[9] U_0 is the activation energy of the barrier in the absence of any flux gradient (pinning energy), T is the temperature, and k is the Boltzmann constant. Thermally activated motion of vortices is assisted by the driving force density F, which is a function in our cylindrical samples of $|B|$ and $\nabla|B|$.[8] Anderson and Kim used a linear relation $U=U_0-FVX$ between the effective energy (U) and the pinning energy in terms of the activation volume V and the pinning length X.

In previous measurements we have found that the pinning energy increases with temperature as other researchers have also reported.[10] Fitting the experimental data to this model we have also found that the pinning energy decreases when the applied magnetic field increases (Fig. 2). We have fitted the field dependence of the pinning energy to an experimental law of the form $U_0=\alpha+\beta/H^n$ (Ref. 2) for different temperatures. We have found that the exponent n is close to 2 (i.e., $n=1.7$ at 82 K and $n=2.1$ at 88 K) and the constant α increases with the temperature, as expected. These values are comparable to those obtained by Földeáki *et al.*[2]

Due to the discrepancies founded with the logarithmic fitting for the data close to $t=0$, we tried a nonlogarithmic theory. For this purpose we have also used the Debye theory to describe magnetic relaxation, as it has been used in other magnetic materials.[11,12]

Magnetic relaxation in Debye theory can be described by an exponential law of the form:

$$\chi(t,T)=\chi_0(T)-\Delta\chi\,\exp(-t/\tau), \tag{2}$$

where $\Delta\chi=\chi(0)-\chi(\infty)$ and τ is the relaxation time. We tried to fit our measurements to this equation, but the fits were not very good. Therefore, to obtain a better description, a distribution of relaxation times was assumed.[3] In this case, we can write the time evolution of the susceptibility in the form:

$$\chi(t,T)=\chi_0(T)-\Delta\chi\int_{U_1}^{U_2}p(U)[1-\exp(-t/\tau)]dU, \tag{3}$$

where $p(U)$ is the normalized distribution of energies, τ the relaxation time which obeys an Arrhenius expression, $\tau=\tau_0\exp(U/kT)$, and U_1 and U_2, respectively, the lower and upper limits of the energy distribution. Many distributions can be chosen but, although a gaussian distribution is physically more realistic, a box distribution gives similar results and is mathematically much simpler as other workers have shown.[13] In the case of a box distribution, $p(U)$ takes the form $p(U)=1/(U_2-U_1)$ if $U_2<U<U_1$ and 0 otherwise.

The existence of a box distribution could be explained in this way: if we suppose that there is a pinning energy, the interactions between vortices reduce the effective energy, and when flux expulsion occurs there are less vortices. The

TABLE I. Field dependence of box distributions for $T=82$ K and $T=88$ K, respectively.

H (Oe)	10	15	25	50	100
U_1 (eV)	0.14	0.14	0.13	0.13	0.13
U_2 (eV)	0.19	0.19	0.19	0.19	0.19
H (Oe)	10	15	25	50	100
U_1 (eV)	0.15	0.14	0.14	0.14	0.14
U_2 (eV)	0.21	0.20	0.20	0.20	0.20

interactions are then smaller and so the effective energy increases with time, because the interaction decreases and the process slows down.[14]

We have fitted our data to this model by means of a nonlinear fitting program which integrates numerically the expression (3). In Table I we present the results of the fits for the different fields. We have also tried an asymmetrical gaussian distribution, finding that the maximum is near to the center of the box distribution. We have chosen $\tau_0=1\times10^{-8}$ s, the pre-exponential factor, as a fixed parameter. The value of τ_0 is comparable to that used in another works.[3] Variations in this parameter of two orders of magnitude increases the value of the energies slightly, as well as the width of the distribution. We can see no field dependence for the effective energies; only a weak dependence of the width of the box on temperature. This temperature dependence can be explained as follows: in a fixed time window, the processes with higher energy only have a reasonable probability of occurrence at higher temperatures and cannot be detected in lower temperatures. The value of the effective energy is smaller than the pinning energy previously obtained because of the influence of the term FVX, but the field dependence of F is too complicated to evaluate because it depends on $|B|$ and $\nabla|B|$.[15]

IV. CONCLUSIONS

We have studied magnetic relaxation by means of measurements of the time evolution of the ac susceptibility of a polycrystalline sample of a BiPbSrCaCuO superconductor for different temperatures and magnetic fields ranging from 10 to 100 Oe. We have analyzed the field dependence of the activation parameters associated with the magnetic relaxation using two theoretical models: the Anderson–Kim model and a box distribution for a superposition of Debye processes. In the case of the Anderson–Kim model we have found a strong field dependence of pinning energy, of the form $U_0=\alpha+\beta/H^n$ with $n\approx2$. However, no sign of a field dependence for the distribution of effective energies has been found.

ESR measurements of the microwave absorption signal associated with weak ferromagnetism in single crystals of $Eu_{2-x}Gd_xCuO_4$ are presented for X band (9.5 GHz) and L band (1.2 GHz) as a function of the Gd concentration. The strong absorption observed at low magnetic fields was interpreted, for samples with low Gd concentration, as due to a field-induced spin reorientation transition occurring at a critical field H_c, coincident with the in-plane magnetic anisotropy effective field H_{eff}^y. For larger x the Cu-Gd magnetic interaction needs to be considered leading to smaller H_c values. Our measurements show that for Gd concentrations in the range $0 \leqslant x \leqslant 1$ the experimental data can be very well fitted with parameters derived from previous measurements. This fact indicates that these compounds have nearly the same in-plane anisotropy effective field, in spite of the small changes in lattice parameters. For $x=2$ lattice distortions increase causing an H_c larger than the expected one. © *1996 American Institute of Physics.* [S0021-8979(96)03008-X]

I. INTRODUCTION

The rate earth cuprates RE_2CuO_4 (RE=Pr,..., Tm), parent compounds of the so-called n-type high T_C superconductors, crystallize in the tetragonal Nd_2CuO_4 T' structure.[1] Pr_2CuO_4 has the largest a lattice parameter which decreases monotonically for the heavier RE compounds due to the smaller rare earth ion size.[2] This lattice reduction causes a distortion of the CuO_2 planes for Eu_2CuO_4 ($a=3.910$ Å) and heavier compounds, consisting of a displacement of the in-plane oxygens [called O(1)] from its centrosymmetrical position. These displacements seem to be ordered, and several superstructures have been found in single crystals with diffraction techniques.[2,3] Copper moments order antiferromagnetically (AF) below room temperature for the whole series. However, coincident with the boundary for lattice distortions, a weak ferromagnetic (WF) component in the magnetization develops, that was attributed to a canting of the copper moment away from a perfect AF alignment.[4] Several experimental techniques have been used to characterize the WF behavior. Among them, microwave absorption proved to be very useful to elucidate the magnetic behavior of the compounds near the WF boundary.[5] X- and Q-band experiments in Eu_2CuO_4 single crystals, slightly doped with Gd, have shown that the WF moment lays in the CuO_2 plane pointing parallel to an easy axis defined by the field cooling (FC) magnetic field and coincident with a [110] crystallographic direction ($[110]_{FC}$). When the external field is applied perpendicular to this axis a field-induced spin reorientation transition occurs at a critical field H_c.[5] More recently[6] it was shown that, for samples with larger amounts of Gd, the interaction between the WF ordered Cu lattice and the Gd paramagnetic (PM) lattice must be taken into account in order to explain several anomalies found in the EPR spectra. In this article we present the Gd concentration dependence of H_c obtained from X-band measurements. We also discuss the L-band results within the proposed model.

II. MODEL

The following expression for the magnetic free energy of the coupled PM–WF system was proposed:[6]

$$F_{\text{eff}} = -K_{\text{eff}}^y m_{\text{WF},y}^2 + K_{\text{eff}}^z m_{\text{WF},z}^2 - \mathbf{m}_{\text{WF}} \cdot \mathbf{H}_0 + \left(\frac{1}{2\chi_{\text{Gd}}}\right) M_{\text{Gd}}^2 - \mathbf{M}_{\text{Gd}} \cdot \mathbf{H}_0 - \lambda' \mathbf{m}_{\text{WF}} \cdot \mathbf{M}_{\text{Gd}}, \quad (1)$$

$\mathbf{m}_{\text{WF}}$ and $\mathbf{M}_{\text{Gd}}$ are the Cu-WF and Gd-PM magnetizations, $2K_{\text{eff}}^y m_{\text{WF}} = H_{\text{eff}}^y$ and $2K_{\text{eff}}^z m_{\text{WF}} = H_{\text{eff}}^z$ are in-plane and out-of-plane magnetic anisotropy fields, λ' is the Cu-Gd coupling constant and $\chi_{\text{Gd}} = xC/(T+\Theta)$ is the Gd molar magnetic susceptibility. This effective free energy describes the equilibrium and the low-energy excitations of the system. The resonance modes can be obtained solving a 6×6 dynamical matrix for $\mathbf{m}_{\text{WF}}$ and $\mathbf{M}_{\text{Gd}}$. Two modes are obtained: a high-energy WF-like mode, and a low-energy PM-like one.

In Fig. 1 we show both modes, as calculated for $\lambda'\chi_{\text{Gd}}=0$ (dashed curves) and $\lambda'\chi_{\text{Gd}}\neq 0$ (solid curves). For $\lambda'\chi_{\text{Gd}}=0$ a softening of the WF mode would occur at a critical field $H_c = H_{\text{eff}}^y$, coincident with the field-induced spin reorientation transition when $\mathbf{H}$ is applied perpendicular to the easy axis (i.e., $\varphi=90°$). Note that for X and L bands a resonance absorption is expected only for $\varphi=90°$. For $\lambda'\chi_{\text{Gd}} \neq 0$ the critical field is reduced by a factor $1 + \lambda'\chi_{\text{Gd}}$ giving

$$H_c = \frac{H_{\text{eff}}^y}{1+\lambda'\chi_{\text{Gd}}}, \quad (2)$$

 0021-8979/96/79(8)/6577/3/$10.00

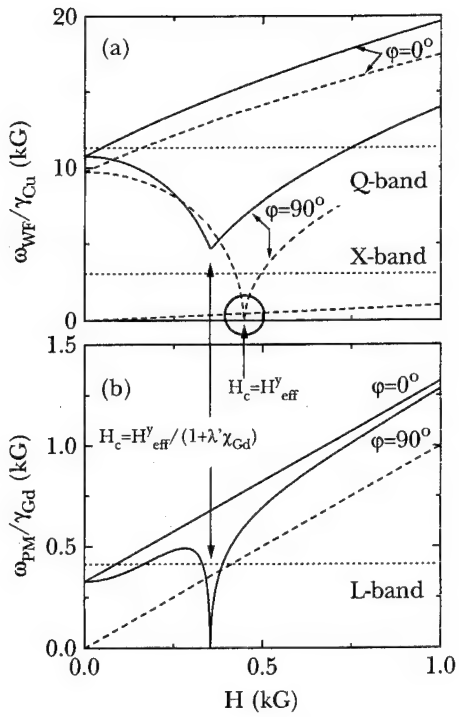

FIG. 1. Magnetic field dependence of (a) the WF-like and (b) the PM-like resonance modes when H is applied within the easy plane (solid curves). The dashed lines, calculated for $\lambda'\chi_{Gd}=0$, illustrate the crossing of modes occurring at H_c. Note the shift of H_c to lower fields when $\lambda'\chi_{Gd}\neq 0$.

and the WF mode does not soften to zero. This would imply that no resonance arising from the WF ordered Cu lattice should be observed at X and L bands. However, a maximum in the microwave absorption may be expected due to nonresonant loses as described in Ref. 5. In addition an energy gap opens in the PM-like mode for $H=0$ given by

$$\left(\frac{\omega_{PM}}{\gamma_{Gd}}\right)_{H=0}=\lambda' m_{WF}\sqrt{H^y_{eff}/[\lambda'^2\chi_{Gd}(T)m_{WF}+H^y_{eff}]}. \quad (3)$$

Due to the temperature dependence of $\chi_{Gd}(T)$ the gap tends to zero for $T=0$ K and increases for $T>0$ because other parameters are only weakly temperature dependent.[6] For $T>T_N$ the energy gap becomes zero again. Because of the anticrossing of the coupled modes an "anomaly" is also predicted in the PM-like branch which softens to zero at H_c.

III. RESULTS AND DISCUSSION

$Eu_{2-x}Gd_xCuO_4$ single crystals were grown following standard flux techniques in Pt crucibles.[7] In all cases crystals grew in the shape of small platelets with the c crystallographic axis perpendicular to the axis. EPR measurements were made in a Bruker ESP 300 spectrometer at X band (9.5 GHz) and L band (1.2 GHz) between 120 and 300 K.

Although the softening of the WF mode at H_c is not complete for $\varphi=90°$ (see Fig. 1), originating a strong reduction in the intensity of the WF line at the X band, it could still be clearly detected in all samples due to nonresonant loses.[5] In L band, however, no line was found for samples with low Gd content ($0\leq x\leq 0.2$) indicating that the gap was large enough to prevent even the observation of nonresonant

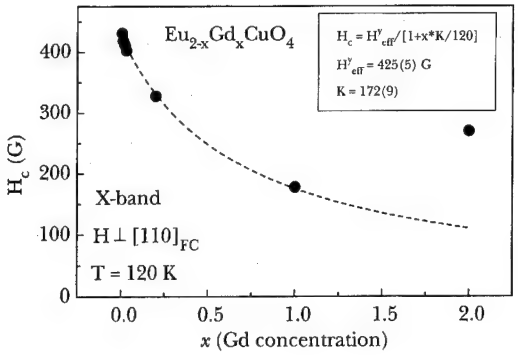

FIG. 2. Spin reorientation critical field, determined from the X-band low field absorption, as a function of x, the Gd concentration. The dashed line is a best fit of the experimental data in the range $0\leq x\leq 1$ using Eq. (2).

losses. We have determined the Gd concentration dependence of H_c, coincident with the X-band resonance field of the WF line, at $T=120$ K and with $H\perp[110]_{FC}$. The experimental data, presented in Fig. 2, were fitted using Eq. (2) in the range $0\leq x\leq 1$. We obtain the following values for the in-plane anisotropy effective field and the Cu-Gd coupling constant: $H^y_{eff}=425(5)$ G and $\lambda'=1.2(1)\times 10^5$ G/(μ_β/Cu-atom). These are consistent with the values found in Refs. 5 and 8 (for samples slightly doped with Gd) and in Ref. 9, respectively. Note that the experimental data can be explained with a single value of the in-plane anisotropy field for all compounds ($0\leq x\leq 1$), although the lattice size varies and consequently the displacement of the oxygen ions might change. We did not include the value measured for Gd_2CuO_4 in the fit because it was proposed[10] that for this compound Eq. (2) should be corrected due to the presence of a metamagnetic-like transition at low fields. In Ref. 10 the value of H^y_{eff} for $x=2$ was estimated, from dc magnetization measurements, to be $\approx$1200 G at $T=120$ K. This value is nearly three times larger than the one measured for samples with lower Gd concentrations[8] probably due to the larger lattice distortions. Correspondingly, the measured H_c value is almost three times larger than that predicted assuming a constant H^y_{eff} (see Fig. 2).

In Fig. 3 we show the EPR spectra of Gd_2CuO_4 mea-

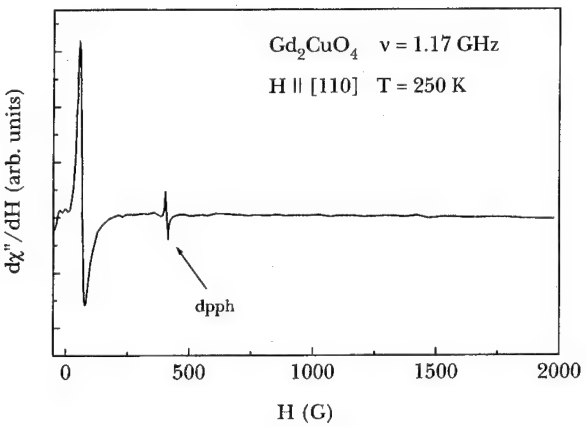

FIG. 3. L-band microwave absorption spectra of a Gd_2CuO_4 single crystal. Note the shift of the ω_{PM} line from $g=2$ (dpph).

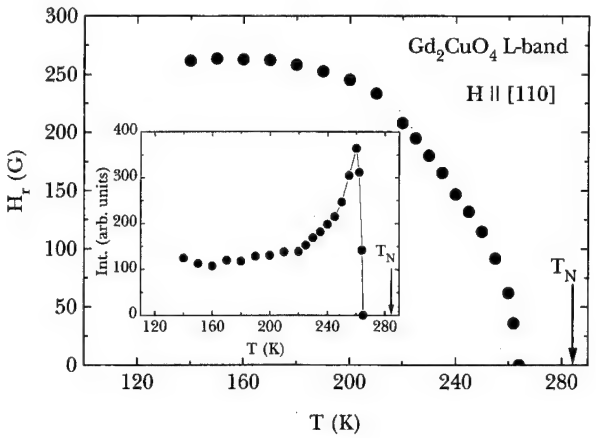

FIG. 4. Temperature dependence of the L-band Gd_2CuO_4 low field resonance line. Note the sharp decrease of the intensity at $T=260$ K, below the Néel temperature (inset).

sured at L band for $T=250$ K. The PM mode in absence of coupling to the Cu lattice would occur at $\omega_{PM}/\gamma_{Gd}=410$ G. Due to the large linewidth of the Gd^{3+} EPR line in Gd_2CuO_4 measured at X band[4] ($\Delta H_{pp}\approx 1500$ G) a superposition of the absorptions occurring at negative and positive fields would cause a strongly asymmetric signal with a broad minimum at ≈ 750 G. Surprisingly a narrow and very intense line is observed at a lower field, $H_r\approx 100$ G. The origin of this absorption may be explained looking at the behavior of the PM-like mode in Fig. 1. From the X-band results we estimate the energy gap of the PM-like mode at $T=120$ K, $(\omega_{PM}/\gamma_{Gd})_{H=0}\approx 300$ G, lower than the L-band frequency $\omega_L/\gamma_{Gd}=410$ G. Thus the microwave absorption should occur at fields lower than that corresponding to $g=2$. When the temperature is increased H_r moves to lower fields (see Fig. 4) and the line disappears at $T=265$ K, i.e., 20 K below T_N. As we have mentioned above, the value of the energy gap of the PM-like mode is expected to increase as T rises and hence $T=265$ K would indicate the temperature where ω_{PM} equals ω_L.

In this description the reduced linewidth of the PM-like absorption may be associated with coupled excitations. In fact, a strong mixture of modes is expected especially when an anticrossing of modes occurs at H_c.

In summary, we have analyzed the variation of the spin reorientation critical field, $H_c = H_{eff}^{y}/(1+\lambda'\chi_{Gd})$, as a function of Gd concentration. We have found that the decrease of H_c for increasing x may be explained (in the range $0\leqslant x\leqslant 1$) in terms of the magnetic coupling between the Cu-WF and the Gd-PM lattices. We have also discussed the origin of the absorption line measured at L band and suggested that it is due to the PM-like branch of the PM-WF coupled modes.

Physics Department and Texas Center for Superconductivity, University of Houston, Houston, Texas 77204

$HgBa_2CuO_{4+\delta}$ (Hg1201) samples with $0.03 \leqslant \delta \leqslant 0.4$ have been obtained. The magnetization of the powdered Hg1201 samples was determined using a Quantum Design SQUID magnetometer. It was observed that while the magnetization of Hg1201 increased with δ in the underdoped region, the magnetization decreased with δ in the overdoped region. These results suggest an increase of n_s/m^* with oxidation in the underdoped region and a decrease in the overdoped region, similar to that reported in underdoped HTSs and overdoped Tl2201 and Tl1201. © *1996 American Institute of Physics.* [S0021-8979(96)03108-6]

I. INTRODUCTION

Soon after the discovery of high-temperature superconductivity (HTS), it was realized that the existence of CuO_2 layers in HTSs is very crucial and the charge carriers in the CuO_2 layers control the physical properties in both the superconducting state and the normal state. T_c is one of the properties that the charge carriers in the CuO_2 layers have a marked effect upon. On the one hand, it was found that there are three different regimes in the relationship of T_c to the number of charge carriers n in the CuO_2 layers (where n is determined from valence balance or thermoelectric).[1–3] The underdoped region is where the superconducting phase appears near the insulating magnetic phase. T_c increases with increased n in this region. The optimal doping region is where T_c approaches the highest values within the given series. Next, comes the overdoped region. In this region, T_c decreases with further increases in n. On the other hand, based on muon spin-rotation (μSR) measurements,[4–6] it was found that T_c vs n_s/m^* forms a double-valued relation in Tl2201 (where n_s is the superconducting condensate density, m^* is the effective mass). This means that as n increases, n_s/m^* increases in the underdoped region, and decreases in the overdoped region. Until now, most studies have concentrated on the underdoped and optimal region, probably because underdoped and optimally doped samples are fairly easy to synthesize for most HTS systems. On the contrary, the overdoped region has been observed in only a few systems. The $HgBa_2CuO_{4+\delta}$ compound (Hg1201) has been shown to be scientifically significant,[7] because it has the highest T_c among all HTS materials that have one CuO_2 plane, and has the widest doping range that can be achieved by changing oxygen content alone.[8] Thus it is a good candidate for studies on charge carrier and doping related properties in the overdoped region.

In this article, we report a study of T_c vs n_s/m^* done by measuring the magnetization volume fluctuation of Hg1201 when oxygen content is varied from 0.03 to 0.4, covering the entire range from $T_c = 0$ K (underdoping region) to $T_c = 20$ K (overdoping region). We observed that the magnetization of Hg1201 increases with δ in the underdoped region and decreases with δ in the overdoped region. The results suggest that a double-valued relation of T_c to n_s/m^* also exists in the Hg1201 compound.

II. EXPERIMENT

All samples were synthesized by a two-step method, i.e., by first forming a precursor of (Ba, Cu) oxides, then reacting HgO with the precursor inside an evacuated quartz tube. Precursor with an initial composition of Ba_2CuO_y was prepared by a solid-state reaction. High-purity powders of BaO (99.95%) were thoroughly mixed in appropriate proportions. The mixed powders were calcined in an alumina crucible at 930 °C for 24 h under a mixed gas of Ar:O=4:1. Three intermediate regrindings were carried out during this period. The composite Hg source used was a prereacted Hg1:2:0:1 pellet made by compacting the thoroughly mixed HgO (99.998%) and pulverized precursor powder. A reactant pellet was sealed in an evacuated quartz tube of fixed volume, together with an extra Ba_2CuO_y precursor pellet. Details were given in Ref. 9. A stainless-steel tube was used to contain the quartz tube as a safety precaution. The whole assembly was then heated to 800–830 °C for 8 h before slow cooling to room temperature. Samples with different oxygen content were obtained by heating as-synthesized samples at different temperatures and oxygen partial pressures for appropriate periods of time.[9] To reach the underdoped region, the sample was heated in a vacuum of $\sim 2 \times 10^{-6}$ Torr at a temperature between 200 and 450 °C for 20–100 h. For the overdoped samples, the as-synthesized compound was heated in a 1–500 bar O atmosphere between 240 and 400 °C for 10–300 h. Phase characterization was performed by x-ray powder diffraction on a Rigaku DMAX/BIII diffractometer. The magnetization was measured using a Quantum Design SQUID magnetometer. The oxygen content δ of the samples were measured by thermogravimetric analysis[8] and calibrated using neutron powder diffraction.[10]

III. RESULTS AND DISCUSSION

Figure 1 shows the x-ray diffraction pattern of one of our as-synthesized samples, which indicated that the Hg1201 sample was nearly single phase. Figure 2 shows the normal state susceptibility as a function of the temperature. The data fits the Curie law, $\chi = \chi_0 + C/T$, very well with $\chi_0 = 1.04 \times 10^{-6}$ emu/g and $C = 2.45 \times 10^{-4}$ emu/g. The magnetization in various magnetic fields H has also been measured. As shown in the inset of Fig. 2, the magnetization

 0021-8979/96/79(8)/6580/3/$10.00

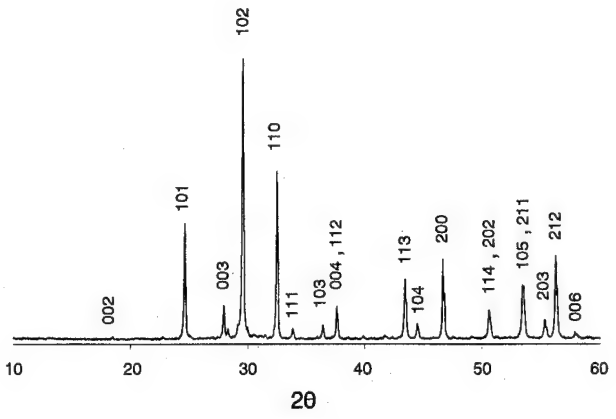

FIG. 1. X-ray diffraction pattern of Hg1201 sample.

changes linearly with H within experimental resolution which suggests negligible ferromagnetic contributions. According to our TEM, SEM, and EDX studies, the paramagnetic contribution results from synthesis related impurities,[11] which were not detectable by x-ray and neutron powder diffraction. Since the magnetization of the samples depends on the percentage of Hg1201 phase inside the samples, we must first be sure all the samples used contain the same percentage of Hg1201 phase if we want to determine how the magnetization of Hg1201 samples change with the oxygen content. To do so, all the samples we used were synthesized at the same time and annealed under differing conditions. So, the samples with different oxygen content should contain similar amounts of impurities. In this study, we were only concerned with the change in magnetization with oxygen content, so these impurities should not effect our results and conclusion.

In an ideal case, the low field magnetization M of superconducting particles is related to λ as $M \propto 1-(\lambda/d)^2$, where d is the diameter of the particles and λ is the penetration depth. In order to ensure uniformity in particle size among the samples, a large quantity of Hg1201 powder was synthesized and ground at the same time, and then separately annealed under different conditions to obtain samples with different oxygen content. The dc magnetization was measured at 5 Oe for samples that were both zero field cooled (ZFC) and field cooled (FC). The result of the ZFC measurement is an overestimation of the true superconducting volume fraction due to porosity. According to the study by Braunisch *et al.*,[12] the results of FC measurements very badly underestimate the superconducting volume fraction for ceramic HTS samples due to pinning and the large penetration depth in the C direction. The real superconducting volume fraction of the samples M should be between M_{FC} and M_{ZFC}. M_{FC} and M_{ZFC} versus oxygen content δ are shown in the Fig. 3. Both M_{FC} and M_{ZFC} increase with δ, are a maximum for optimally doped Hg1201 and decrease with further increase in oxygen content. The T_c vs M $[M=(M_{ZFC}+M_{FC})/2]$ are shown in Fig. 4. The curve appears to be double valued in nature. Since $n_s/m^* \sim 1/\lambda^2$, T_c vs n_s/m^* follows a "boomerang path" like that in Tl2201 and T1201.

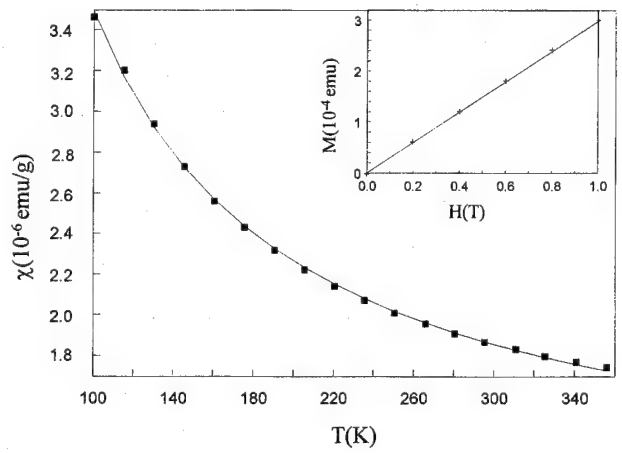

FIG. 2. The normal state susceptibility as a function of the temperature for one of our as synthesized Hg1201 samples [fit of $\chi=1.04\times10^{-6}+2.45\times10^{-4}/T$ (emu/g)]. Inset: Magnetization M as a function of magnetic field H.

IV. CONCLUSION

The magnetization of Hg1201 with $0.03 \leqslant \delta \leqslant 0.4$ has been studied. The results have shown that the T_c vs n_s/m^* also forms a "boomerang path" in Hg1201, which is similar to that in HTSs in the underdoped region and Tl2201 and Tl1201 in the overdoped region.

A new approach involving the use of fluorides has been adopted to synthesize phase-pure Pb-substituted Hg-1223 superconductors under ambient conditions. A representative sample is characterized using x-ray, SQUID magnetometer, and ac susceptibility techniques. In a measuring field of 1 G, a sharp diamagnetic onset is observed at 132 K and perfect flux screening persists up to 122 K. On approaching T_c the irreversibility line follows a power law with exponent $\alpha=2.2$. From the ac susceptibility data, in the context of the Bean critical state model, the critical current density at helium temperatures is estimated to be 1.5×10^6 A/cm^2. © *1996 American Institute of Physics.* [S0021-8979(96)42008-2]

I. INTRODUCTION

The discovery by Putilin *et al.*[1] of superconductivity at 94 K in $HgBa_2CuO_{4+\delta}$ and the subsequent report by Schilling *et al.*[2] of superconductivity above 130 K in $HgBa_2Ca_2Cu_3O_{8+\delta}$ initiated intense research in these mercury compounds. They both belong to the homologous series of $HgBa_2Ca_{n-1}Cu_nO_{2n+2+\delta}$ which today has five members ($n=1-5$), with Hg-1223 showing the highest T_c. It was observed that T_c of the Hg-1223 phase increases with pressure to 164 K at 30 GPa,[3] indicating that even higher critical temperatures might be obtained at ambient pressure if the internal pressure could be increased by, say, optimizing the doping levels.

A major problem encountered in the synthesis of the Hg compounds is the difficulty in obtaining phase-pure samples. It has been shown that a small amount of Pb facilitates the formation of a single phase.[4] Fluorine doping in Bi-2223 has been shown to enhance the stability and to increase the critical temperature.[5] It is thus of interest to study the effect of fluorine doping in the mercury-based system.

In this work we study the magnetic properties of Pb-substituted Hg-1223 samples synthesized using fluorides.

II. EXPERIMENT

A precursor of nominal composition $Ba_2Ca_2Cu_4O_x$ was prepared using barium, calcium, and copper nitrates as the starting materials. The nitrates were weighed out and mixed in a dry box and then fired for 6 h at 900 °C under flowing oxygen after a heat-up to 900 °C in 6 h. One mole of the fired precursor was mixed with 0.8 moles of HgO and 0.2 moles of PbF_2 in a dry box, pelletized and sealed in a 0.4 mm outer diameter quartz tube after back filling with a tenth of a Torr of oxygen. The quartz tube with the sample is then fired at 850 °C for 25 h after heat-up to the firing temperature in 1 h. The samples are characterized without further annealing.

The x-ray powder diffraction pattern collected within $5°\leqslant 2\theta \leqslant 80°$ using a Siemens D5000 diffractometer shows mainly the lines that belong to the Hg-1223 phase (Fig. 1).

The dc susceptibility measurements were performed using Quantum MPMS$_2$ SQUID magnetometer. All measurements, in fields ranging from 1 G to 10 kG, were performed during the warming scan after zero field cooling the samples to 10 K. The ac susceptibility measurements were performed using a home-built two-position ac susceptometer with a three-coil mutual inductance bridge. Driving fields were varied from 10 mOe to 2 Oe rms at 190 Hz.

III. RESULTS AND DISCUSSION

Figure 2 shows a typical field cooled (FC) and zero field cooled (ZFC) warming up scan in 1 G. Using the dimensions of the sample ($7.0\times1.5\times0.8$ mm^3) a ZFC susceptibility of -1.02 (complete flux expulsion) is obtained. The flux expulsion is better than 95% even up to temperatures as high as 122 K. The flux expulsion for FC is only 12%. This big difference is explained by strong pinning—at the thin surface layer during ZFC and in the bulk of the sample during FC.

The magnetic susceptibility was measured at different fields, ranging from 1 to 1000 G. All scans are shown in Fig. 3 together with an ac susceptibility measurement at 10 mG rms. As the field is increased there appear signs of a second

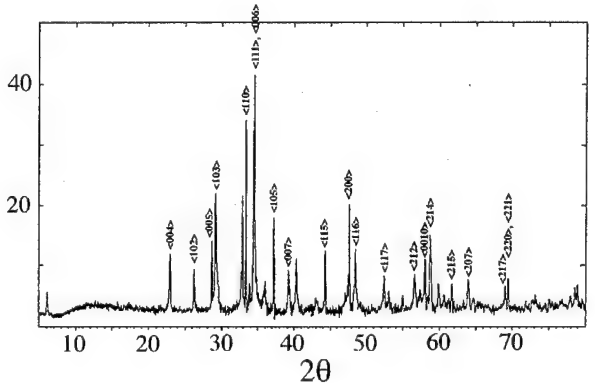

FIG. 1. X-ray powder diffraction pattern identifying intensity peaks that belong to the Hg-1223 phase.

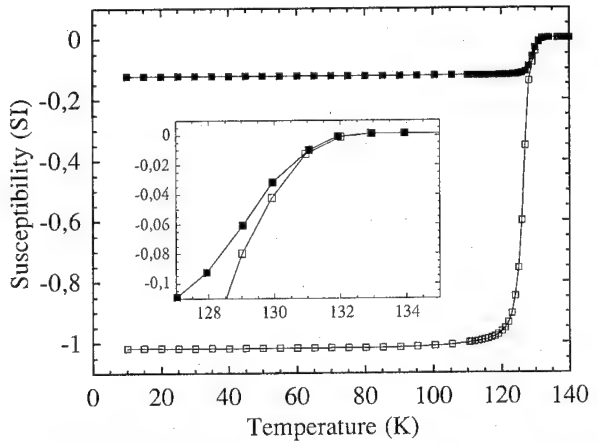

FIG. 2. ZFC and FC dc susceptibility measured in a field of 1 G. In the inset is shown the two curves branching off at the irreversibility point.

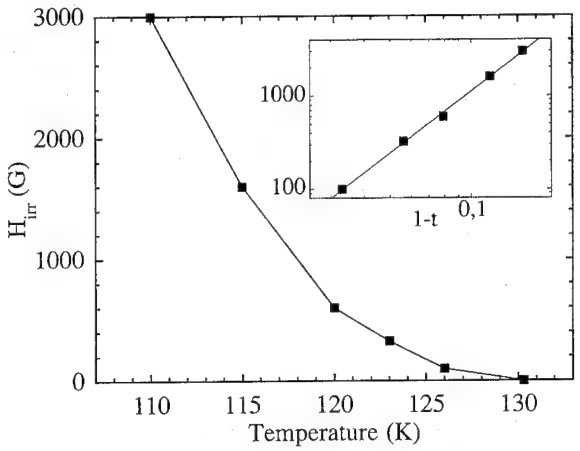

FIG. 4. The irreversibility line. The inset shows a fit to a power law with the exponent $\alpha=2.2$.

phase with a higher critical current. There is almost no change in susceptibility at fields from 300 to 500 G indicating a weaker field dependence of this phase.

The location of the irreversibility line is important from applications point of view. The irreversibility line is obtained from the points in the T-H plane where the FC and ZFC curves split. These points can be determined either by measuring FC and ZFC temperature scans in a constant field or measuring M/H loops at a constant temperature. We determined these point by measuring M/H loops at six different temperatures. We chose the criterion for irreversibility as $\Delta M=0.02$ emu/cm^3, where ΔM is the magnetization difference in decreasing and increasing field. On approaching T_c we find a power law dependence $H_{\rm irr}\propto(1-t)^{\alpha}$ with the exponent, $\alpha=2.2$ (Fig. 4).

To get further insight in the magnetic properties we studied the ac susceptibility as a function of temperature and field. The complex susceptibility $\chi=\chi'-i\chi''$ gives additional information since the imaginary part χ'' corresponds to energy dissipation in the material and can be used to deduce various parameters such as the critical current density. The

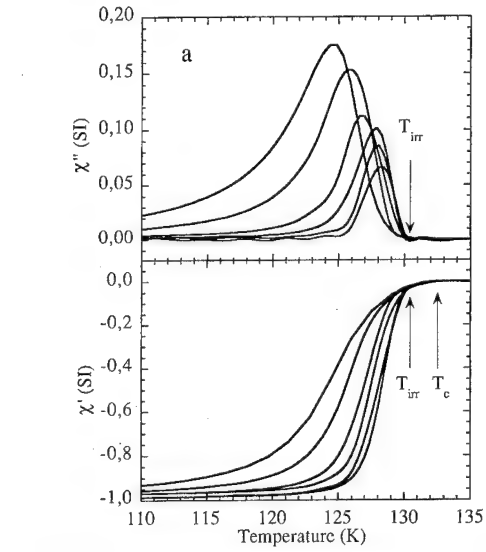

FIG. 5. Imaginary (a) and real (b) part of the complex ac susceptibility measured with driving fields 0.01, 0.03, 0.1, 0.3, 1, and 2 Oe.

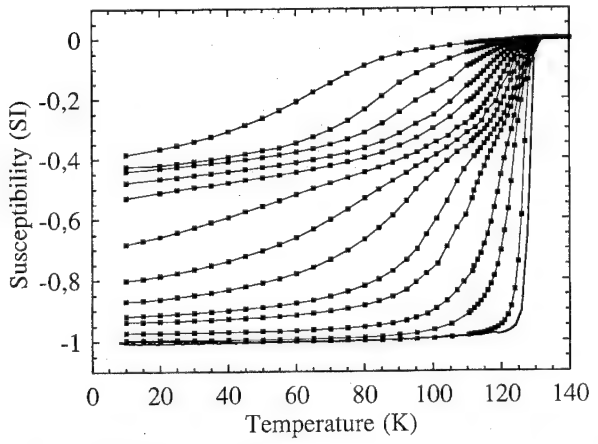

FIG. 3. Susceptibility measured in fields: 1, 5, 10, 20, 30, 50, 70, 100, 150, 200, 300, 500, and 1000 G. Also shown is the real part of the ac susceptibility measured in 10 mG rms.

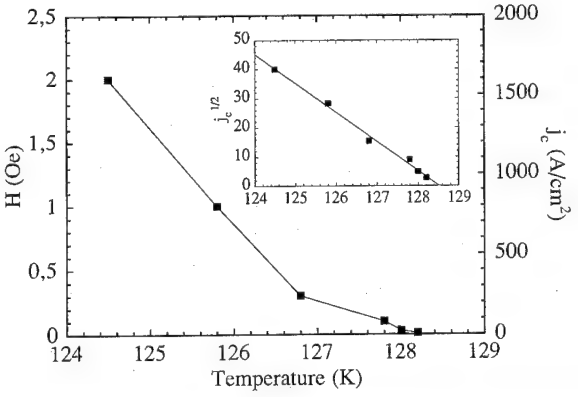

FIG. 6. Peak field and critical current density as a function of temperature. The inset shows a fit $j_c(T)=1.5\times10^6(1-t)^2$ A/cm^2.

real part χ' is approximately equivalent to the ZFC dc susceptibility and can be used to measure ZFC curves at very low field strengths.

We measured the temperature dependence of the complex susceptibility at six different driving fields (Fig. 5). The diamagnetic transition onset is located at 132 K. Below T_{irr}, at about 130.3 K, this diamagnetic response becomes field dependent and the dissipation appears.

According to the Bean critical model the peak in χ'' corresponds to the field just penetrating into the center of the sample and at this point there exists a simple relationship between this field H_p (in A/m) and the critical current density:[6]

$$H_p = J_c R.$$

Approximating our sample geometry to a long cylinder of radius 1 mm we can thus calculate the critical current density as a function of temperature (Fig. 6). Assuming a power law dependence we find the critical current density at helium temperatures to be about 1.5×10^6 A/cm^2.

IV. CONCLUSION

In conclusion we have studied the magnetic properties of phase-pure F-doped Pb-substituted Hg-1223 samples. While it is still premature to claim the important role of fluorine in this system, we observe a high critical temperature and good magnetic properties.

Magnetization studies on organic single-crystal superconductors of κ-(BEDT-TTF)$_2$Cu[N(CN)$_2$]Br with the field H parallel to the b axis (perpendicular to the conducting plane) show anomalous field and temperature dependence of vortex pinning in the mixed state. At high temperatures, the magnetization M decays with increasing field with a power-law dependence. The normalized relaxation rate $S=d(\ln M)/d(\ln t)$ decreases monotonically with H. At low temperatures ($T<7$ K), a change of sign in the curvature of $M(H)$ is observed, accompanied by a corresponding change in S as a function of H. Measurement of the irreversibility field H_{rev} shows a universal power-law dependence of H_{rev} on $(1-T/T_c)$ in the temperature range investigated. We suggest that the magnetic anomaly observed is due to a dimensional crossover in the nature of vortex pinning.
 [S0021-8979(96)03208-2]

The discovery of ambient pressure organic superconductor κ-(BEDT-TTF)$_2$X family [BEDT-TTF denotes bis(ethylenedithio)tetrathiafulvalene and X a monovalent anion] with $T_c\sim 11$ K has generated considerable interest in the study of anisotropic magnetic properties in the mixed state. The material has an intrinsic layered structure consisting of alternating sheets of metallic (dimerized BEDT-TTF molecules) and insulating (anion X) planes. The anisotropy constant γ defined as $\sqrt{M_\perp/M_\parallel}$ has been reported of the order of 100 or more.[1–5] Except the low T_c value, the organic superconductor is very similar to the highly anisotropic $Bi_2Sr_2CaCu_2O_{8+y}$ (BSCCO) and $Tl_2Ba_2Ca_{n-1}Cu_nO_{4+2n}$ (TBCCO) compounds. Moreover, since it is free of secondary phases commonly present in the oxide superconductors, the organic superconductor may prove to be an ideal system to investigate the anisotropic magnetic properties. A careful comparative study in the mixed state in this structurally homogeneous system will contribute to our understanding of the more complex high-temperature oxide superconductors.

We report here magnetization measurements on organic single-crystal superconductors of κ-(BEDT-TTF)$_2$Cu[N(CN)$_2$]Br with the field H parallel to the b axis (perpendicular to the conducting plane). Our measurements show anomalous field and temperature dependence of vortex pinning in the mixed state. At high temperatures, the magnetization M decays with increasing field with a power-law dependence. The normalized relaxation rate $S=d(\ln M)/d(\ln t)$ decreases monotonically with H. At low temperatures ($T<7$ K), a change of sign in the curvature of $M(H)$ is observed, accompanied by a corresponding change in S as a function of H. Measurement of the irreversibility field H_{rev}, shows a universal power-law dependence of H_{rev} on $(1-T/T_c)$ in the temperature range investigated with $H_{rev}\propto(1-T/T_c)^{3/2}$. We suggest the anomaly observed is due to a dimensional crossover in the nature of vortex pinning.

Single crystals of κ-(BEDT-TTF)$_2$Cu[N(CN)$_2$]Br superconductors were synthesized by the electrocrystallization technique described elsewhere.[6] Several crystals were used in these measurements with average dimensions of $1\times0.5\times0.1$ mm. Extensive measurements were made on one crystal with $T_c=11$ K. Measurements were performed with the use of a Quantum Design magnetometer with low-field options. A typical hysteresis loop was measured after the sample was zero-field cooled (ZFC) to a set temperature and the magnetization was measured with the superconducting magnet in the persistent mode. Scan length varying from 4 to 6 cm gave similar results. Relaxation measurements were performed in field in ZFC condition. A typical remanent field after quenching the magnet was less than 20 mG. Samples were placed with the field parallel to the b axis.

Figure 1 shows an overlay of the magnetization as a function of field at different temperatures. At high temperatures $T>7$ K, M decreases in a power-law field dependence with $M\propto H^{-n}$ and $n=2/3$. The same exponent is observed for temperature up to 10 K.[7] Below 7 K, a shoulder-like feature is developed in $M(H)$ at H around 200 G, with a corresponding change in the curvature of $M(H)$. The effect is most pronounced at a lower temperature of 6 K. Further decrease in temperature broadens and smears out the change.

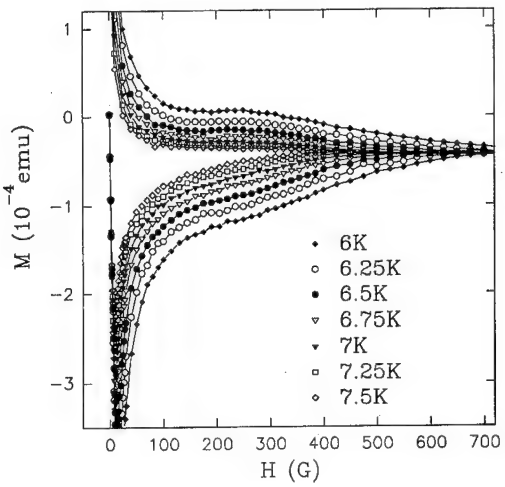

FIG. 1. Magnetization as a function of field at different temperatures.

 0021-8979/96/79(8)/6586/3/$10.00

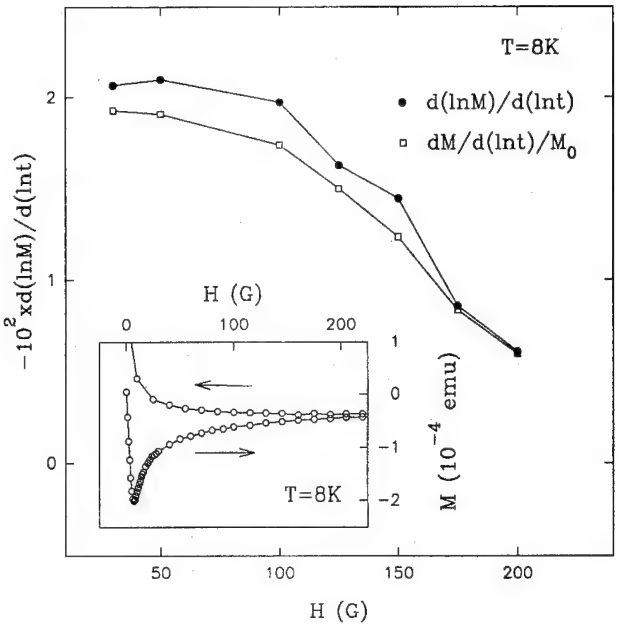

FIG. 2. Normalized relaxation rate as a function of H at 8 K. The inset shows the hysteresis loop at the same T.

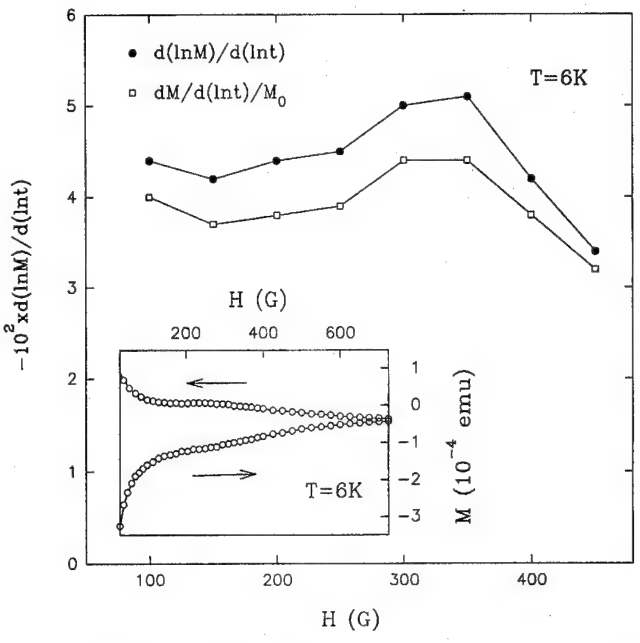

FIG. 3. Normalized relaxation rate as a function of H at 6 K. The inset shows the hysteresis loop at the same T.

Figure 2 plots the normalized relaxation rate as a function of field. S is defined as the average slope of ln M vs ln t. Since the magnetization does not decay strictly with power-law dependence with time nor linear with ln t. We have extrapolated both the average $d(\ln M)/d(\ln t)$ (in solid circles) and the average $dM/d(\ln t)/M_0$, where M_0 is the initial magnetization (in open squares). The magnitude of the normalized relaxation rate is similar in both extrapolations, as well as its field dependence. The inset shows the corresponding hysteresis loop at the same temperature of 8 K. The arrows indicate the direction of increasing and decreasing field.

Shown in Fig. 3 is a similar plot of the relaxation rate at a lower temperature of 6 K. Unlike the monotonic field dependence observed at higher temperatures, the normalized relaxation rates as defined by both extrapolations show a slight increase at about 300 G and decrease again at higher field. The peak in S is roughly correlated with the secondary peak field of the corresponding hysteresis magnetization loop, as shown in the inset.

Figure 4 is a semi-log plot of the irreversibility field as a function of temperature. The irreversibility field $H_{\rm rev}$ here is defined as the onset field at which the magnetizations on both ascending and descending directions overlap. The temperature range we had investigated was limited to above 5 K. Measurements of $H_{\rm rev}$ at lower temperatures on the same compound have been reported by Lang *et al.*,[5] as shown by the solid circles. They are consistently higher than ours in the overlapping temperature regime. The difference might be due to different disorders, thus, pinning strengths among samples studied. If we neglect the difference in the magnitude of $H_{\rm rev}$, a change of curvature in $H_{\rm rev}(T)$ with T is clearly visible. The solid line is a fit to $H_{\rm rev}=H_0(1-T/T_c)^{\alpha}$ with $\alpha=3/2$. The inset shows a log–log plot of $H_{\rm rev}$ vs T, with the straight line given by the above fit.

The magnetization observed for the κ-(BEDT-TTF)$_2$Cu[N(CN)$_2$]Br compound is qualitatively similar to the anomalous magnetization reported for the oxide high T_c superconductors,[8–10] especially the BSCCO and TBCCO compounds. Two main similarities are observed. First, a crossover temperature $T_{\rm cr}$ in the magnetization behavior exists in both families. In the case of $Tl_2Ba_2CuO_6$,[10] the anomalous magnetization disappears above a characteristic temperature of about 60 K ($T_c=92$ K). Below 60 K, a second peak in magnetization is developed for field greater than the first penetration field. Second, both families show very similar temperature dependence of the irreversibility

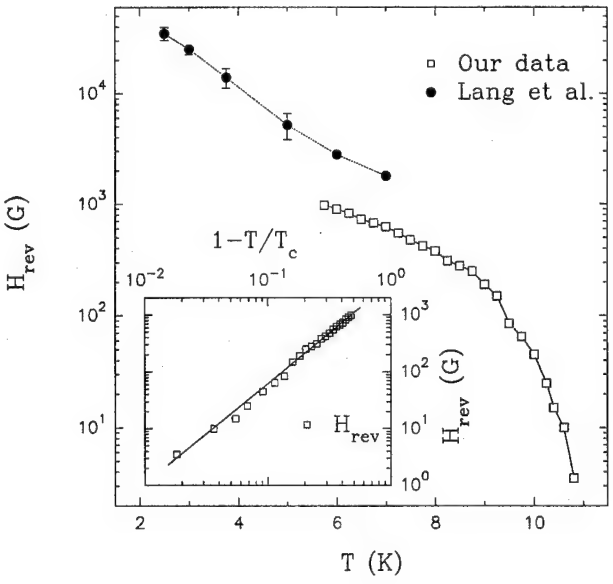

FIG. 4. $H_{\rm rev}$ as a function of T. The inset plots the same data in a log–log scale.

field line. At high temperatures, $H_{rev} \propto (1-T/T_c)^{\alpha}$ with the same exponent $\alpha=3/2$. At low temperatures, a change of curvature is observed in $H_{rev}(T)$. For $Tl_2Ba_2CuO_6$, this temperature corresponds to the crossover temperature T_{cr}. In the case of organic superconductor, our present data cannot pinpoint the temperature at which H_{rev} changes its curvature. However, results published by Lang *et al.* suggest this temperature is in the range of 5–6 K, very close to the crossover temperature of 7 K.

The mechanism giving rise to the anomalous magnetization in the mixed state has been of recent interest, particularly in the high-temperature oxide superconductors. Various mechanisms have been since proposed to explain the observed effect. In the case of oxides, the understanding of the anomalous secondary peak is complicated by the fact that the system tends to have oxygen inhomogeneities, resulting in superconducting phases with different critical temperatures. Because of this inhomogeneity, one possible explanation is that the increased pinning at high fields is due to the suppression of superconductivity of the lower T_c phases. However, the characteristic peak field should be of the order of H_{c2} of the low T_c phases in this model. Except for YBCO, typical peak field observed for BSCCO and TBCCO is of the order of 10^3 G or less, much less than the second critical field. In the case of the organic superconductors, to our knowledge, the organic κ-(BEDT-TTF)$_2$Cu[N(CN)$_2$]Br compound contains no secondary, lower T_c phases.[1] Thus, the enhanced pinning at high fields and low temperatures cannot be due to the secondary phase model.

Other models based on the collective pinning effects, the matching effect, etc., have also been proposed. In the case of collective pinning model,[8] the peak effect is attributed to the slow relaxation of large vortex bundles. The normalized relaxation rate is given by $S=k_BT/[U_0+\mu k_BT \ln(t/t_0)]$, where U_0 is the barrier height, μ is the exponent defined in the $U(j) \propto j^{-\mu}$, t is the measurement time and t_0 some attempt time. With increasing field the volume of the vortex bundle increases, resulting in an increase in the magnitude of the pinning barrier and smaller S. Unlike most oxide materials, a maximum S in the vicinity of secondary peak is observed in the organic compound, as shown in Fig. 3. This result contradicts sharply the collective pinning model as the mechanism for the enhanced pinning effect. Rather, as will be discussed later, it is consistent with a decrease in the pinning volume due to dimensional crossover from three-dimensional (3D) vortex line to two-dimensional (2D) pancakes. The anomalous field and temperature dependence also excludes a matching effect model in which a peak in critical current is expected when the vortex lattice and the defect structure become commensurate with each other.[9]

The anomalous magnetization in the organic material is consistent with a dimensional crossover model proposed recently for $Tl_2Ba_2CuO_6$.[10] In this model, the secondary peak at high fields is due to the pinning of the 2D vortices. The crossover from 3D vortex line pinning to 2D pancake pinning occurs at the onset of the second peak. The critical field for dimensional crossover for very anisotropic systems has been predicted theoretically and given by[11,12] $H_{cr} \approx \phi_o/\lambda_J^2$, where $\lambda_J=\gamma s$, γ is the anisotropy constant, and s is the separation between the superconducting layers. A large anisotropy corresponds to a smaller critical field. In contrast to the collective pinning model, the pinning barrier is expected to decrease at the transition due the smaller volume of the 2D pancakes compared to the 3D lines, resulting in a larger S. Experimentally, the critical field is identified by the onset of the rising magnetization. For oxide superconductors, it is associated with the field where M reaches the minimum. For the organic superconductors, the gradual transition in $M(H)$ makes the precise determination of H_{cr} very difficult. For order of magnitude estimate, we take the approximate peak field as the critical field, i.e., $H_{cr} \approx 200$ G. Using the lattice spacing of 15 Å as the separation between the superconducting layers, $\gamma \approx 200$ is obtained. The large anisotropy is consistent with the reported values of similar compounds.

In summary, we have reported detailed magnetization studies on single crystals of a highly anisotropic organic superconductor κ-(BEDT-TTF)$_2$Cu[N(CN)$_2$]Br. The anomalous magnetization is observed below the crossover temperature of about 7 K. The irreversibility line shows a universal power-law temperature dependence $H_{rev} \propto (1-T/T_c)^{3/2}$ at high temperatures. The normalized relaxation rate shows a maximum near the onset of the magnetic anomaly for temperatures below 7 K. The results are consistent with the model of a dimensional crossover from 3D to 2D pinning. The gradual transition observed is qualitatively in agreement with the weak intrinsic pinning of the organic superconductors.

Experimental evidence of a crossover in the vortex dimensionality in high-T_c superconductors

A. García, X. X. Zhang, and J. Tejada
Departament de Física Fonamental, Universitat de Barcelona, Diagonal 647, E-08028 Barcelona, Spain

Quantum motion of vortices in high-temperature superconductors (HTSCs) was studied via magnetic relaxation measurements performed with a commercial superconducting quantum interference device magnetometer. At a fixed temperature, the field dependence of the time-logarithmic magnetic relaxation rate normalized to the first magnetization value, $R=|d(M/M_0)/d\ \ln(t)|$, was investigated in different polycrystalline HTSCs: TlBaCaCuO (2212 and 2223 single phases), YBaCuO (123 phase), and (Hg,Tl)BaCaCuO (1223 phase). The results obtained for TlBaCaCuO 2223 phase and (Hg,Tl)BaCaCuO show a common trend: R increases linearly with magnetic field up to a certain value, the dimensional crossover field $H_{3D\text{-}2D}$, above which it becomes field-independent. $H_{3D\text{-}2D}$ is a characteristic field which depends on the anisotropy parameter and the interlayer spacing of the material. The field dependence of R can be ascribed to a crossover in the dimensionality of the object involved in the quantum process: above $H_{3D\text{-}2D}$, the longitudinal dimension of the tunneling object, L_c, is smaller than the interlayer distance, so the object is of two-dimensional (2D) nature (2D pancake vortices). Below $H_{3D\text{-}2D}$, 2D vortices in neighboring layers become coupled, so the tunneling object becomes three-dimensional (3D) in nature (3D flux-lines). The field dependences of R obtained for TlBaCaCuO 2212 phase and YBaCuO show only the 2D and 3D vortex regimes, respectively. Well agreement between theoretical estimates and experimental values for the dimensional crossover field and normalized relaxation rates is achieved. © *1996 American Institute of Physics.* [S0021-8979(96)81308-5]

It is well known that, because of their layered structure and the confinement of conductivity in the CuO_2 planes, the superconductive properties of high-T_c superconductors (HTSCs) present a very anisotropic behavior. In some cases, this behavior can be described as three-dimensional (3D), whereas in other cases as two-dimensional (2D). The crossover between both dimensionalities takes place when some characteristic length along the c axis is of the order of the interlayer spacing d, the physical meaning of this characteristic length being different for each property. Therefore, at the same point in the $H-T$ plane some properties are 2D-like while some others are 3D-like, resulting in a complicated phase diagram. Among these properties, thermal fluctuations, pinning, and creep of vortices are of special interest for the study of the decay of critical currents in HTSCs.

A crossover in the dimensionality of thermal fluctuations at very low temperatures has been independently predicted by Vinokur *et al.*[1] and Feigel'man *et al.*:[2] thermal fluctuations are two-dimensional as long as the vortex lattice spacing in the ab-plane, $a_0\simeq(\Phi_0/B)^{1/2}$, remains smaller than the effective Josephson length characterizing the interlayer coupling along the c-axis, $R_J=\gamma d$, where $\gamma\equiv(\lambda_c/\lambda_{ab})$ is the anisotropy parameter of the material (λ_c and λ_{ab} are the London penetration depths along the c axis and ab plane, respectively). This conduction can be equivalently expressed in terms of the magnetic field as $H_a>H_{3D\text{-}2D}$, where

$$H_{3D\text{-}2D}\simeq\Phi_0/(\gamma d)^2 \tag{1}$$

is called the dimensional crossover field. When the opposite inequality holds, thermal fluctuations become 3D.

In the case of pinning, the characteristic length of the problem is the longitudinal dimension of the pinned object, L_c. A flux-line in the mixed state of a HTSC can be pictured as a stack of 2D pancake vortices lying in adjacent CuO_2 layers, connected by Josephson vortices.[3] Whenever $L_c<d$, 2D pancake vortices are independently pinned in each copper-oxide layer, and pinning is 2D in nature; in the opposite case, 2D pancake vortices lying in adjacent layers are coupled along the c-axis and pinning becomes 3D. Although, in principle, the dimensionalities of pinning and thermal fluctuations are independent one from each other, the crossover between 2D and 3D pinning of individual vortices at very low temperatures is predicted[1] to be also ruled by $H_{3D\text{-}2D}$.

As for the dimensionality of creep, the characteristic length in the general case of thermal activation is the perpendicular dimension of the object with respect to the hopping direction.[4] At very low temperatures, however, creep is dominated by quantum motion of individual vortices and the evolution of magnetization with time is essentially logarithmic for very long periods. The expressions for the 3D and 2D quantum relaxation rates normalized to the first magnetization value, $R=|d(M/M_0)/d\ \ln(t)|$, in the limit of strong ohmic dissipation, are given by the QCC theory (the subscript "d" stands for "dissipative limit"):[5]

$$R_{d,3D}\simeq(e^2/\hbar)(\rho_n/L_c),\quad \text{for } L_c>d; \tag{2a}$$

$$R_{d,2D}\simeq(e^2/\hbar)(\rho_n/d),\quad \text{for } L_c<d. \tag{2b}$$

In the Hall tunneling limit (zero dissipation), the expressions are the following (the subscript "H" stands for "Hall limit"):[6]

$$R_{H,3D}\simeq(n_s\xi^2L_c)^{-1},\quad \text{for } L_c>d; \tag{3a}$$

$$R_{H,2D}\simeq(n_s\xi^2d)^{-1},\quad \text{for } L_c<d\ . \tag{3b}$$

 0021-8979/96/79(8)/6589/3/$10.00

In these expressions, $(e^2/\hbar)\simeq 4.1$ kΩ is the quantum of resistance, ρ_n is the normal state resistivity in the ab plane extrapolated at zero temperature, and $L_c\simeq(\xi/\gamma)(J_0/J_c)^{1/2}$ is the collective-pinning length along the c-axis, where the superconducting coherence length ξ, deparing current density J_0, and critical current density J_c, denote in ab-plane values. Finally, n_s is the bulk density of superelectrons.

Notice that the criterion that distinguishes the creep dimensionality at very low temperatures is again the relation between L_c and d, or, equivalently, H_a and $H_{3D\text{-}2D}$: the 3D quantum rate holds for $H_a<H_{3D\text{-}2D}$, while in the opposite case is valid the 2D quantum rate. Notice also that the 3D quantum rate is directly proportional, through L_c [see (2a) and (3a)], to γ. Recently, Daemen *et al.*[7] demonstrated that the anisotropy parameter is not a constant in HTSCs, but an increasing function of H_0, directly reflecting the field dependence of the penetration depth along the c-axis, $\lambda_c(H_a)$. Thus, the 3D quantum rate is expected to increase as H_a increases up to $H_{3D\text{-}2D}$, above which a crossover to the field-independent [see (2b) and (3b)] 2D quantum rate should occur. In this article we show that the study of the field dependence of the normalized relaxation rate at a fixed very low temperature can be a very useful tool for the experimental detection of the dimensional crossover field.

Different polycrystalline systems were investigated: bulk sintered $YBa_2Cu_3O_7$ (Y-123), $Tl_2Ba_2Ca_2Cu_3O_{10}$ (Tl-2223), and $(Hg,Tl)Ba_2Ca_2Cu_3O_8$ (Hg-1223), and powder $Tl_2Ba_2CaCu_2O_8$ (Tl-2212). Details on each sample preparation are described elsewhere.[8] A commerical (Quantum Design) a.c. superconducting quantum interference device magnetometer ($1.8<T<400$ K; $H_{max}=55$ kOe) was used for the experiments. The procedure performed for each magnetic relaxation measurement was the following. The sample was first cooled from well above the superconducting transition temperature T_c down to the target temperature with a magnetic field on [field-cooling (FC) process]. Once the target temperature was stable (the temperature stability in the low temperature range was 0.01 K), the field was removed and the time evolution of the remanent magnetization was recorded. Before each new measurement, trapped flux lines were removed by warming the sample well above T_c. At a given temperature, the process was repeated with different magnetic fields applied during the FC process. For each field, the first magnetization point was recorded at 60 s, and subsequent data were taken every 70 s, during a period of ~1 h.

In the whole magnetic field range investigated ($1<H_a<50$ kOe), all relaxation curves are linear with the logarithm of time in the scanned time window, except for an initial nonlinear decay, which could correspond to a reconfiguration of the inhomogeneous flux distribution caused by the sudden suppression of the magnetic field just before the measurement started. The initial nonlinear regime is enhanced in the Tl-2212 system, probably due to sample degration or signal contribution from the powder container. Only the linear regime of each curve was fitted to a time-logarithmic law, with great accuracy for all curves in all the samples.

Figure 1 presents the magnetic field dependence of the normalized relaxation rates of Hg-1223 at $T=2.8$ K and Tl-2223 at $T=2.4$ K. We show elsewhere[9] that the quantum regime manifests itself up to ≃2.5–3 K for $H_a=3$ and 6 kOe in Tl-2223, but only up to ≃2.1 K for $H_a=3$ kOe in Hg-1223. Therefore, while the normalized relaxation rate obtained for Tl-2223 at 2.4 K lies in the quantum regime, that obtained for Hg-1223 at 2.8 K falls off, but near that regime. Thus, in this case, R should be not far from its quantum value, so we will trust the results at 2.8 K as representative of the magnetic field dependence of the actual quantum rate. Let us now turn to the discussion of the results. Both curves appearing in Fig. 1 show a common trend: R increases with H_a up to ≃10–16 kOe, and subsequently reaches a saturation value (≃1.55% for Tl-2223 and ≃1.85% for Hg-1223). As mentioned above, this behavior characterizes a transition in the dimensionality of the pinned object, from 3D to 2D as H_a increases, the experimental dimensional crossover field being $H_{3D\text{-}2D}\simeq$10–16 kOe for both samples. Substitution of $\gamma\simeq 20$ (Ref. 10) and $d\simeq 18$ Å (Ref. 11) in Eq. (1) gives $H_{3D\text{-}2D}\simeq 16$ kOe for Tl-2223, in excellent agreement with the

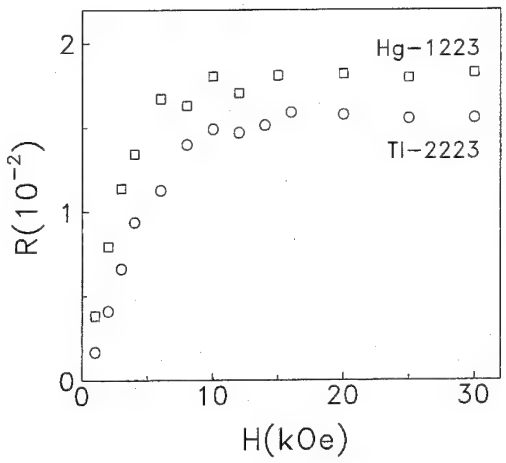

FIG. 1. Magnetic field dependence of the normalized relaxation rates corresponding to the remanent magnetization obtained for Tl-2223 at $T=2.4$ K (circles) and Hg-1223 at $T=2.8$ K (squares).

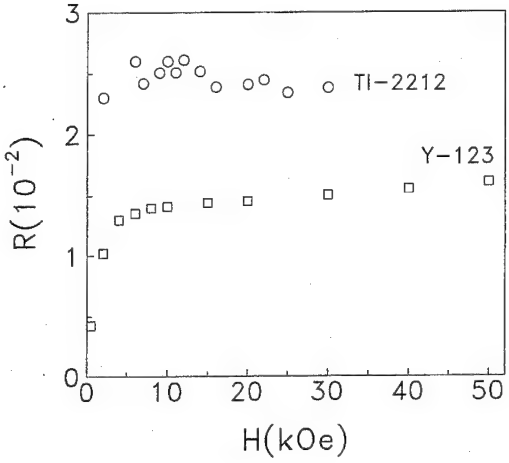

FIG. 2. Normalized relaxation rate as a function of the magnetic field applied during the FC process for Tl-2212 (circles) and Y-123 (squares) at $T=2.4$ K.

TABLE I. Relevant parameters for the different samples. From top to bottom: anisotropy parameter (γ); interlayer spacing (d); experimental (exp $H_{3D\text{-}2D}$) and estimated (est $H_{3D\text{-}2D}$) dimensional crossover field; experimental (exp R_{2D}), and dissipatively (est $R_{d,2D}$) and Hall estimated (est $R_{H,2D}$), 2D quantum rate.

	Tl-2223	Hg-1223	Tl-2212	Y-123
γ	20	25–30	350	8
d (Å)	18	16	16	12
exp $H_{3D\text{-}2D}$ (kOe)	10–16	10–16	···	···
est $H_{3D\text{-}2D}$ (kOe)	16	···	0.07	225
exp R_{2D} (%)	1.55	1.85	2.4	···
est $R_{d,2D}$ (%)	2	2.3	2.4	3
est $R_{H,2D}$ (%)	6	7	7	9

experimental result. A similar estimate for Hg-1223 is not available for lack of its anisotropy parameter in the related literature. Nevertheless, from the experimental value of $H_{3D\text{-}2D}$ we can give an estimate of γ. Using Eq. (1) and assuming a value for d similar to the c axis of the tetragonal unit cell, $d \simeq 16$ Å, $\gamma \simeq 30$ is obtained, similar to that of Tl-2223 ($\gamma \simeq 20$) and Bi-2223 ($\gamma \simeq 30$),[12] and larger than that of the 1223 phase of the Tl-free Hg-based system ($\gamma \simeq 7$).[13] Finally, substitution of typical HTSCs values [$\rho_n \simeq 15\ \mu\Omega$ cm, $n_s \simeq 10^{12}$ cm^{-3}, $\xi \simeq 30$ Å] in Eqs. (2b) and (3b) gives an estimate of the 2D quantum plateau. Thus, $R_{d,2D} \simeq 2\%$ and $R_{H,2D} \simeq 6\%$ for Tl-2223, and $R_{d,2D} \simeq 2.3\%$ and $R_{H,2D} \simeq 7\%$ for Hg-1223, are obtained, in good qualitative (in the case of $R_{d,2D}$, also quantitative) agreement with the experimental plateau values.

The magnetic field dependence of the normalized relaxation rates of Tl-2212 and Y-123 at $T = 2.4$ K is shown in Fig. 2. Two different behaviors can be observed. For Tl-2212, the data are scattered around a plateau of $\simeq 2.4\%$, the minimum value of H_a being 2 kOe. In the case of Y-123, R presents an initial fast increase up to $H_a = 10$ kOe, above which slows down but does not reach a constant value. Both dependences can be understood by estimating the dimensional crossover field of each sample. Substitution in Eq. (1) of $\gamma \simeq 350$ (Ref. 14) and $d \simeq 15$ Å (Ref. 11), and $\gamma \simeq 8$ (Ref. 15) and $d \simeq 12$ Å (Ref. 16), gives $H_{3D\text{-}2D} \simeq 0.07$ and $\simeq 225$ kOe for Tl-2212 and Y-123, respectively. This means that in the case of Tl-2212 we are detecting only the 2D regime, while only the 3D regime shows up for Y-123. A more accurate magnetic fields scan of the latter, including extension to fields >55 kOe, is needed in order to clarify the two different increasing regimes which cannot be simply understood in the context of the present work. Finally, the experimental plateau value observed for Tl-2212, $\simeq 2.4\%$, is in excellent quantitative agreement with the 2D dissipative estimate [Eq. (2b)], $R_{d,2D} \simeq 2.4\%$, but compares only qualitatively to the Hall estimate [Eq. (3b)], $R_{H,2D} \simeq 7\%$. Table I summarizes the relevant experimental and estimated parameters of the different samples investigated.

In summary, we have investigated the magnetic field dependence at very low temperatures of the normalized relaxation rate of four different HTSCs. A crossover in the dimensionality of the object involved in the quantum process has been detected in two samples (Tl-2223 and Hg-1223). In the other samples, only 2D (Tl-2212) or 3D(Y-123) behavior could be observed. An exhaustive scan of the whole magnetic field range is needed to obtain more accurate values of the dimensional crossover field $H_{3D\text{-}2D}$.

The magnetooptical technique was used to directly observe the magnetic flux penetration in single crystals of the La–Sr–Cu–O superconductor. The large size of the crystals (several millimeters along the three axes) allows for observations to be made along the different crystalline orientations. In a previous study,[1] we reported on direct measurements of critical currents and the dependence of their anisotropy on the amount of Sr doping. When looking at the behavior of vortices which are parallel to the Cu–O planes, we observed that the roughness of the flux fronts was greatly magnified for the highly anisotropic samples. This suggested that the vortices were moving between the planes, as if they were in independent channels. In this communication, we report on observations made when an additional field component is applied along the *c* axis. Our experiments show that this additional component strongly suppresses the vortex penetration, drastically reducing the apparent anisotropy of the critical currents. We argue that this behavior is consistent with a picture in which the vortices easily move ("glide") between the Cu–O planes, and only feel the pinning potential when they are tilted by the additional field component, and thus forced to "puncture" the planes. In order to build high-temperature superconductor (HTS) multichip modules (MCMs), it is necessary to grow several epitaxial layers of YBCO that are separated by thick dielectric layers without seriously affecting the quality of the YBCO layers. In this work, we have successfully fabricated YBCO/YSZ/SiO_2/YSZ/YBCO structures on single-crystal $LaAlO_3$ substrates using a combination of pulsed laser deposition for the YBCO layers and ion-beam-assisted rf sputtering to obtain biaxially aligned YSZ intermediate layers. The bottom YBCO layer had a $T_c \sim 89$ K, $J_c \sim 7.2\times10^5$ A/cm^2 at 77 K, whereas the top YBCO layer had a $T_c \sim 86$ K, $J_c \sim 6\times10^5$ A/cm^2 at 77 K. The magnetic field and temperature dependence of J_c for the YBCO films in the multilayer have been obtained. The results for each of the YBCO layers within the YBCO/YSZ/SiO_2/YSZ/YBCO structure are quite similar to those for a good quality single-layer YBCO film. © *1996 American Institute of Physics.* [S0021-8979(96)03308-9]

I. INTRODUCTION

In electronic applications of high-temperature superconductor (HTS) thin films, the critical current density (J_c) is an important characteristic. One of the potential applications of high-temperature superconducting films is as electronic interconnects on a multichip module (MCM).[1] Since there are a minimum of two HTS thin films, separated by thick dielectric layers required, in HTS multichip modules (MCMs), it is necessary to know if the quality of the HTS layers is still maintained after the entire fabrication process is completed. In addition to the critical temperature (T_c) and critical current density at zero field, the dependence of J_c on an externally applied magnetic field and the temperature for the entire multilayer structure is crucial information for electronic applications. The YBCO/YSZ/SiO_2/YSZ/YBCO multilayer structure has been fabricated by Reade *et al.*[2] They reported cracking in the top YBCO layer, which limited their investigation of the properties of the multilayered structure.

In this article, we report a study of the temperature and magnetic field dependence of J_c for both YBCO layers in a YBCO/YSZ/SiO_2/YSZ/YBCO multilayer structure[3] performed by the magnetization method. Our results show that the temperature and magnetic field dependence of J_c of the YBCO layers of these samples are similar to those of high quality single-layer YBCO thin films.

II. EXPERIMENT

The YBCO/YSZ/SiO_2/YSZ/YBCO multilayer samples investigated here were prepared by using a combination of pulsed laser deposition and ion-beam-assisted magnetron sputtering. Details of the technique will be described elsewhere.[3] In short, a 200-nm-thick $YBa_2Cu_3O_{7-\delta}$ (bottom YBCO, layer 1) film was deposited on a single-crystal $LaAlO_3$ substrate (100 orientation and area 1×1 cm^2) by pulsed laser ablation at a substrate temperature of ~750 °C. Ion-beam-assisted rf sputtering was used to deposit biaxially aligned 200-nm-thick yttria-stabilized zirconia (YSZ) as a capping layer (layer 2). Next a 1-μm-thick, amorphous SiO_2 layer (layer 3) was deposited on layer 2 at room temperature by rf sputtering. The capping layer (YSZ) is used to prevent diffusion of the third SiO_2 layer into the top YBCO layer. A fourth layer (biaxially aligned YSZ) was then deposited on the SiO_2 layer to a thickness of 200 nm using the same method as for layer 2. This layer is very important. It not only functions as protection against the diffusion of the third SiO_2 layer into the YBCO layer, it also allows good epitaxial YBCO growth if it has a well-aligned structure. Finally, the top YBCO layer (layer 5) was deposited by laser ablation under the same conditions as was used for layer 1.

The orientation of the YSZ and YBCO layers was characterized by x-ray diffraction. The magnetization $M(H)$ loop was measured using a Quantum Design Magnetometer in fields up to 4 T, applied parallel to the c-axis direction and at a fixed temperature. This was repeated for different temperatures ranging from 5 to 77 K. The values of J_c were calculated using Bean's model. The electrical resistance was measured using the standard four-lead technique.

III. RESULTS AND DISCUSSION

X-ray diffraction data showed that all samples investigated here were single-phase highly c-axis oriented with very good in-plane epitaxy (Fig. 1). There were no cracks observed in the top YBCO layer. The resistance $R(T)$ and magnetization $M(T)$ of the samples were carefully measured for each YBCO layer. Figure 2 shows the typical resistance as a function of temperature for the top YBCO layer. The

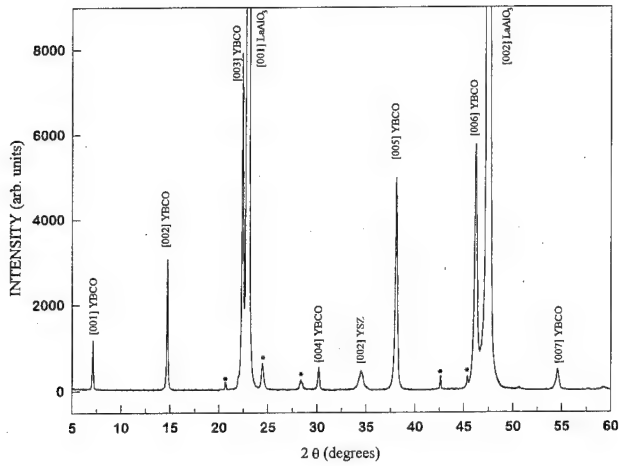

FIG. 1. θ-2θ x-ray diffractometer pattern for the YBCO/YSZ/SiO_2/ YSZ/ YBCO structure on [001] $LaAlO_3$ (*: indicate substrate impurity peaks seen in the bare substrates of the same batch).

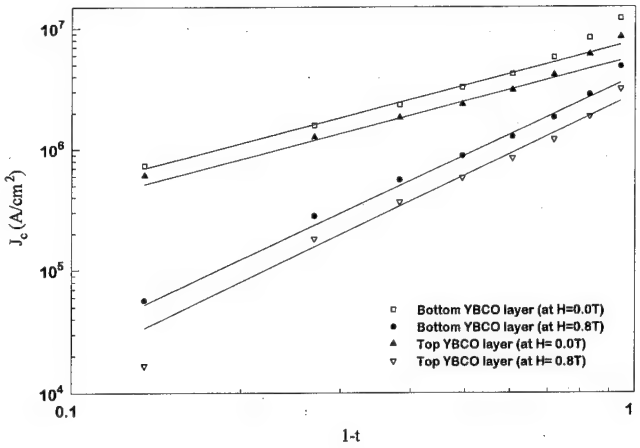

FIG. 3. Logarithmic plots of J_c vs $1-t$ for each of the YBCO layers within the multilayer structure. Straight lines are the curve fits to $(1-t)^n$, where $n\sim1.3$ for $H=0.0$ T and $n\sim2.1$ for $H=0.8$ T.

zero resistance temperature for this YBCO layer is about 86 K with a transition width of about 2 K. The $M(T)$ data for a multilayer sample are shown in the inset of Fig. 2. As can be seen in the inset of Fig. 2, the onset transition of the $M(T)$ curve is about 89 K. A second transition (indicated by the arrow in the inset of Fig. 2) is consistent with the T_c of the top YBCO layer measured by the transport method (Fig. 2). In order to verify this, T_c was remeasured again after the top layer of YBCO was etched away by using a dilute EDTA solution, and the onset transition was found to be about 89 K.

The critical current density J_c of the samples were measured by the magnetization method and calculated using Bean's model. For a rectangular single-layer film, J_c can be calculated from the following formula:[4]

$$J_c=10[M_+(H)-M_-(H)]/L_1[1-(L_1/3L_2)]V. \qquad (1)$$

In Eq. (1), $M_+(H)$ and $M_-(H)$ are the magnetization of the decreasing and increasing field branches in electromagnetic units (emu), respectively; V is the volume of the thin film in cm^3; L_1 and L_2 are the short and long sides of the samples in cm, respectively. We have assumed that J_c is independent of the B field and excluded the anisotropic critical currents in the above calculation. In order to determine J_c of both the top and bottom YBCO layers, the magnetization $M^m_+(H)$ and $M^m_-(H)$ for the multilayer film was measured first, then the magnetization $M^b_+(H)$ and $M^b_-(H)$ for the bottom layer was measured after the top layer of YBCO was etched away. In this article we use superscript t and b for the parameters related to the top and bottom YBCO layer in the multilayer film, then J_c for the bottom layer should be

$$J^b_c=10[M^b_+(H)-M^b_-(H)]/L^b_1[1-(L^b_1/3L^b_2)]V^b, \qquad (2)$$

and for the top layer in the multilayer film,

$$J^t_c=10\{[M^m_+(H)-M^b_+(H)]-[M^m_-(H)-M^b_-(H)]\}/L^t_1[1-(L^t_1/3L^t_2)]V^t. \qquad (3)$$

The J_c of the top YBCO layer was found to be about 6×10^5 A/cm^2, and a value of $\sim7.2\times10^5$ A/cm^2 was obtained for the bottom layer at 77 K under zero magnetic field. J_c, as a

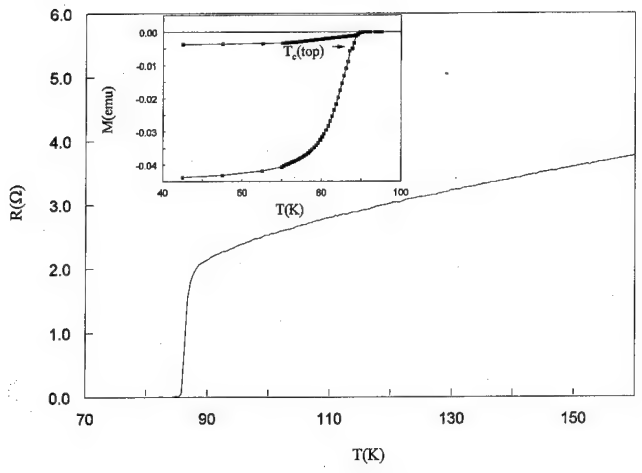

FIG. 2. Resistance vs temperature for the top YBCO layer in the YBCO/ YSZ/SiO_2/YSZ/YBCO/$LaAlO_3$ multilayer structure. Inset: magnetization M as a function of T for the entire multilayer structure.

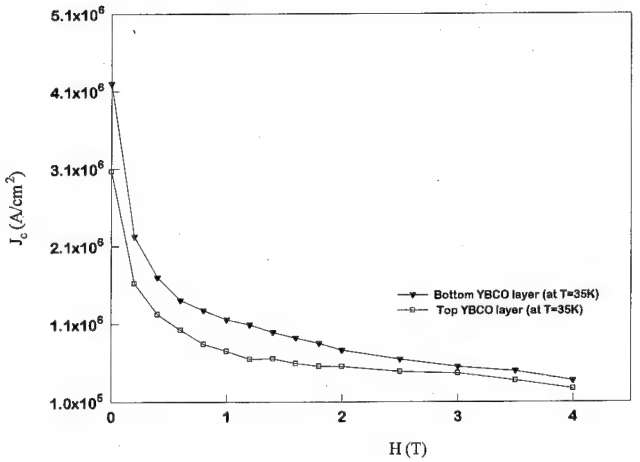

FIG. 4. Magnetic field dependence of J_c for top and bottom YBCO layers at 35 K. Field is applied perpendicular to $a-b$ plane.

function of $(1-t)$, is shown in Fig. 3 for different values of the magnetic field, where $t=T/T_c$. It was found that, for both YBCO layers, the temperature dependence of J_c is similar to that for a good quality, single-layer YBCO film.[5–7] The magnetic field dependence of J_c for both YBCO layers at 35 K are shown in Fig. 4. It clearly shows that J_c for both top and bottom YBCO films essentially has the same magnetic field dependence as that for the high quality, single-layer YBCO film.[5–7]

IV. SUMMARY

A good quality YBCO multilayer structure has been fabricated using laser ablation and ion-beam-assisted rf sputtering. The dependence of J_c on the temperature and magnetic field for both YBCO layers in the multilayer has been determined. The results suggest that the temperature and magnetic field dependence of J_c of the YBCO layers in the multilayer structure are not altered appreciably by the multilayer growth processes.

Flux trapping and levitation forces in directionally solidified superconducting $YBa_2Cu_3O_7$ ingots

J. Mora, M. Carrera, X. Granados, J. Fontcuberta, S. Piñol, and X. Obradors

$YBa_2Cu_3O_7$ cylinders with 10%–20% of Y_2BaCuO_5 and 1% CeO_2 additions have been directionally solidified under a temperature gradient. It is shown that a steady growth regime of domains, typically 1 cm in diameter, is established after polynucleation at the bottom of the cylinders on the substrate interface. The length of the region where a steady growth proceeds is limited by the liquid loss, which induces an enrichment in unreacted Y_2BaCuO_5 in the upper part of the cylinder and a polycrystalline structure. The vertical and lateral magnetic levitation forces and flux trapping profiles have been measured and a direct correlation with the size and location of the domains has been found. © *1996 American Institute of Physics.* [S0021-8979(96)03408-5]

I. INTRODUCTION

Development of high T_c superconducting materials for levitation and stabilization purposes needs an optimization of bulk electromagnetic properties of relatively large shaped specimens. To this regard the first issue is to obtain single domain ingots, free from large angle grain boundaries. Magnetic levitation applications based in $YBa_2Cu_3O_7$ (YBCO) bulk superconducting materials can nowadays be developed because melt processing techniques allow the fabrication of big tiles with high critical currents.[1,2] The growth process of these big tiles (2–3 cm in diameter) is however complex and several techniques, such as top seeding, have been used to control the nucleation processes.[3,4] Directional solidification under a small temperature gradient is the simplest method to control the growth process and it has been indeed used successfully in the growth of long YBCO bars with small cross sections ($\phi \approx 8$ mm).[5,6] The extension of this methodology to bigger cross sections is not without difficulties and an exhaustive study of the process methodology, in connection with microstructural observations and levitation force measurements, is needed. In this work we present preliminary results concerning the growth process of cylinders having 20 mm in diameter, as well as characterize their texture, flux trapping properties, and magnetic levitation forces.

II. DIRECTIONAL SOLIDIFICATION

Presintered cylindrical pellets with a typical height of 30 mm and a diameter of 20 mm, and compositions: (A) (123)+10 wt. % (211), (B): 123+15% 211, and (C): 123 +20% 211, are slowly cooled at 1 °C/h from a maximum temperature of 1060 °C in a temperature gradient of 10 °C/cm. All samples contain 1 wt. % CeO_2 addition because it allows to optimize the melt viscosity and to refine the resultant 211 precipitate size.[5,6] In this work, only samples nucleated at the bottom are investigated. The alumina substrates are covered by some CeO_2 powder in order to avoid reaction with the ceramic block.

From microstructural observations, using polarized light, scanning electron microscopy, and x-ray diffraction pole figures,[7] we can conclude that three regions characterize these cylinders. In region I above the interface with the substrate, a multinucleation process occurs. In region II a few domains remain after a growth competition stage (typically 2–4, depending on the 211 content). No major porosity was observed in the samples and the 211 precipitates were distributed homogeneously in this initial region of the crystallization (about 10 mm in height). However, when advancing vertically along the cylinder, a progressive increase of the concentration of 211 phase is observed due to some liquid loss which perturbs the steady growth of the big domains and, finally, originates new nucleation phenomena (region III). We conclude then that only the central 10–20 mm of the cylinder can be used to investigate the levitation force of these materials.

X-ray pole figures indicated that in zone II the bigger domain has the c axis aligned along the cylinder axis while the c axis of the secondary domains lie 30–45 deg apart. Finally, in region III, where an enrichment in 211 phase occurs, the number of domains is much higher indicating a multinucleation process.[7]

Inductive critical currents of small pieces (few mm) extracted from single domains have been found to be very similar to those previously published on samples with similar concentration of 211 particles (up to 10^5 A/cm^2 at 77 K and zero field).[8]

III. LEVITATION FORCES

The integral vertical levitation force (F_z) and the transversal force (F_x) were measured for different samples at 77 K by using a triaxial force sensor based on strain gauges and having a computer controlled movement along two perpendicular (z,x) axis. All the materials were tested with the same NdFeB (PM) having $\phi=25$ mm, $h=20$ mm, and $B_r=0.3$ T placed above the superconducting cylinders (SCs) of dimensions: $\phi=19$ mm, $h\approx 13$ mm. The relative displacement of the superconductor and the magnet was done quasistatically (1.2 mm/s). Because of the growing conditions it will become important to distinguish between measurements performed approaching the magnet towards the top (Top) or the bottom (Bot) of the samples. In Fig. 1(a) we show a typical levitation force loop obtained, after a zero field cooling (ZFC) procedure, for sample B in the Top configuration. In the figure we also include the hysteresis loop obtained after the first cycle, where it is clear that the trapped flux considerably decreases the vertical force. This effect can be

 0021-8979/96/79(8)/6596/3/$10.00

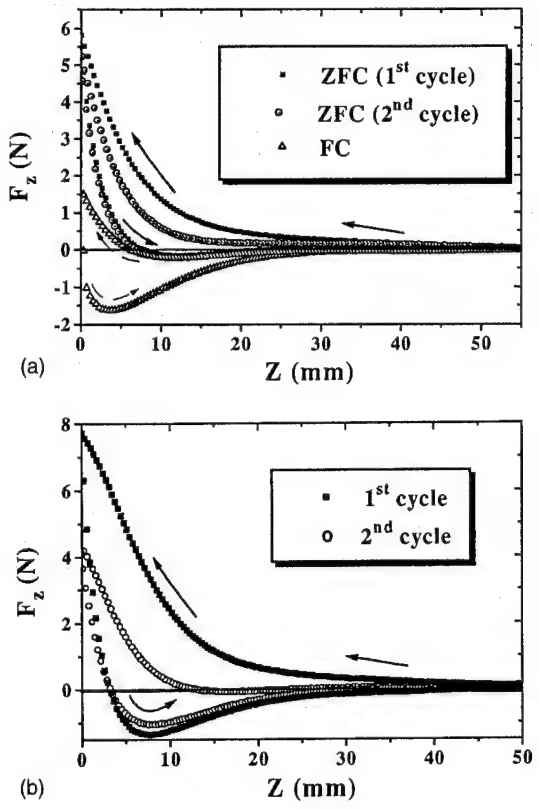

FIG. 1. Axial force vs displacement loops obtained for sample B in the Top (a) and Bot (b) configurations after a ZFC process. In (a) FC measurements are also included.

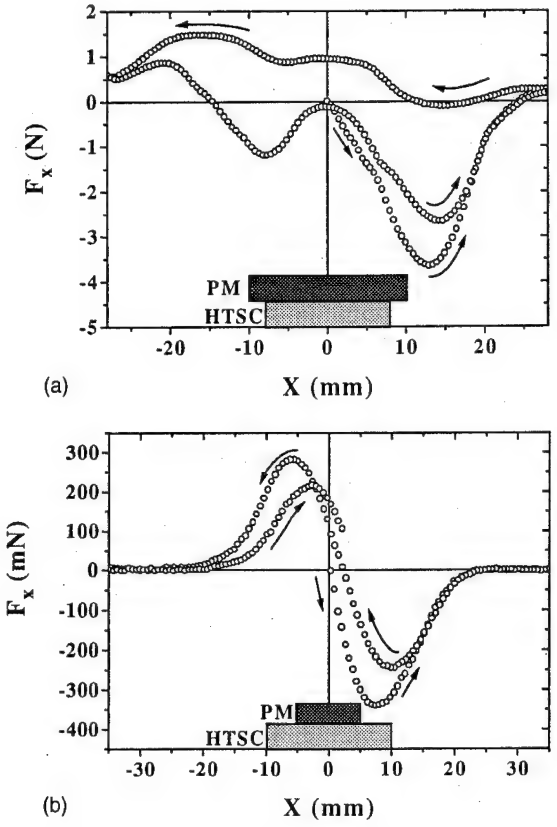

FIG. 2. Transverse force vs lateral displacement after a FC process. (a) and (b) refer to measurements performed with the larger and smaller PM, respectively.

even better appreciated in the hysteresis loop obtained after a FC procedure where trapped flux is greater [see Fig. 1(a)] and the maximal repulsive force is only about 1/4 of the force obtained after a ZFC. This difference arises because of the higher magnetization obtained after a ZFC process in samples having strong flux pinning where the flux front does not penetrate the sample completely. In Fig. 1(b) we show the force versus displacement loops obtained for sample B in the Bot configuration (two domains in the x-ray pole figures). The essential features of this figure are identical to those of the Top configuration, however $F_z(z)$ is significantly lower in the Top case. This result is in agreement with the observation of a multidomain growth in the upper part of the cylinders (near Region III) as discussed above. Similarly, the maximum repulsive force of sample C only achieves 47% of that on B sample, also in agreement with the increase in the number of domains in the x-ray pole figures. The maximal ideal repulsive force for our particular SC/PM geometry assuming a fully shielded state has been evaluated using finite element electromagnetic calculations.[9] We have estimated that the measured maximal F_z is about 45% of the ideal corresponding to a magnetic pressure of 5.7 N/cm^2. Similar percentages have been reported recently.[10]

The axial levitation force of a permanent magnet over a superconductor is proportional to the z component of the vector: $d\mathbf{F}=(\mathbf{M}\cdot\nabla)\mathbf{B}_{ex}dV$, where $\mathbf{B}_{ex}$ is the induction generated by the magnet and $\mathbf{M}$ is the magnetization of the superconductor. If large angle grain boundaries exist among the single domains, flux penetration occurs through these boundaries and the critical state is established only within the single domains. In this way M and F_z are reduced even if J_c remains constant within the domains.

Transverse force measurements were also obtained when a lateral displacement was introduced after a field cooling process. A typical hysteresis loop is displayed in Fig. 2(a) where the magnet stays at 1.5 mm above the superconductor B (15% 211). The stiffness constant corresponding to the linear recuperation force observed near the origin was found to be 300 N/m. Although this value is similar to that observed by other authors in similar geometries,[11] we should recall that the shape of the $F_x(x)$ loop is strongly dependent on the particular configuration PM/SC used. As an example, we have performed $F_x(x)$ measurements by using a PM with reduced dimensions (ϕ=12 mm, h=5 mm, and B_r=0.12 T). Comparison of Figs. 2(a) and 2(b) strongly emphasizes this important technological point and illustrates that the maximal restoring force is obtained when the PM reaches the edges of the SC. We also note that a clear asymmetry is observed in the transversal force hysteresis loops $F_x(x)$. This anomalous behavior reflects the absence of cylindrical symmetry associated to the two prominent domains observed in the x-ray texture analysis. We suggest that transversal force hysteresis loops can be used as a sensitive tool to detect the existence of a multidomain structure without uniaxial symmetry. Similar measurements performed for sample C have revealed smaller lateral forces.

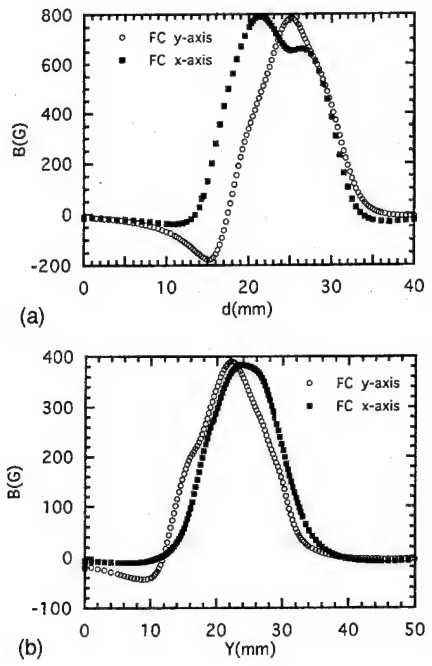

FIG. 3. Remanent induction $B_z(x)$ and $B_z(y)$ flux profiles scanned along two perpendicular directions after a 0.29 T FC process. (a) B sample Bot, (b) B sample Top.

An additional test of the sample homogeneity can be gained by means of remanence magnetic field profiling with Hall microprobes. Measurements have been performed in the remanent state, after cooling the samples in fields of 0.29 T generated by a permanent magnet. In Fig. 3(a) we show $B_z(x)$ and $B_z(y)$ flux profiles in B sample (Bot). A prominent asymmetry, similar to that observed in transverse force measurement, is appreciated. Measurements have also been performed in the Top configuration where a decrease of the remanence is found in agreement with the lower levitation forces [Fig. 3(b)]. This unequal electromagnetic behavior of both faces of the superconducting sample also raises the question of the relevance of the thickness on the final performance of the samples.

Flux mapping measurements can be used to compute the current distribution in the superconducting samples.[12] However the multidomain character of the samples introduces a some uncertainty concerning the definition of the critical state. Further theoretical analysis of these measurements will be reported elsewhere.[9]

In conclusion, we have shown that the directional solidification process allows the fabrication of long cylinders of $YBa_2Cu_3O_7$ for developing big tiles for magnetic levitation applications. The optimization of the performance of these tiles requires to limit the multinucleation process which induces the formation of several domains and reduces the levitation force.

Magnetostatic effect of the micron-size ferromagnetic particle array on a two-dimensional superconductor was investigated. In the bare Nb film, a sharp drop in magnetization due to the flux rearrangement was observed, whereas this behavior was not observed for the Nb film with the ferromagnetic particles arranged on top. The difference in the magnetization curves may be attributed to the regulated flux penetration process by the ferromagnetic particle array. © *1996 American Institute of Physics.* [S0021-8979(96)01108-2]

I. INTRODUCTION

The hybrid system is a two-dimensional superconducting film covered with ferromagnetic square particles of micron size. The magnetic particles are arrayed in a square lattice and are uniaxially magnetized along an edge. The array produces a spatially modulated stray field which periodically suppresses the superconducting order parameter of the underlying Nb film. The hybrid system thus exhibits some interesting behaviors. The transition temperature measured in a perpendicularly applied magnetic field to the Nb film surface shows the quantum oscillation[1,2] reminiscent of the Little–Parks oscillation.[3] Moreover, the particle acts as a magnetic flux guide which regulates the flux penetration into the Nb film.[4] Interesting behaviors are also observed in the field dependence of the magnetization. The hysteresis loop of the bare Nb film exhibits an anomalous magnetization drop below 2.5 mT, while that of the hybrid system does not show such a tendency[4] except for the periodical flux jumps. These flux jumps are attributed to the flux quantization into the normal core created by the stray field of the particle.[5]

In this study, we focus our discussion on the origin of the magnetization drop observed in the bare Nb film in relation to the magnetostatic effect observed in the hysteresis loop of the hybrid system.

II. EXPERIMENT

An array of ferromagnetic amorphous $Sm_{33}Co_{67}$ particles were fabricated on a Nb film of 20 nm thickness by means of high-resolution electron-beam lithography and sputter deposition techniques. The details of the sample preparation are described in Refs. 1 and 5. During the deposition of $Sm_{33}Co_{67}$, the magnetic field of 50 mT was applied parallel to an edge of the particles. This procedure induced the uniaxial magnetic anisotropy of 1×10^5 J/m^3 along the edge. It is remarked that the magnetic particles are sandwiched by Si_3N_4 buffer and protecting layers (20 nm in thickness) in order to avoid the superconducting proximity effect and the oxidation of the particle surface. The array consists of 2×10^5 square particles with an edge length of 2 μm, a thickness of 200 nm, and a separating distance of 4 μm. The dimensions of the underlying Nb film are 2 mm×2 mm×20 nm. With the aim of clarifying the effect of the

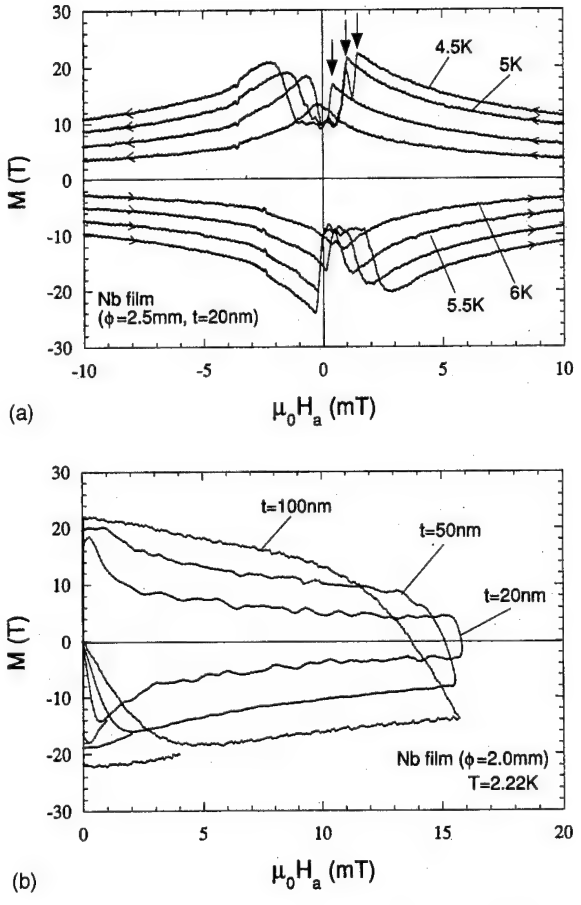

FIG. 1. Magnetic hysteresis loops for Nb films without magnetic particles. (a) and (b) show the variation of the loop with temperature and thickness, respectively. The arrows in (a) indicate the peak field H_p.

[a]Present address: Department of Materials Science, Faculty of Engineering, Tohoku University, Sendai 980-77, Japan.

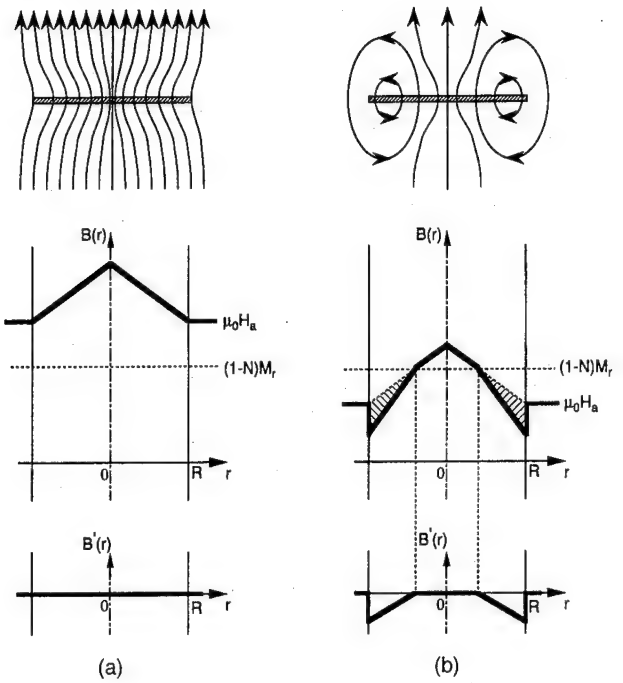

FIG. 2. Schematic view of the flux line profiles and the flux density distributions inside the Nb film in the case of (a) $\mu_0 H_a > (1-N)M_r$ and (b) $\mu_0 H_a < (1-N)M_r$, where B and B' represent the flux density due to the external field and the stray field, respectively.

aspect ratio on the rearrangement of the flux distribution, the following disk-shaped Nb films with different diameters D and thickness t were prepared, denoted as NB1 ($D=2.5$ mm, $t=20$ nm), NB2 ($D=2.0$ mm, $t=20$ nm), NB3 ($D=2.0$ mm, $t=50$ nm), and NB4 ($D=2.0$ mm, $t=100$ nm).

The magnetic hysteresis loop was measured as a function of temperature by using a rotating sample SQUID magnetometer[5] and a vibrating sample magnetometer. Prior to the magnetization measurement, the sample was zero field cooled to the desired temperature, and then the measurement was performed in perpendicularly applied magnetic fields to the Nb film surface between -20 and $+20$ mT.

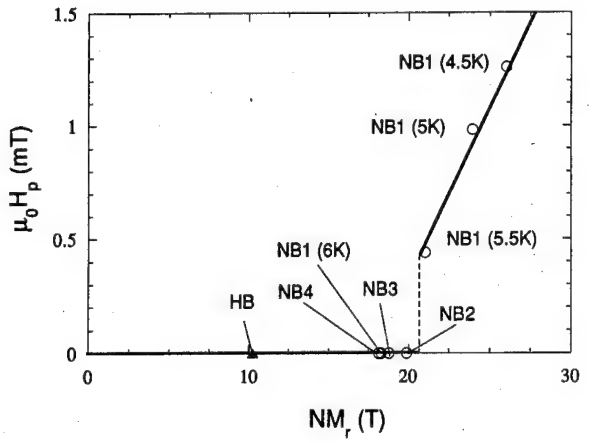

FIG. 3. Relationship between the peak field $\mu_0 H_p$ and the stray field exerting near the edge of the sample NM_r for the Nb films (open circles) and for the hybrid system (closed triangle).

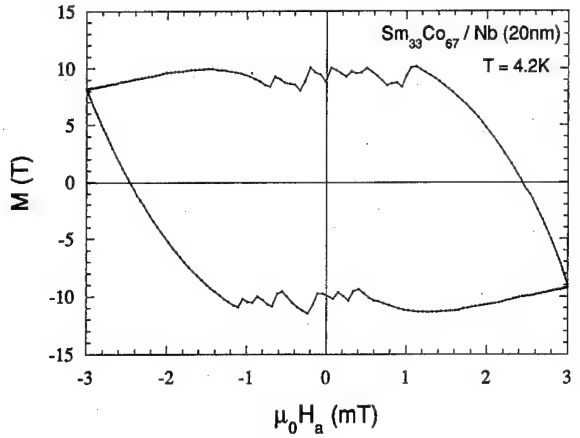

FIG. 4. Magnetic hysteresis loops for the Nb film with ferromagnetic $Sm_{33}Co_{67}$ particles.

III. RESULTS AND DISCUSSION

The temperature dependence of the hysteresis loops of the NB1 sample is shown in Fig. 1(a), where the arrow indicates the peak field $\mu_0 H_p$ at which the magnetization begins to exhibit a steep fall. The peak field gradually decreases with increasing temperature from 4.5 K and disappears at 6 K. Hysteresis loops as a function of Nb thickness are shown in Fig. 1(b) for the film with a constant diameter of 2.0 mm. As seen in the figure, no magnetization drop is observed. It should be noticed that the drop is not observed in the sample NB2 with the same thickness as the sample NB1, the hysteresis loop of which exhibits the magnetization drops below 5.5 K. This suggests that the aspect ratio t/D may play an important role for the appearance of the magnetization drop. From the fact that the aspect ratio is in proportion to the demagnetizing factor N, the magnetization drop is considered to be mainly related to the stray field due to the pinned flux lines in the superconducting Nb film rather than the two dimensionality of the superconductor. In the case of the hybrid film, the magnetostatic effect of the particles must be taken into account because the ferromagnetic particles regulate the flux density distribution inside the superconductor.

Here we limit the discussion to the demagnetizing process in the magnetization curve. The pinned flux lines inside the superconducting Nb film produce a strong stray field near the edge of the film. By using the demagnetizing factor N and the remanent magnetization M_r, the stray field is generally expressed as $-NM_r$ which directs opposite to the direction of M_r. The magnetic flux density B along the external field H_a inside the superconductor is given by $B=\mu_0 H_a+(1-N)M_r$. When the external field is higher than the demagnetizing field given by $(1-N)M_r$, the whole pinned flux lines are in equilibrium with the external field. Thus, the flux density distribution may have the distribution obtained from the Bean's critical state model, as shown in Fig. 2(a). On the contrary, when the field is lower than $(1-N)M_r$, the number of pinned flux lines is larger than that of the flux lines due to the external field, resulting in the closed-flux loops near the edge. Near the edge, these closed-flux lines are opposite to the flux lines penetrated near the

center of the film. Therefore, the flux density near the edge is reduced from the one expected from the Bean's model [see Fig. 2(b)]. The reduction causes the steep drop in magnetization at the peak field of order $(1-N)M_r$. In reality, similar behaviors of the flux inversion have been observed in high-T_c $Bi_2Sr_2CaCu_2O_{8-\delta}$ single crystal by means of magneto-optical method.[6,7] As the critical current density J_c decreases with an increase of temperature, the remanent magnetization M_r also decreases, and thus the peak field is reduced. At 6 K, the stray field near the edge of the superconducting film may be too small to lead the flux penetration in a negative sense.

The magnitude of the stray field near the edge is nearly equal to NM_r. The demagnetizing factor N can be evaluated from the initial susceptibility as $N=1+1/\chi$ if the Nb film is perfectly diamagnetic below $\mu_0 H_{c1}$ (~0.3 mT). The remanent magnetization M_r can be deduced by fitting the hysteresis loops using the conventional critical-state model. Figure 3 shows the relationship between the peak field H_p and the demagnetizing field NM_r. Note that the flux rearrangement due to the stray field occurs only when $NM_r>20.5$ T.

Figure 4 shows the magnetic hysteresis loop of the hybrid system consisting of $Sm_{33}Co_{67}$ particles and the Nb film (2 mm×2 mm×2 nm): The system does not exhibit any magnetization drop, and the remanent magnetization is remarkably reduced. The difference between magnetic behaviors of the Nb films with and without the ferromagnetic particles is interpreted as follows. The superconducting order parameter in the Nb film with ferromagnetic particles is periodically modulated by the stray field due to the particles. This reduces the remanent magnetization compared to the bare Nb film. In order to estimate the stray field, the demagnetizing factor N was calculated to be 0.972 by approximating the shape of the 2 mm square Nb film by a 2 mmϕ circle. This yields the stray field $NM_r=10.2$ T, which is smaller than the critical value ($NM_r=20.5$ T). Another feature observed in the hybrid system is the flux guide effect due to the amorphous $Sm_{33}Co_{67}$ particles with high susceptibility. The particles accumulate the external flux lines and guide them into the normal state cores.[4] The presence of the flux guide effect can be proved by the periodical flux jumps as shown in Fig. 4. The periodicity $\Delta B=0.267$ mT gives the area where the flux is quantized as $S=7.79\times10^{-12}$ m^2 from the relation $\Delta B=\phi_0/S$. The value coincides well with half of the unit cell area containing a normal core; $(1/2)S_{\text{unit}}=8.0\times10^{-12}$ m^2. These ferromagnetic particles act as the artificial flux pinning centers which are homogeneously distributed in the hybrid film. Therefore, the average flux density gradient in the Nb film takes a constant value as expected from the Bean model. This reduces the apparent demagnetizing factor and the stray field near the edge of the Nb film. As a result, the flux rearrangement does not take place in the hybrid film.

"Standing" diffusion of electromagnetic fields in superconductors with gradual resistive transitions

I. D. Mayergoyz and M. Neely
Electrical Engineering Department, University of Maryland, College Park, Maryland 20742

Electromagnetic field diffusion in superconductors with gradual resistive transitions may exhibit a peculiar (anomalous) mode which does not exist in superconductors with sharp (ideal) resistive transitions. This is a "standing" mode. In the case of this mode, the electromagnetic field on a superconductor boundary increases with time, while the region occupied by the electromagnetic field within the superconductor does not expand. In this paper, an exact analytical solution to the appropriate nonlinear diffusion equation is derived. It is demonstrated that this solution can be physically interpreted as the standing mode. The standing mode solution is also obtained by using a "rectangular profile" approximation and these two results are compared. © *1996 American Institute of Physics.* [S0021-8979(96)03508-1]

Models for superconducting hysteresis are based on the analytical study of electromagnetic field diffusion in hard superconductors. In the critical state model,[1–3] this study is usually performed under the assumption of ideal (sharp) resistive transition. This assumption appreciably facilitates the calculation of distribution of electric currents in superconductors of simple shapes (plane slabs, circular cross-section cylinders) and leads to the rate independent models for superconducting hysteresis.

Actual resistive transitions in superconductors are gradual, and they are customarily described by the power law:[4–6]

$$E=\left(\frac{J}{k}\right)^n, \quad (n>1). \tag{1}$$

In the above expression, E is electric field, J is current density, and k is a parameter which coordinates the dimensions in (1). The exponent "n" is a measure of the sharpness of the resistive transition and it varies in the range 7–1000.

The above power law can be used as a constitutive equation for hard superconductors. This leads to the following nonlinear diffusion equation for the current density in the case of 1D problems:

$$\frac{\partial^2 J^n}{\partial z^2}=\mu_0 k^n \frac{\partial J}{\partial t}. \tag{2}$$

Previously, the analytical self-similar solutions of Eq. (2) were derived for zero initial condition and the following boundary condition:

$$J_0(t)=J(0,t)=ct^p, \quad (t\geqslant 0,\ p\geqslant 0). \tag{3}$$

It has been found that the electromagnetic field diffusion in superconductors with gradual resistive transitions has some features which are very similar to the electromagnetic field diffusion in superconductors with ideal resistive transitions. Namely, it has been found that for $n\geqslant 7$ the actual profile of electric current density is almost rectangular. This has prompted the suggestion to approximate the actual current density profile by a rectangular one with the height equal to the instantaneous value $J_0(t)$, of the current density on the boundary of the superconductor (see Fig. 1). This "rectangular profile" approximation has led to the following equation for the zero front $z_0(t)$, of the current density:

$$\int_0^t J_0^n(\tau)d\tau=\frac{\mu_0 k^n}{2}[J_0(t)z_0^2(t)-J_0(0)z_0^2(0)], \tag{4}$$

which is valid for any monotonically increasing boundary condition $J_0(t)$.

In this paper, we intend to show that electromagnetic field diffusion in superconductors with gradual resistive transitions may exhibit a peculiar (anomalous) mode which does not exist in superconductors with ideal resistive transitions. This is a standing mode. In the case of this mode, the electromagnetic field on a superconductor boundary increases with time, while the region occupied by the electromagnetic field does not expand. We shall first find the condition for the existence of this mode by using the "rectangular profile" approximation and formula (4). Then, we shall derive the exact expressions for the standing mode through the analytical solution of nonlinear diffusion Eq. (2), that is without resorting to the rectangular profile approximation. Finally, we shall compare these two results.

To start the discussion, we turn to Eq. (4) and try to find such a monotonically increasing boundary condition $J_0(t)$ for which the zero front $z_0(t)$, stands still. To this end, we assume that $z_0(t)=z_0=$const, and, by differentiating both sides of (4), we arrive at:

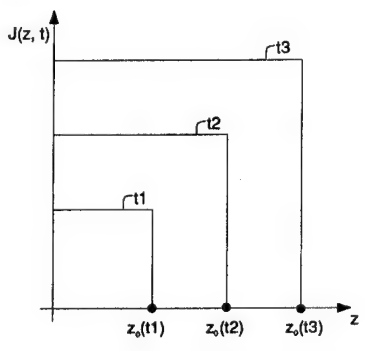

FIG. 1. Rectangular approximation of current density profiles inside the superconducting half-space.

 0021-8979/96/79(8)/6602/3/$10.00

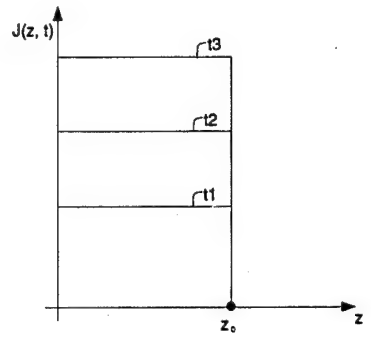

FIG. 2. Rectangular approximation of the standing mode.

$$J_0^n(t)=\frac{\mu_0 k^n}{2} z_0^2 \frac{dJ_0(t)}{dt}. \tag{5}$$

The last expression can be transformed as follows:

$$\frac{2}{\mu_0 k^n z_0^2} dt=\frac{dJ_0(t)}{J_0^n(t)}. \tag{6}$$

By integrating both parts of (6), we obtain:

$$\frac{2}{\mu_0 k^n z_0^2} t=\frac{1}{n-1}\left[J_0^{1-n}(0)-J_0^{1-n}(t)\right]. \tag{7}$$

From (7), we derive:

$$J_0(t)=\frac{1}{\left(J_0^{1-n}(0)-\dfrac{2(n-1)}{\mu_0 k^n z_0^2} t\right)^{1/n-1}}. \tag{8}$$

The last expression can be represented in the form:

$$J_0(t)=\frac{c}{(t_0-t)^{1/n-1}}, \tag{9}$$

where:

$$c=\left(\frac{\mu_0 k^n z_0^2}{2(n-1)}\right)^{1/n-1}, \quad t_0=\frac{\mu_0 k^n z_0^2 J_0^{1-n}(0)}{2(n-1)}. \tag{10}$$

Thus, we have established that, if the current density on the boundary of superconducting half-space varies with time according to the expressions (9)–(10), then the zero front $z_0(t)$, of the current density stands still during the time interval $0 \leqslant t < t_0$. In other words, during this time interval the electromagnetic field diffusion exhibits a standing mode. This mode is illustrated by Fig. 2.

It is desirable to express the boundary condition for the standing mode in terms of magnetic field $H_0(t)$ on the superconductor boundary. This can be easily accomplished by using (9) and Ampere's Law, which leads to:

$$H_0(t)=\frac{c z_0}{(t_0-t)^{1/n-1}}. \tag{11}$$

Our previous derivation has been based on the "rectangular profile" approximation for the electric current density. Next, we shall derive the expressions for the standing mode solution without resorting to the above approximation, but rather through an analytical solution of the nonlinear diffusion Eq. (2). It is remarkable that the standing mode solution can be obtained by using the method of separation of variables. Actually, this is the only solution which can be obtained by this method. According to the method of separation of variables, we look for the solution of Eq. (2) in the form:

$$J(z,t)=\varphi(z)\psi(t). \tag{12}$$

By substituting (12) into (2), after simple transformations we derive:

$$\frac{1}{\varphi(z)} \frac{d^2\varphi^n(z)}{dz^2}=\frac{\mu_0 k^n}{\psi^n(t)} \frac{d\psi(t)}{dt}. \tag{13}$$

This means that

$$\frac{\mu_0 k^n}{\psi^n(t)} \frac{d\psi(t)}{dt}=\lambda, \tag{14}$$

$$\frac{1}{\varphi(z)} \frac{d^2\varphi^n(z)}{dz^2}=\lambda, \tag{15}$$

where λ is some constant.

By integrating (14), we easily obtain:

$$\psi(t)=\left(\frac{\mu_0 k^n}{(n-1)\lambda(t_0-t)}\right)^{1/n-1}, \tag{16}$$

where t_0 is a constant of integration.

Equation (15) is more complicated than Eq. (14) and its integration is somewhat more involved. To integrate Eq. (15), we introduce the following auxiliary functions:

$$\varphi^n(z)=\theta(z), \quad R(z)=\frac{d\theta(z)}{dz}. \tag{17}$$

From (17) and (15), we derive:

$$\frac{dR}{dz}=\frac{d^2\theta}{dz^2}=\frac{d^2\varphi^n}{dz^2}=\lambda\varphi(z)=\lambda\theta^{1/n}(z). \tag{18}$$

On the other hand

$$\frac{dR}{dz}=\frac{dR}{d\theta}\cdot\frac{d\theta}{dz}=R\frac{dR}{d\theta}=\frac{1}{2}\frac{d(R^2)}{d\theta}. \tag{19}$$

By equating the right-hand sides of (18) and (19), we obtain

$$\frac{d(R^2)}{d\theta}=2\lambda\theta^{1/n}. \tag{20}$$

By integrating Eq. (20), we find:

$$R(z)=\sqrt{\frac{2n}{n+1}}\lambda[\theta(z)]^{n+1/2n}. \tag{21}$$

In (21), a constant of integration was set to zero. This can be justified on physical grounds. Indeed, the magnetic field should vanish at the zero front, that is at the same point where $J(z,t)$ vanishes. By using (12) and (17), it can be shown that the magnetic field and $J(z,t)$ are proportional to $R(z)$ and $\theta^{1/n}(z)$, respectively. This means that the above two functions should vanish simultaneously. This is only possible if the integration constant in (21) is set to zero.

Next, by using (17) in (21), we find:

$$\frac{d\theta(z)}{dz}=\sqrt{\frac{2n}{n+1}}\,\lambda[\theta(z)]^{n+1/2n}. \tag{22}$$

By integrating (22), we derive:

$$[\theta(z)]^{n-1/n}=\frac{(n-1)^2}{2(n+1)n}\,\lambda(z_0-z)^2, \tag{23}$$

where z_0 is a constant of integration.

From (17) and (23), we obtain:

$$\varphi(z)=\left[\frac{(n-1)^2\lambda}{2(n+1)n}\,(z_0-z)^2\right]^{1/n-1}. \tag{24}$$

Now, by substituting (16) and (24) into (12), we find the following analytical (and *exact*) solution of nonlinear diffusion Eq. (2):

$$J(z,t)=\left[\frac{(n-1)\mu_0 k^n(z_0-z)^2}{2(n+1)n(t_0-t)}\right]^{1/n-1}. \tag{25}$$

It is remarkable that, as a result of substitution, the constant λ cancels out, and the solution (25) does not depend on λ at all.

The obtained solution (25) can be physically interpreted as follows. Suppose that at time $t=0$ the electric current density satisfies the following initial condition:

$$J(z,0)=\begin{cases}\left[\dfrac{(n-1)\mu_0 k^n(z_0-z)^2}{2(n+1)nt_0}\right]^{1/n-1}, & \text{if } 0\leqslant z\leqslant z_0\\ 0, & \text{if } 0\leqslant z\leqslant z_0\end{cases}. \tag{26}$$

Suppose also that the current density satisfies the following boundary condition during the time interval $0\leqslant t<t_0$:

$$J_0(t)=J(0,t)=\left[\frac{(n-1)\mu_0 k^n z_0^2}{2(n+1)n(t_0-t)}\right]^{1/n-1} \tag{27}$$

Then, according to (25), the exact solution to the initial-boundary value problem (26)–(27) for the nonlinear diffusion Eq. (2) can be written as follows:

$$J(z,t)=\begin{cases}\left[\dfrac{(n-1)\mu_0 k^n(z_0-z)^2}{2(n+1)n(t_0-t)}\right]^{1/n-1}, & \text{if } 0\leqslant z\leqslant z_0\\ 0, & \text{if } z>z_0.\end{cases} \tag{28}$$

This solution is illustrated by Fig. 3 and it is apparent that it has the physical meaning of the standing mode. It is also clear from formula (28) (and Fig. 3) that the above solution has the following self-similarity property: the profiles of electric current density for different instants of time can be obtained from one another by dilation (or contraction) along the J-axis. In other words, these profiles remain similar to one another. This suggests that solution (28) can be derived by using dimensional analysis. However, we shall not delve further into this matter.

From the practical point of view, it is desirable to express the boundary condition (27) for the standing mode in terms of magnetic field $H_0(t)$ on the superconductor boundary. According to Ampere's Law, we have:

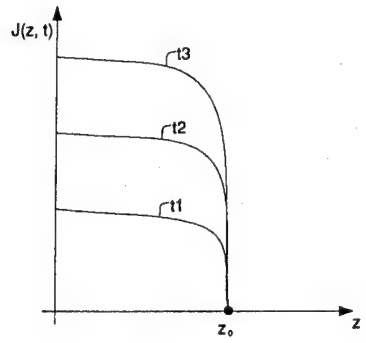

FIG. 3. Current density profiles corresponding to the exact analytical solution of the diffusion equation.

$$H_0(t)=\int_0^{z_0} J(z,t)\,dz. \tag{29}$$

By substituting (28) into (29) and performing the integration, we obtain:

$$H_0(t)=\frac{n-1}{n+1}\,z_0\left[\frac{(n-1)\mu_0 k^n z_0^2}{2(n+1)n(t_0-t)}\right]^{1/n-1}. \tag{30}$$

It is also instructive to compare the above exact standing mode solution with the standing mode expressions derived on the basis of the rectangular profile approximation. First, it is clear from formula (28) (and Fig. 3) that, for sufficiently large "n", the actual current density profiles for the standing mode are almost rectangular. Second, it is apparent that the boundary condition (27) can be written in the form (9) with "c" and "t_0" defined as follows:

$$c=\left[\frac{(n-1)\mu_0 k^n z_0^2}{2(n+1)n}\right]^{1/n-1},$$

$$t_0=\frac{(n-1)\mu_0 k^n z_0^2 J_0^{1-n}(0)}{2(n+1)n}. \tag{31}$$

By comparing (31) with (10), it can be concluded that for sufficiently large "n" these expressions are practically identical. Thus, the rectangular profile approximation is fairly accurate as far as the prediction of the standing mode diffusion is concerned.

The origin of the standing mode can be elucidated on physical grounds as follows. Under the boundary condition (27), the electromagnetic energy entering the superconducting material at any instant of time is just enough to affect the almost uniform increase in electric current density in the region ($0\leqslant z\leqslant z_0$) already occupied by the field, but insufficient to affect the further diffusion of the field into the material.

Low-temperature specific heat of the degenerate supersymmetric t-J model in one dimension

Kong-Ju-Bock Lee
Department of Physics, Ewha Womans University, Seoul 120-750, South Korea

P. Schlottmann
Department of Physics, Florida State University, Tallahassee, Florida 32306

We consider the one-dimensional SU(N)-invariant t-J model, which consists of electrons with N spin components on a lattice with nearest-neighbor hopping t constrained by the excluded multiple occupancy of the sites and spin-exchange J between neighboring lattice sites. The model is integrable and has been diagonalized in terms of nested Bethe ansatze at the supersymmetric point $t=J$. The low-T specific heat is proportional to T. The γ-coefficient is extracted from the thermodynamic Bethe-ansatz equations and is expressed in terms of the spin wave velocities and the group velocity of the charges for arbitrary N, band filling, and splitting of the levels (magnetic and crystalline fields). Our results contain the following special cases: (i) For $N=2$ the traditional spin-1/2 supersymmetric t-J model, (ii) for exactly one electron per site the SU(N)-Heisenberg chain, and (iii) for $N=4$ the two-band supersymmetric t-J model with crystalline field splitting.
 [S0021-8979(96)03608-8]

One-dimensional (1D) conductors are an active topic of research with experimental realizations in organic (quasi-1D) conductors, polymers, Peierls insulators, and mesoscopic systems. The discovery of high-temperature superconductivity renewed the interest in low-dimensional superconductors and antiferromagnets. Many normal state properties of the 2D high-T_c superconductors cannot be reconciled with the standard Fermi liquid theory and a Luttinger-liquid picture (marginal Fermi liquid) similar to 1D conductors has been proposed to explain some of the features.[1]

Two of the most studied systems of correlated electrons are the Hubbard and t-J models. The two models are equivalent to each other for a large on-site repulsion U (small J) and a band occupation close to half-filling, but the t-J model is by itself an exciting problem for all parameter values. The t-J Hamiltonian is given by

$$H=-t\sum_{is} P(c_{is}^{\dagger}c_{i+1s}+c_{i+1s}^{\dagger}c_{is})P + J\sum_{iss'} (c_{is}^{\dagger}c_{is'}c_{i+1s'}^{\dagger}c_{i+1s}-n_{is}n_{i+1s'}), \quad (1)$$

where t is the hopping matrix element between nearest neighbor sites, P is a projector excluding the multiple occupancy of every site, $|s|\leq S$ is the spin index ($N=2S+1$), J is the exchange coupling, and n_{is} is the number operator.

The 1D t-J model was found to be integrable at the supersymmetric point $t=J$ by Sutherland.[2] The supersymmetry is related to a graded permutation of N fermionic (spin waves) and one bosonic (holes) degrees of freedom. For $N=2$ the ground state properties, the classification of states and the thermodynamic equations were presented in Ref. 3. These results were used to calculate the spectrum of elemental excitations[4] and the exponents for the long-distance asymptotic of correlation functions.[5] The Bethe ansatz solution was then extended to an arbitrary number of spin components N to obtain the classification of states, thermodynamics,[6] ground state properties,[7,8] the excitation spectrum,[8] and the asymptotic behavior of correlation functions.[9]

Model (1) contains several interesting limiting cases: (i) for $N=2$ the traditional (supersymmetric) t-J model,[2,3] (ii) for exactly one electron per site the SU(N)-invariant Heisenberg chain,[2] and (iii) for $N=4$ the two-band supersymmetric t-J model with crystalline field splitting.[10]

In this paper, we calculate the low-temperature specific heat for the supersymmetric t-J model for arbitrary band filling, number of components, and splitting between the bands (magnetic and crystalline fields). We first restate some equations of the Bethe ansatz solution,[6,8] then we expand the free energy and the band energies in powers of T, and finally we express the γ-coefficient of the specific heat in terms of the Fermi velocities of the charges and spin waves.

The model is solved in terms of N nested Bethe ansatz. Each Bethe ansatz eliminates one internal degree of freedom and gives rise to one set of rapidities, $\{\xi_{\alpha}^{(l)}\}$, $l=0,\ldots,N-1$, $\alpha=1,\ldots,M_l$, with the set $l=0$ corresponding to the charge rapidities. All rapidities within a given set have to be different, leading to Fermi statistics for the rapidities. The rapidities are self-consistent solutions of the Bethe ansatz equations and have in general, complex values. They are classified[6] into (i) real charge rapidities, (ii) complex spin and charge rapidities, and (iii) strings of complex spin rapidities. States of class (iii) represent excited spin states which are not populated in the ground state and do not contribute to the low-T specific heat. Classes (i) and (ii) are present in the ground state and have Fermi surfaces that contribute to the γ-coefficient of the specific heat. They correspond to complexes of n electrons ($n\leq N$), sometimes called bound states, defined by strings of the form

$$\xi_p^{(l)}=\zeta^{(n)}+ip/2,\quad l\leq n-1\leq 2S,$$

$$p=-(n-l-1),-(n-l-3),\ldots,(n-l-1),$$

where $\zeta^{(n)}$ is a real rapidity characterizing the center of mass of the cluster.

 0021-8979/96/79(8)/6605/3/$10.00

In the ground state, the real rapidities $\zeta^{(l)}$ are densely distributed in the interval $|\zeta|\geqslant B_l$, while the complementary interval $|\zeta|\leqslant B_l$ corresponds to empty states (holes). A central role is played by linear integral equations of the type[6–8]

$$\begin{aligned} &X_l(\zeta)+\sum_{q=1}^{2S}\int_{|\zeta'|>Bq}d\zeta' X_q(\zeta')K_{l,q}(\zeta-\zeta') \\ &\quad-\int_{-Q}^{Q}d\zeta' X_N(\zeta')F_l(\zeta-\zeta')=Z_l(\zeta), \\ &X_N(\zeta)+\sum_{q=1}^{2S}\int_{|\zeta'|>Bq}d\zeta' X_q(\zeta')F_q(\zeta-\zeta') \\ &\quad-\int_{-Q}^{Q}d\zeta' X_N(\zeta')D_{2S}(\zeta-\zeta')=Z_N(\zeta), \end{aligned} \tag{2}$$

where (2) holds for $l=1,\ldots,2S$, $Q=B_N$, and $Z_l(\zeta)$ are the driving terms. Here, $F_l(\zeta)$, $D_l(\zeta)$, and $K_{l,r}(\zeta)$ are the Fourier transforms of

$$\begin{aligned} &\hat{F}_l(\omega)=\sinh(l\omega/2)/\sinh(N\omega/2), \\ &\hat{D}_l(\omega)=\exp(-|\omega|/2)\hat{F}_l(\omega), \\ &\hat{K}_{l,r}(\omega)=-\delta_{l,r}+\exp(|\omega|/2)\sinh[\min(l,r)\omega/2] \\ &\qquad\times\sinh\{[N-\max(l,r)]\omega/2\}/ \\ &\qquad\sinh(\omega/2)\sinh(N\omega/2). \end{aligned} \tag{3}$$

We introduce a ground state density of states, $\rho_l(\zeta)$, for each set of real rapidities $\zeta^{(l)}$, which for particles (holes) is nonzero only in the interval $|\zeta|\geqslant B_l(|\zeta|\leqslant B_l)$. These densities satisfy integral equations of the type (2) ($X_l=\rho_l$) with driving terms $Z_l(\zeta)=F_{N-l}(\zeta)$ and $Z_N(\zeta)=D_1(\zeta)$. The integration limits B_l and Q are determined by the number of electrons with each component, $n_m N_a=[M^{(m-1)}-M^{(m)}]$, where N_a is the number of sites, $m=1,\ldots,N$, $M^{(0)}=N_e$ is the total number of electrons, $M^{(N)}=0$, and

$$n_m=\sum_{q=N-m+1}^{N}\int_{|\zeta|>B_q}d\zeta\rho_q(\zeta). \tag{4}$$

The thermal population of the states is determined by energy bands $\epsilon_l(\zeta)$, which for low T can be expanded in powers of T by means of a Sommerfeld expansion, $\epsilon_l=\epsilon_l^{(0)}+T^2\epsilon_l^{(2)}+\ldots$. The energy potentials $\epsilon_l^{(0)}$ satisfy equations of the type (2) with[6]

$$\begin{aligned} &Z_l(\zeta)=2\pi F_{N-l}(\zeta)-l(N-l)\Delta_l/N \\ &Z_N(\zeta)=-2-\mu+2\pi D_1(\zeta), \end{aligned} \tag{5}$$

where μ is the chemical potential and the parameters Δ_l are the magnetic and crystalline fields determining the splitting of the multiplet. The $\epsilon_l^{(0)}(\zeta)$ are even functions, which monotonically decrease with $|\zeta|$. The conditions $\epsilon_l(\pm B_l)=0$ relate the set of integration limits $\{B_l\}$ and Q to the set of external fields $\{\Delta_l\}$ and μ. The $\epsilon_l^{(2)}$ satisfy Eqs. (2) with

$$\begin{aligned} Z_l(\zeta)&=(\pi^2/6)\partial\epsilon_N^{-1}[F_l(\zeta-Q)+F_l(\zeta+Q)] \\ &\quad+(\pi^2/6)\sum_{q=1}^{N-1}\partial\epsilon_q^{-1}[K_{l,q}(\zeta-B_q)+K_{l,q}(\zeta+B_q)], \\ Z_N(\zeta)&=(\pi^2/6)\partial\epsilon_N^{-1}[D_{2S}(\zeta-Q)+D_{2S}(\zeta+Q)] \\ &\quad+(\pi^2/6)\sum_{q=1}^{2S}\partial\epsilon_q^{-1}[F_q(\zeta-B_q)+F_q(\zeta+B_q)], \end{aligned} \tag{6}$$

where $\partial\epsilon_q^{-1}=|d\epsilon_q^{(0)}/d\zeta|_{B_q}^{-1}$ and $\partial\epsilon_N^{-1}=|d\epsilon_N^{(0)}/d\zeta|_Q^{-1}$.

Similarly, the Sommerfeld expansion of the free energy yields the γ-coefficient

$$\begin{aligned} \gamma/N_a&=(2\pi^2/3)\left[\partial\epsilon_N^{-1}D_1(Q)+\sum_{q=1}^{2S}\partial\epsilon_q^{-1}F_{N-q}(B_q)\right] \\ &\quad+2\int_{-Q}^{Q}d\zeta D_1(\zeta)\epsilon_N^{(2)}(\zeta) \\ &\quad-2\sum_{q=1}^{2S}\int_{|\zeta|>B_q}d\zeta F_{N-q}(\zeta)\epsilon_q^{(2)}(\zeta). \end{aligned} \tag{7}$$

From the structure of (5)–(7) all contributions to γ are proportional to $\partial\epsilon_q^{-1}$ for some q. We first compute the contributions arising from the internal degrees of freedom ($q<N$) and later those of the charges ($q=N$). Defining

$$\epsilon_l^{(2)}(\zeta)=(\pi^2/6)\sum_{r=1}^{2S}\partial\epsilon_r^{-1}\varphi_l^{(r)}(\zeta), \tag{8}$$

where $\varphi_l^{(r)}(\zeta)$ satisfies (2) with

$$\begin{aligned} &Z_l^{(r)}(\zeta)=[K_{l,r}(\zeta-B_r)+K_{l,r}(\zeta+B_r)],\ l<N, \\ &Z_N^{(r)}(\zeta)=[F_r(\zeta-B_r)+F_r(\zeta+B_r)], \end{aligned} \tag{9}$$

the coefficient of the term in (7) proportional to $\partial\epsilon_q^{-1}$ is

$$\begin{aligned} &(\pi^2/3)\left\{2F_{N-q}(B_q)+\int_{-Q}^{Q}d\zeta D_1(\zeta)\varphi_N^{(q)}(\zeta)\right. \\ &\left.\quad-\sum_{r=1}^{2S}\int_{|\zeta|>B_r}d\zeta F_{N-r}(\zeta)\varphi_r^{(q)}(\zeta)\right\},\ q<N. \end{aligned} \tag{10}$$

To show that the curly bracket in (10) reduces to $2\rho_q(B_q)$ we consider the expression

$$\begin{aligned} &\sum_{s=1}^{2S}\int_{|\zeta|>B_s}d\zeta\rho_s(\zeta)[K_{q,s}(\zeta-B_q)+K_{q,s}(\zeta+B_q)] \\ &\quad-\int_{-Q}^{Q}d\zeta\rho_N(\zeta)[F_q(\zeta-B_q)+F_q(\zeta+B_q)], \end{aligned} \tag{11}$$

which by making use of (9) can be rewritten as

$$\sum_{s=1}^{2S}\int_{|\zeta|>B_s}d\zeta\rho_s(\zeta)\Big\{\varphi_s^{(q)}(\zeta)+\sum_{r=1}^{2S}\int_{|\zeta'|>B_r}d\zeta'\varphi_r^{(q)}\times(\zeta')K_{s,r}(\zeta-\zeta')-\int_{-Q}^{Q}d\zeta'\varphi_N^{(q)}(\zeta')F_s(\zeta')\Big\}$$

$$-\int_{-Q}^{Q}d\zeta\rho_N(\zeta)\Big\{\varphi_N^{(q)}(\zeta)-\int_{-Q}^{Q}d\zeta'\varphi_N^{(q)}(\zeta')D_{2S}(\zeta-\zeta')+\sum_{r=1}^{2S}\int_{|\zeta'|>B_r}d\zeta'\varphi_r^{(q)}(\zeta')F_r(\zeta-\zeta')\Big\}.$$

Using (2) in the second and fifth terms this expression simplifies to

$$\sum_{r=1}^{2S}\int_{|\zeta|>B_r}d\zeta F_{N-r}(\zeta)\varphi_r^{(q)}(\zeta)-\int_{-Q}^{Q}d\zeta D_1(\zeta)\varphi_N^{(q)}(\zeta). \quad (12)$$

On the other hand, using (2), expression (11) can be rewritten as $2F_{N-q}(B_q)-2\rho_q(B_q)$. Equating this to (12) we notice that (10) reduces to $(2\pi^2/3)\rho_q(B_q)$.

We now consider the charge fluctuations, i.e., the terms in (7) that are proportional to $\partial\epsilon_N^{-1}$. Following the same procedure above we define $\epsilon_l^{(2)}(\zeta)=(\pi^2/6)\partial\epsilon_N^{-1}\psi_l(\zeta)$, where $\psi_l(\zeta)$ satisfies (2) with

$$Z_l(\zeta)=[F_l(\zeta-Q)+F_l(\zeta+Q)],\ l<N,$$
$$Z_N(\zeta)=[D_{2S}(\zeta-Q)+D_{2S}(\zeta+Q)], \quad (13)$$

and the coefficient of the term in (7) proportional to $\partial\epsilon_N^{-1}$ is

$$(\pi^2/3)\Big\{2D_1(Q)-\sum_{r=1}^{2S}\int_{|\zeta|>B_r}d\zeta F_{N-r}(\zeta)\psi_r(\zeta)+\int_{-Q}^{Q}d\zeta D_1(\zeta)\psi_N(\zeta)\Big\}. \quad (14)$$

To show that the curly bracket in (14) reduces to $2\rho_N(Q)$ we consider the expression

$$\int_{-Q}^{Q}d\zeta\rho_N(\zeta)[D_{2S}(\zeta-Q)+D_{2S}(\zeta+Q)]-\sum_{q=1}^{2S}\int_{|\zeta|>B_q}d\zeta\rho_q(\zeta)[F_q(\zeta-Q)+F_q(\zeta+Q)], \quad (15)$$

which using (2) is reduced to $2\rho_N(Q)-2D_1(Q)$. On the other hand, expression (15) is first rewritten with the aid of (13) and (14), and then (2) is used to obtain

$$\int_{-Q}^{Q}d\zeta D_1(\zeta)\psi_N(\zeta)-\sum_{q=1}^{2S}\int_{|\zeta|>B_q}d\zeta F_{N-q}(\zeta)\psi_q(\zeta). \quad (16)$$

Therefore, we have that (14) reduces to $(2\pi^2/3)\rho_N(Q)$.

Elemental excitations from the ground state are obtained by adding (particle excitation) or removing (hole excitation) a rapidity $\zeta_0^{(l)}$ from one of the sets. There are N branches of elemental excitations with energy and momentum given by[8]

$$\Delta E_l(\zeta_0)=|\epsilon_l(\zeta_0)|,$$
$$p_l(\zeta_0)=2\pi\int_{-\infty}^{\zeta_0}d\zeta[\rho_l(\zeta)+\rho_{lh}(\zeta)], \quad (17)$$

with the Fermi surface at $\epsilon_l(\pm B_l)=0$. The respective Fermi velocities are given by the slope of the dispersion at the Fermi points[8]

$$v_F^{(l)}=|d\epsilon_l(\zeta)/d\zeta|_{B_l}/2\pi\rho_l(B_l). \quad (18)$$

Therefore, the γ-coefficient can be written as

$$\gamma/N_a=(\pi/3)\sum_{l=1}^{N}(v_F^{(l)})^{-1}. \quad (19)$$

In summary, the Fermi statistics of the low-energy excitations gives rise to a low-T specific heat proportional to T. In general, there are $(N-1)$ spin wave branches and one branch of charge excitations contributing to γ. In the absence of external fields all spin wave branches have the same group velocity,

$$v_{sw}=\frac{1}{N}\frac{2\pi+\int_{-Q}^{Q}d\zeta\,\exp(2\pi\zeta/N)\epsilon_N(\zeta)}{1+\int_{-Q}^{Q}d\zeta\,\exp(2\pi\zeta/N)\rho_N(\zeta)}, \quad (20)$$

and (19) reduces to $\gamma/N_a=(\pi/3)[1/v_{ch}+(N-1)/v_{sw}]$. Plots of v_{ch} and v_{sw} for several N as a function of band filling can be found in Ref. 8.

For one electron per site ($Q=0$) model (1) reduces to the SU(N) Heisenberg chain. The band of N-strings is filled in this limit, so that the charge excitations are suppressed (they have a gap) and do not contribute to γ. Therefore, γ consists only of the $2S$ terms of the spin wave branches. In the absence of external fields $v_{sw}=2\pi/N$ for all branches and $\gamma/N_a=N(N-1)/6$, which agrees with previous results for the $S=1/2$ (Ref. 11) and $S=1$ (Ref. 12) Heisenberg chains [note that the Heisenberg exchange in model (1) equals 1/2]. The limits of $T\to0$ and $H\to0$ can be interchanged, contrary to what we claimed previously.[13,14]

Our results are also valid for the supersymmetric two-band t-J model, which can be mapped onto model (1) for $N=4$. The four degrees of freedom correspond to charges, the splitting between the bands and the Zeeman splitting of each of the bands. Expressions for the four Fermi velocities (and plots as a function of band splitting for one electron per site and zero magnetic field) can be found in Ref. 10.

Magnetic and thermodynamic properties of $Sr_2LaFe_3O_9$

J. T. Wang

C. L. Lin and T. Mihalisin
Department of Physics, Temple University, Philadelphia, Pennsylvania 19122

Measurements of the magnetization, specific heat, and ^{57}Fe Mössbauer spectrum are presented for $Sr_2LaFe_3O_9$. The temperature dependence of the specific heat and magnetization indicates that $Sr_2LaFe_3O_9$ undergoes an antiferromagnetic transition at T_N=203 K. The small entropy removal ΔS and small effective paramagnetic moment μ_{eff} suggest an itinerant character for the Fe moment in this compound. In low applied fields, the zero field cooled (ZFC) and field cooled (FC) magnetization below T_N exhibit a hysteretic behavior indicating the existence of some ferromagnetic correlation. This behavior is suppressed by high applied fields. The ^{57}Fe Mössbauer spectrum measured at 4.2 K for $Sr_2LaFe_3O_9$ indicates two superimposed hyperfine fields of 260 and 450 kOe with area ratios of 1/3 and 2/3, respectively, consistent with previous measurements.
 [S0021-8979(96)03708-4]

I. INTRODUCTION

Since the discovery of high-T_c cuprate superconductors,[1,2] investigations of superconductivity and magnetism of d-electron based oxides with the perovskite structure have received renewed interest. Fe based oxides are not superconducting, but have interesting magnetic properties. $CaFeO_3$ and $SrFeO_3$ have antiferromagnetic transitions at T_N=115 and 134 K, respectively.[3–6] T_N for both systems decreases when one reduces the oxygen content. The ^{57}Fe Mössbauer measurements[5,6] below T_N show that $SrFeO_3$ has a single magnetic hyperfine field. However, $CaFeO_3$ shows two kinds of hyperfine fields with nearly equal intensities.[5,6] Takano *et al.*[5,6] were the first to propose a model of charge disproportionation, $2Fe^{4+} \rightarrow Fe^{3+} + Fe^{5+}$, to explain the two distinct hyperfine fields for the $CaFeO_3$ system. They have also studied the $Ca_{1-x}Sr_xFeO_3$ and $Sr_{1-x}La_xFeO_3$ systems[5,6] and found behavior similar to that observed for $CaFeO_3$. Later, Battle *et al.*[7–9] extensively investigated the $Sr_{1-x}M_xFeO_{3+y}$ system with M=rare earths and $0 \leqslant y \leqslant 1$ by Mössbauer spectroscopy and neutron diffraction measurements, and observed similar phenomena.

The temperature and magnetic field dependence of thermodynamic and magnetic properties for the $Sr_{1-x}M_xFeO_3$ system has not been investigated. We have measured the specific heat, magnetic susceptibility, and the Mössbauer spectrum at 4.2 K for $Sr_2LaFe_3O_9$.

II. EXPERIMENT

Polycrystalline $Sr_2LaFe_3O_9$ samples were prepared using the solid state reaction technique. The appropriate amounts of high purity $SrCO_3$, La_2O_3, and Fe_2O_3 were thoroughly mixed and then pressed into pellets 1/2 in. in diameter. The pellets were reacted in air at 1300–1400 °C for three days and were then very slowly cooled to room temperature. They were again ground to a fine powder and the entire procedure was repeated. After the materials were sintered in air twice, they were annealed in flowing oxygen, at a pressure slightly higher than atmospheric pressure, at 1000 °C for one day. X-ray diffraction and high power, high resolution electron microscopy measurements at room temperature were used to check sample homogeneity and lattice parameters. The results indicated that no detectable amount of second phase was present, and that the sample crystallizes with the cubic perovskite structure with a lattice constant of a=3.875 Å. This value is consistent with that previously reported[7,8] and suggests that the oxygen content is close to 9 in this compound. The magnetization was measured from 1.8 to 400 K in applied magnetic fields up to 5.5 T using a commercial SQUID magnetometer. The ^{57}Fe Mössbauer spectra were measured at 4.2 K using a liquid helium cryostat. The specific heat was measured from 15 to 300 K using the semiadiabatic heat pulse method.

III. RESULTS AND DISCUSSION

We have measured the temperature dependence of the specific heat for $Sr_2LaFe_3O_9$. The specific heat for this material has not been reported previously. We show the $C(T)$ data from 180 to 220 K in Fig. 1. It can be seen that in the vicinity of the anomaly the specific heat increases significantly from 125 J/mole K at 180 K to 480 J/mole K at 203 K and exhibits a λ type second order magnetic phase transition. This is in contrast to the first order transition proposed previously from Mossbauer measurements.[7] To obtain the magnetic contribution $\Delta C(T)$ to the specific heat, we first fit a smooth curve to the data from 15 to 150 K and from 205 to 250 K, and then subtract this smooth curve from the total specific heat $C(T)$. The entropy removal ΔS associated with the magnetic transition can be calculated by integrating $\Delta C(T)/T$. We obtain a value of ΔS=2.3 J/mole Fe K for this

 0021-8979/96/79(8)/6608/3/$10.00

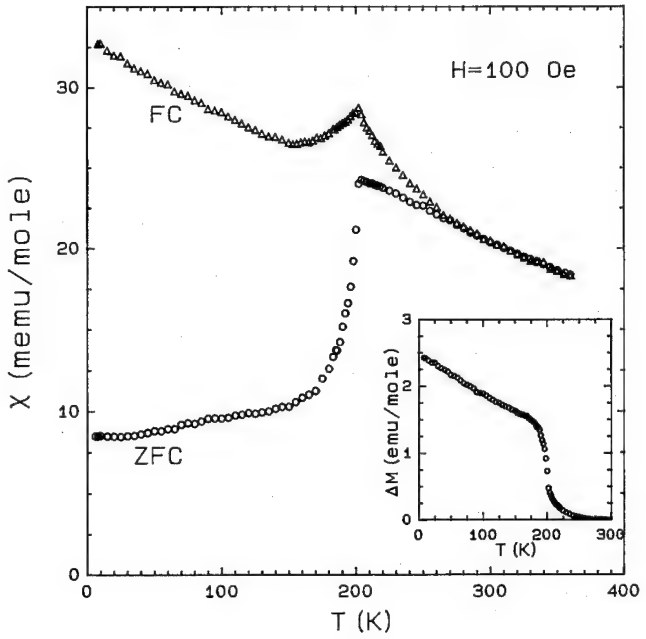

FIG. 3. The temperature dependence of the magnetic susceptibility measured at $H=100$ Oe for $Sr_2LaFe_3O_9$. FC: field cooled data and ZFC: zero field cooled data. Inset: ΔM vs T. (See the definition of ΔM in text.)

system. This value is much smaller than the value of $R\ln(2s+1)=14.9$ J/mole K which one would expect for localized spin $s=5/2$ Fe atoms.

The ^{57}Fe Mössbauer spectrum measured at 4.2 K for $Sr_2LaFe_3O_9$ is shown in Fig. 2. It is similar to that previously observed at 78 K by Battle *et al.*[7,8] This spectrum can be fit by two distinct magnetic hyperfine fields 260 and 450 kOe with different isomer shifts. It is interesting that the molar ratio of La to Sr in this compound is the same as the area ratio for the two hyperfine fields, i.e., both ratios are 1/2. Takano *et al.*[5,6] and Battle *et al.*[7,8] have explained two hyperfine fields in terms of a charge disproportionation, i.e., two charge states Fe^{3+} and Fe^{5+} below the magnetic transition. They have also interpreted the room-temperature Mössbauer spectrum, which shows a single dip with no quadruple splitting, in terms of the average valence state. However, it is still not clear why Fe ions in this material occupying identical equivalent sites exhibit two charge states below T_N resulting in two distinct hyperfine fields. Further studies are required to clearly understand this interesting phenomena.

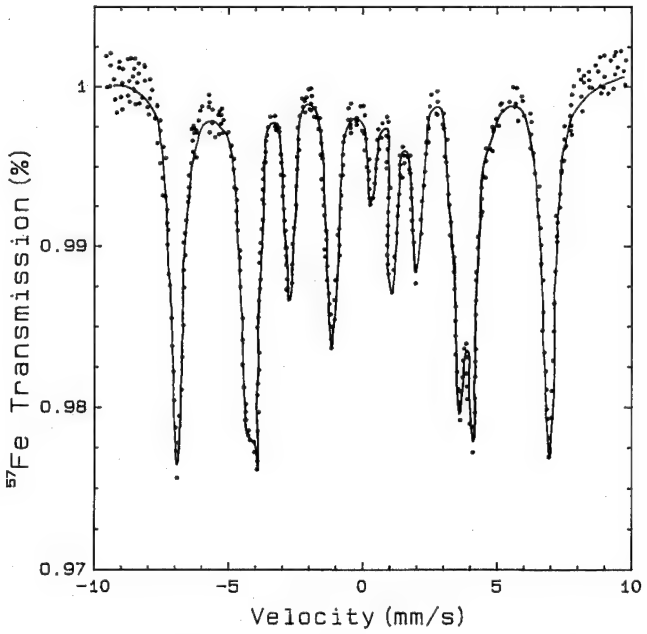

FIG. 2. ^{57}Fe Mössbauer spectrum measured at 4.2 K for $Sr_2LaFe_3O_9$.

Shown in Fig. 3 is the temperature dependence of the magnetic susceptibility $\chi(T)$ measured at $H=100$ Oe for $Sr_2LaFe_3O_9$. The sample was initially cooled in zero field to 5 K, an applied field of 100 Oe was turned on and the zero field cooled (ZFC) magnetic susceptibility was measured as the sample warmed up to 400 K. Then the field cooled data (FC) were measured at 100 Oe as the sample was cooled from 400 to 5 K. Both ZFC and FC data exhibit a cusp behavior indicating an antiferromagnetic transition at $T_N=203$ K for this material. T_N determined from $\chi(T)$ is in good agreement with that obtained from our specific heat measurement, and from magnetization measurements by another group.[7] It has been shown[8] that T_N decreases with decreasing oxygen content in $Sr_2LaFe_3O_9$. The fact that our sample has a T_N of 203 K suggests that it has an oxygen content very close to 9.

The $\chi(T)$ data above T_N for the FC branch show a Curie–Weiss behavior, i.e., $\chi(T)=c/T-T^*$. By plotting $1/\chi(T)$ vs T, we obtain a negative T^* value of -195 K consistent with the antiferromagnetic nature of the ordering. From the Curie constant c, we obtain a value for μ_{eff} of 3.0 μ_B per Fe atom. This is much smaller than the value of 5.55 μ_B previously reported.[7] The latter value is close to the theoretical value of 5.9 μ_B for Fe atoms, and therefore is consistent with a localized electron model. However, our smaller

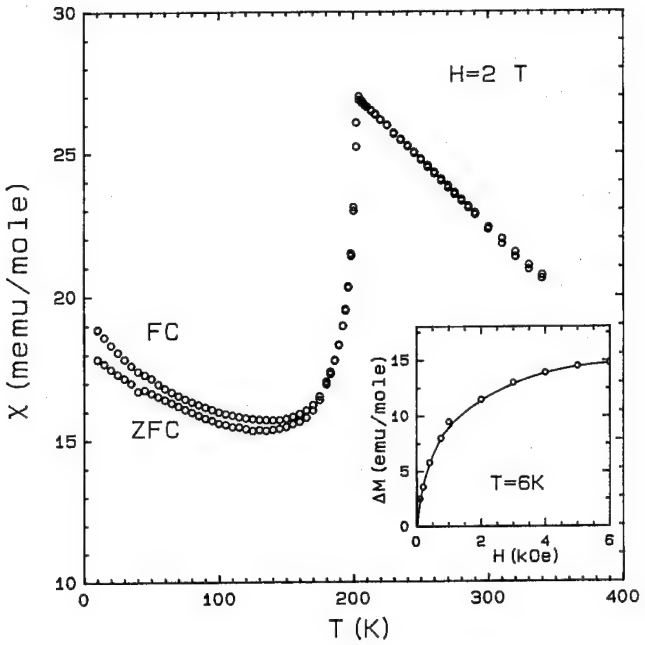

FIG. 4. The temperature dependence of the magnetic susceptibility measured at $H=2$ T for $Sr_2LaFe_3O_9$. Inset: ΔM vs H measured at $T=6$ K.

values for both μ_{eff} and ΔS indicate itinerant magnetism in the $Sr_2LaFe_3O_9$ system.

It can be seen in Fig. 3 that the ZFC data decrease dramatically just below T_N and then decrease more gradually at low temperatures. However, the FC curve behaves differently below T_N. It decreases initially (with decreasing temperature), reaches a minimum, and then increases monotonically at low temperatures. The increase in $\chi(T)$ as one lowers the temperature in the FC branch indicates the existence of a ferromagnetic component in this compound. Shown in the inset of Fig. 3 is the difference in magnetization $\Delta M(T)$ between the FC and ZFC data, that is, the ZFC data subtracted from the FC data. $\Delta M(T)$ exhibits a typical ferromagnetic behavior. This behavior has also been observed in other Fe based oxides, e.g., $YBa_2Fe_3O_8$[10] and annite mica.[11] We have also measured the isothermal magnetization at several low temperatures in applied fields between 5 and -5 T for $Sr_2LaFe_3O_9$, and observed a hysteretic behavior, i.e., remanent magnetization (not shown).

Shown in the inset of Fig. 4 is the field dependence of ΔM at $T=6$ K. ΔM initially increases significantly and then saturates gradually at high applied fields. Consequently, the difference between the FC and ZFC $\chi(T)$ data will become smaller when one increases the applied field. Shown in the main portion of Fig. 4 are the $\chi(T)$ data measured in a field of 2 T. The difference between the FC and ZFC curves is greatly reduced from that observed at low fields.

Neutron diffraction measurements[9] on $Sr_2LaFe_3O_9$ have shown that the magnetic structure can be described in terms of a spin density wave commensurate with the crystal lattice. The noncubic antiferromagnetic structure might be responsible for a magnetic moment canting in an external field giving rise to a ferromagnetic component for the FC curve.

In conclusion both the specific heat and magnetization measurements indicate that an antiferromagnetic transition occurs at $T_N=203$ K in $Sr_2LaFe_3O_9$. The observed entropy removal and effective paramagnetic moment are much smaller than those that one would expect if the magnetism were due to well-localized moments associated with the Fe atoms. The FC and ZFC magnetic susceptibility curves show hysteretic behavior which is suppressed by applied fields. The ^{57}Fe Mössbauer spectrum measured at 4.2 K is consistent with two superimposed magnetic hyperfine fields, as previously observed at 78 K.[7,8]

Results are presented concerning the magnetic properties at low temperatures of mechanically alloyed samples of the $Fe_xMn_{0.7-x}Al_{0.3}$ ($0.4 \leq x \leq 0.5$) series. According to these results the samples were characterized as having a broad spectrum of relaxation times related to the occurrence of clustering. Also, in the particular case of the $x=0.40$ sample, we were able to detect a reentrant spin glass freezing transition. © *1996 American Institute of Physics.* [S0021-8979(96)03808-0]

I. INTRODUCTION

The combination[1] of structural disorder and competing ferromagnetic (F) and antiferromagnetic (AF) interactions brings about the possibility of the occurrence of spin glass (SG) behavior in the FeMnAl system. Nevertheless, and despite the amount of already published work,[2–7] both theoretical and experimental, the magnetic properties of this ternary system must still be explored in more detail. To summarize those previously obtained results, let us say that Pérez Alcazar *et al.*[2] showed that disordered bcc samples of this system with Mn and Al contents ranging from 20 up to 35 at. % and from 20 up to 30 at. %, respectively, showed a complex structure for the line in the phase diagram defined by the compositions for which the Curie temperature coincided with the room temperature. This behavior was interpreted by Rosales Rivera *et al.*[3] as related to the occurrence of a SG phase. The presence in the $Fe_{0.50}(Mn_xAl_{1-x})_{0.50}$ series of such a SG phase was reported, on the basis of Mössbauer results, by Kobeissi.[4] A reentrant spin glass (RSG) behavior, linked to the presence in addition to disorder and competing interactions of some paramagnetic sites, has been recently shown to occur in $Fe_{0.45}Mn_{0.30}Al_{0.25}$.[5,6] Finally, Bremers *et al.* presented evidence of RSG in $Fe_{0.49}Mn_{0.11}Al_{0.40}$ samples.

The preparation of samples by means of solid state reaction techniques seems to be specially interesting[8] from the point of view of the study of the influence of the disorder on the magnetic behavior, since these techniques usually have associated control parameters allowing a gradual introduction of both structural (random site occupation) and microstructural (chemical clustering) disorder. In the particular case of the preparation technique used in this work, mechanical alloying, we can mention, among these control parameters, the milling time and intensity and the mass of precursor materials-to-mass of the milling balls ratio.

II. PREPARATION OF SAMPLES AND EXPERIMENTAL TECHNIQUES USED

In the present work we will report on the preparation and low-temperature magnetic properties of the alloy series $Fe_xMn_{0.7-x}Al_{0.3}$ ($0.4 \leq x \leq 0.5$). Our samples were mechanically alloyed using a planetary ball mill (Fritsch Pulverisette 7). The precursor pure elemental powders (<40 μm particle size, 99.99% purity) were sealed under inert atmosphere in stainless steel jars together with balls of the same material in a mass of powders-to-mass of the balls ratio of 1:12. That mixture was milled for 72 h. The phase distribution of the as-milled material was examined by means of x-ray diffractometry (XRD, Cu $K\alpha$). The magnetic properties of the samples (measured in the form of pressed powder cylinders) were investigated using a SQUID magnetometer (5 T, 1.7–400 K), an ac susceptometer (4.2–300 K, operated at a dc field value of 10 Oe, ac field amplitude of 3 Oe, and 175 Hz frequency) and a constant acceleration type Mössbauer spectrometer with a ^{57}Co source.

III. RESULTS

In Fig. 1, we present the XRD patterns measured in all the prepared samples. As can be observed, all of the samples exhibited bcc-type reflections exclusively.

In Fig. 2, we have plotted the temperature dependence of the ac magnetic susceptibility measured, after zero field cooling, in the $x=0.50$, 0.475, and 0.45 samples. In all of them we observed a broad plateau which indicated a very wide spectrum of relaxation times. Different from this, the results corresponding to the $x=0.40$ sample (Fig. 3) revealed a well-defined (but still wide) maximum at ~120 K.

In agreement with the former results, the curves corresponding to the temperature dependence of the low field (75 Oe) dc magnetic moment measured after cooling the $x=0.40$

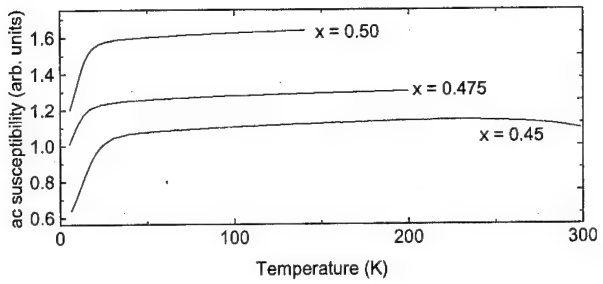

FIG. 2. Temperature dependence of the ac susceptibility measured in the $x=0.50$, 0.475, and 0.45 samples.

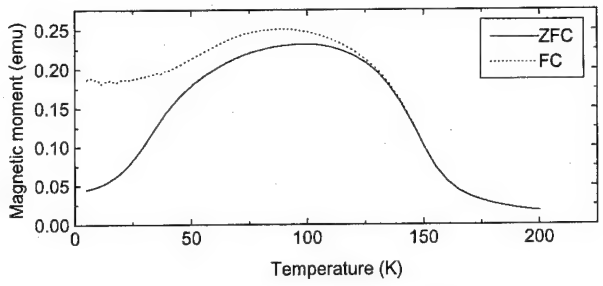

FIG. 4. Temperature dependence of the low field magnetic moment of the $x=0.40$ sample measured after zero field cooling and field cooling.

sample under a field of 75 Oe (shown in Fig. 4) coincided (down to the sensitivity of our magnetometer) for temperatures above 130 K.

The Mössbauer spectra taken in the $x=0.40$ sample at different temperatures in the range from 15 up to 58 K are shown in Fig. 5(a). All the spectra are broad and unresolved, indicating the occurrence of a high degree of disorder in the samples. The best fit of these spectra was obtained using two hyperfine field distributions (HFDs) and a paramagnetic line. The associated hyperfine field probability distributions resulting from the fits are presented in Fig. 5(b). As is apparent from the figure, the HFDs shift towards the low-field range when the temperature is increased.

The average hyperfine field associated with the distributions evolved with temperature as shown in Fig. 6. From the extrapolation to higher temperatures of these data, it is possible to observe that the average hyperfine field should vanish at ~80 K, that is at a temperature clearly lower than that corresponding to the maxima observed in the temperature dependence of the ac susceptibility and the low field zero field cooled magnetic moment. Also and remarkably, a kink was observed in the temperature evolution of the hyperfine field at ~30 K. In agreement with this the temperature dependence of the area of the paramagnetic line considered in the fit of the spectra (see Fig. 7) exhibited a clear increase above 40 K.

IV. DISCUSSION

From our Mössbauer data obtained in the $x=0.40$ sample two major conclusions can be inferred: on the one side, the order temperature associated to the measured hyperfine field is of the order of 80 K and on the other, following the ideas presented in Ref. 9, the sample exhibits reentrant spin glass behavior. The last point was evidenced by the kink observed in the temperature dependence of the average hyperfine field which can be understood as linked to the appearance (as the temperature is decreased) of an extra contribution to that field coming from the moments which at temperatures higher than that of the kink behaved as paramagnetic and freezed below it. This idea is confirmed by the temperature dependence of the percentage of the total spectral area associated to the paramagnetic line: it peaks at temperatures slightly higher than those of the kink in the average hyperfine field versus temperature curve, indicating an increase, linked to the defreezing process, of the number of moments which behave paramagnetically.

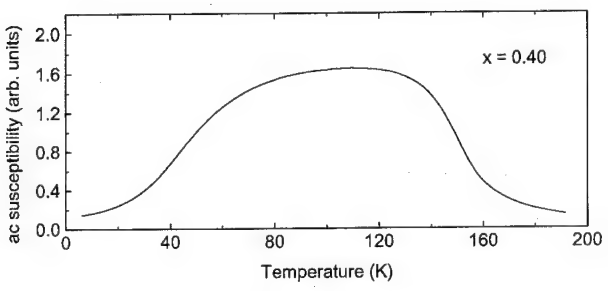

FIG. 3. Temperature dependence of the ac susceptibility measured in the $x=0.40$ sample.

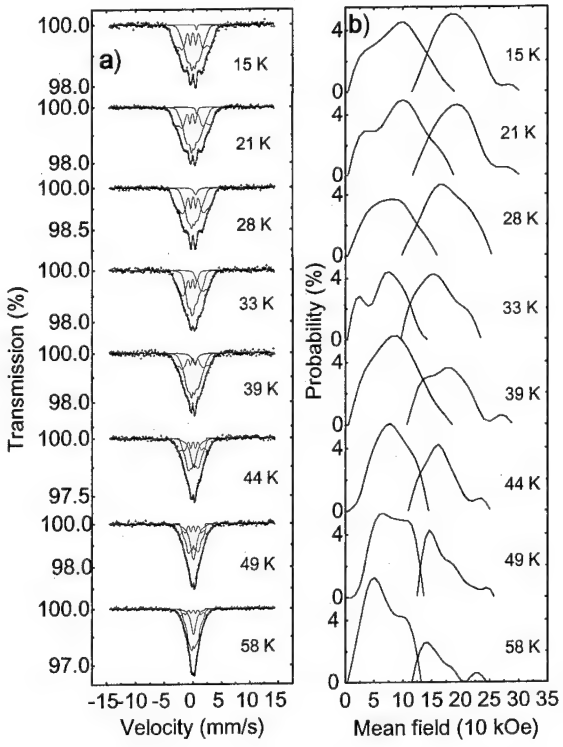

FIG. 5. (a) Mössbauer spectra measured in the $x=0.40$ sample at different temperatures. (b) Hyperfine field probability distributions in the sample with $x=0.40$ evaluated from the fit of the spectra shown in (a). The different subspectra considered are also indicated.

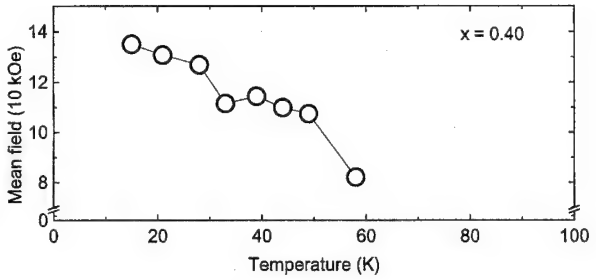

FIG. 6. Temperature dependence of the average hyperfine field of the $x=0.40$ sample.

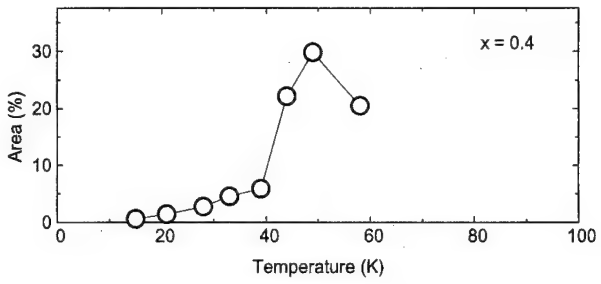

FIG. 7. Temperature dependence of the percentage of the total area associated to the paramagnetic lines used to fit the spectra in Fig. 5(a).

In contrast with the Mössbauer results, magnetometric and susceptometric data obtained in this sample, althoughqualitatively indicating the occurrence of a freezing process, evidenced measurable magnetic moments and susceptibilities at temperatures higher than at which, according to our Mössbauer data, the hyperfine field should vanish. A similar behavior, i.e., the observation in the Mössbauer spectra of broad and unresolved structures at temperatures at which magnetometric techniques are able to detect indications of magnetic order, has been previously reported in a number of different systems[10–14] and is usually related to the occurrence of a range of relaxation times covering many decades, being magnetic field sensitive and linked to the existence of clusters. In our particular case, the broad maxima detected in the susceptibility versus temperature curves of all the examined samples are a further confirmation of the occurrence of clusters.

Regarding the origin of the proposed clusters, let us remember the out-of-equilibrium nature of the preparation process and the fact that the samples were measured in the as-milled state. Then, it is possible to envisage the presence of both chemical (linked to compositional fluctuations) and magnetic (linked to exchange fluctuations) clusters which should result in a wide distribution of local fields. A study of the magnetic properties of structurally relaxed samples is currently being carried out in order to clarify this point.

Neutron scattering measurements revealed that even a seemingly perfect crystal of $KNiCl_3$ at room temperature may segregate into two phases with different lattice distortions in the basal ab plane at temperatures below $T \approx 270$ K. In phase A, distortion leads to an increase of the unit cell size by a factor of 3, giving rise to nuclear Bragg peaks of type $(h/3,h/3,l)$. In phase B the distortion gives rise to Bragg peaks at $(3h/4,0,l)$, with integer h and l. Two different magnetic structures have been observed with $T_N = 12.5$ and 8.6 K in phases A and B, respectively. Magnetization measurements confirm the values of T_N found by neutron scattering for the two magnetic structures. © *1996 American Institute of Physics.* [S0021-8979(96)00608-2]

The great interest in magnetic properties of the hexagonal ABX_3-type compounds is due to the fact that they provide good examples of triangular-lattice antiferromagnets. By varying A, B, and X (where A is an alkali metal, B is a bivalent metal of $3d$ group, and X is a halogen) one can create systems with different type of magnetic interactions. For example, $CsCoBr_3$ and $CsCoCl_3$ may be described as Ising antiferromagnets,[1] $CsFeBr_3$ and $CsFeCl_3$ are usually referred to as singlet ground state magnets because the Fe^{2+} ion has locally a singlet ground state $(m_s=0)$,[2,3] $CsNiCl_3$ and $CsMnI_3$ are nearly Heisenberg systems with small easy-axis anisotropy,[4,5] while other Heisenberg antiferromagnets $CsMnBr_3$ and $RbMnBr_3$ exhibit strong XY-type anisotropy.[6,7] It has been found that a variety of new magnetic properties exists in these types of compounds, such as field-induced phase transitions from the triangular phase to a collinear one, incommensurate–commensurate phase transitions, critical behavior associated with a chiral degeneracy, and unusual phase diagrams. A common feature of all of these systems is that the exchange interactions in the chains of $3d$ ions along the hexagonal axis are much stronger than those in the basal plane.[4]

Here we present the results of elastic neutron scattering measurements and magnetization measurements on $KNiCl_3$, an example of the Heisenberg triangular antiferromagnet. Particular interest in the "$KNiCl_3$ family" of crystals may be attributed to the experimental opportunity to investigate the magnetic properties of the easy-plane triangular lattice antiferromagnets with partially released spin frustration.[8,9] In contrast to the fully frustrated triangular spin systems, such as in $CsMnBr_3$, the crystal distortions in the $KNiCl_3$ family break the symmetry of the interaction between neighboring in-plane magnetic ions. The theory predicts a different type of behavior,[10–12] especially in an applied magnetic field,[13] according to different distortions of the ideal hexagonal packing and consequently of the 120° spin structure.

The neutron scattering measurements were carried out on the $N5$ and $C5$ triple-axis spectrometers at the NRU reactor at the Chalk River Laboratories and on the double-axis spectrometers at McMaster University Nuclear Reactor. A pyrolytic graphite (002) reflection was used for the monochromator, the incident and scattered neutron energy was fixed at 3.52 THz at Chalk River and at 3.36 THz at McMaster. A pyrolytic graphite filter at room temperature and a nitrogen-cooled sapphire filter were installed in the beam to remove higher-order contamination. The collimation was typically 0.47°–0.56°–2.5°. Liquid-helium cryostats with a minimum temperature 1.7 K were used at Chalk River Laboratories, while at McMaster University we used only liquid nitrogen for the sample cooling. The single-crystal samples were aligned in two different ways, so that the horizontal scattering plane contained either (hhl) or $(h0l)$ reflections indexed in the hexagonal cell with $a=11.80$ Å and $c=5.94$ Å.

We investigated three large crystals of $KNiCl_3$ in our neutron scattering experiments. All of them were prepared using the Bridgman method and were cylindrical in a shape with length approximately 10–20 mm and diameter ~10 mm. At room temperature all three crystals gave identical scattering patterns consistent with the space group $P6_3cm$. This structure is distinguished from the undistorted high-temperature structure with space group $P6_3/mmc$ by a shifting of two thirds of the $NiCl_3$ chains along the c axis.[14] Further structural phase transitions just below room temperature have been reported by Machida *et al.*[15] We observe a dramatic difference between crystals after cooling through these transitions at 285 and 274 K.

In crystal number 1 (volume ~0.8 cm^3) scans in the (hhl) plane of the reciprocal lattice revealed new Bragg peaks at position $(h/3,h/3,l)$. The intensity of these peaks was small, increasing gradually as the temperature decreases, though even at the lowest temperature it did not exceed half a percent of the intensity of the main reflections. No new nuclear peaks were found for scans in the $(h0l)$ plane. None of the main Bragg peaks change in intensity when passing through the phase transition. From these observations it is concluded that (1) the low-temperature unit cell is rotated through 90° about the c axis from the room-temperature unit cell and enlarged to $\sqrt{3}a$, $\sqrt{3}a$, and c, (2) the distortion of the low-temperature structure is small so that the structure does

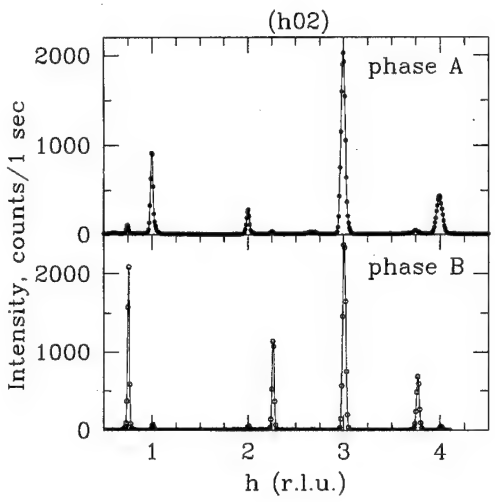

FIG. 1. Bragg-peak intensity of $KNiCl_3$ at $T=4.2$ K observed with $(h02)$ scans. For sample 1 (top), phase A is the majority phase and for sample 2 (bottom), phase B is the majority phase.

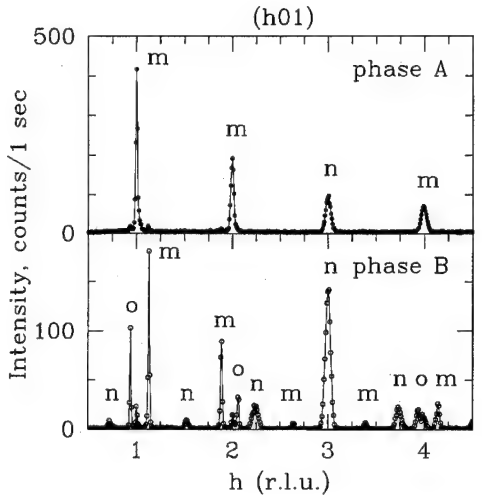

FIG. 2. Bragg-peak intensity of $KNiCl_3$ at $T=4.2$ K for phase A (top) and B (bottom) along the $(h01)$ direction of the reciprocal lattice. Nuclear peaks are designated "n," in-plane magnetic peaks "m," and out-of-plane magnetic peaks "o."

not differ much from the structure at room temperature. This tripling of the unit cell volume is quite common for materials with this crystal structure. Further measurements on a powder sample[16] confirmed this conclusion; the powder neutron scattering pattern looks similar at all temperatures except those where magnetic ordering appeared. We call the low-temperature structure of this crystal phase A.

In crystal number 2 (volume ~ 1.2 cm^3), whose low-temperature phase we call phase B, the change of crystal structure below and above the phase transition temperature is less common. Instead of room-temperature peaks at position $(h0l)$, with l even, new peaks appeared at $(h+q,0,l)$ with $q=0$ for $h=3n$ (n integer), $q=-\frac{1}{4}$ for $h=3n+1$ and $q=\frac{1}{4}$ for $h=3n+2$. Figure 1 shows the intensity of nuclear Bragg peaks of $(h02)$ type at $T=4.2$ K for both crystals. Inspection of the scattering patterns from the two crystals shown in Fig. 1 demonstrates that neither crystal is homogeneous; that is a small amount of phase A is present in the second crystal, as well as a small amount of phase B in the first one. Our rough estimation of the phase ratio $A:B$ gives 97:3 for the first crystal and 10:90 for the second one. For each crystal this ratio is repeatable and does not depend upon the cooling rate. To investigate the spatial distribution of phases A and B in the second crystal we restricted the horizontal size of the neutron beam to 2 mm and measured the intensity of the peaks from both phases while moving the beam along the cylindrical sample. This simple experiment showed that phase A in the second crystal is mostly located on the top and bottom of the cylinder, while phase B occurs mostly in the middle.

Crystal number 3 was prepared and studied to investigate the influence of the annealing process on the crystal structure of $KNiCl_3$. A neutron diffraction pattern of this crystal was measured immediately after preparation and again after annealing for 12 days at a temperature of 250 °C. No significant change was found and in both cases the third crystal gave reflections consistent with phase B.

As a consequence of the existence of two different crystal modifications, two different magnetic structures have been observed in phases A and B (see Fig. 2). In both cases magnetic reflections (hkl) are only observed for l odd because of the strong antiferromagnetic interactions along the chains.

In phase A the magnetic Bragg peaks are at $(h,0,2l'+1)$ and the magnetic structure is in-plane triangular with the angles between two nearest neighbor spins close to 120°. The nonzero intensity of the reflection (001) (not shown in Fig. 2) shows that there are deviations from 120°. These are brought about by the nonequivalent interchain exchange interaction[17] and correspond to nonzero magnetization in one basal plane. Note, that antiferromagnetic alignment of spins along the chains results in the net magnetization remaining exactly zero for zero external field.

The bottom of Fig. 2 shows the Bragg-peak intensity for phase B along the $(h01)$ direction of reciprocal space. The magnetic peaks are sharper than the nuclear peaks. This might suggest distortions of the nuclear structure to lower symmetry. The magnetic peaks would come from single domains while the nuclear peaks are an unresolved superposition of different domains. Not all of the observed peaks lie in the $(h0l)$ plane, we have seen additional reflections located slightly below and slightly above the scattering plane due to relatively open vertical resolution. The insertion of a vertically focusing monocromator significantly increased the intensity of these peaks, while by decreasing the vertical size of the detector it is possible to decrease the intensity to zero. All magnetic Bragg peaks located in the scattering plane can be indexed as $[\frac{3}{8}(2h+1),0,2l+1]$ and are designated an "m" on Fig. 2. The overall magnetic scattering pattern in phase B, including peaks above and below the scattering plane, is identical to that observed in another XY-like antiferromagnet on a distorted stacked triangular lattice, $RbMnBr_3$, at high magnetic field.[7] The analogy with $KNiCl_3$ may help resolve some unanswered questions about the magnetic properties of $RbMnBr_3$. For example, the presence of

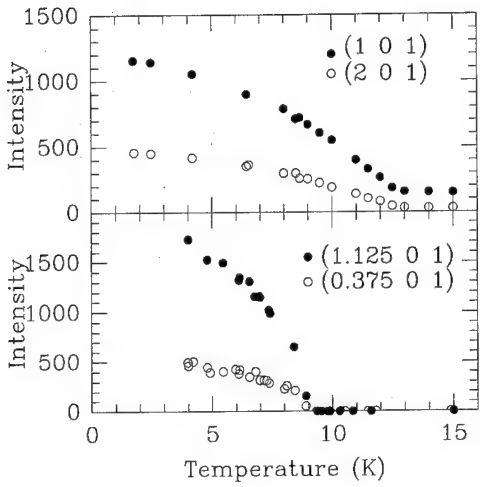

FIG. 3. Integrated intensity of the magnetic Bragg peaks of $KNiCl_3$ vs temperature for phase A (top) and B (bottom).

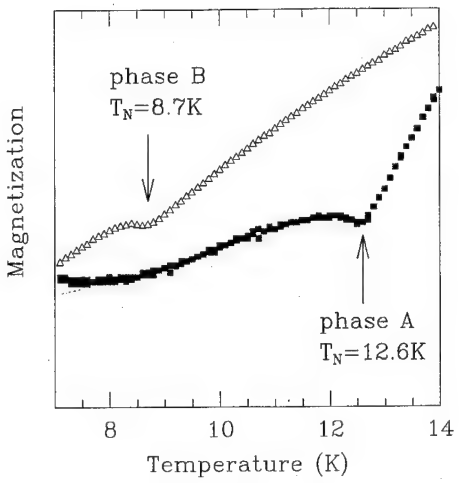

FIG. 4. The temperature dependence of the magnetization of $KNiCl_3$ at $H=0.75$ T, $H\perp c$, in arbitrary units. The arrows at 12.6 and 8.7 K correspond to the ordering temperature for phases A and B, respectively.

two magnetic structures with different ordering wave vector and ordering temperatures found in $RbMnBr_3$ by one group of authors[7] and not by another,[18] is likely to be attributed to a different phase ratio $A:B$ in the two samples. Despite the similarity of the crystal structures, the magnetic structure of $RbMnBr_3$ at low magnetic field in phase B differs from phase B of $KNiCl_3$ in that it is an incommensurate ordered structure with magnetic Bragg peaks at $(h/8\pm\delta,\ h/8\pm\delta,\ l)$ with $\delta=0.0183$.

Figure 3 shows the temperature dependence of the integrated intensity of the magnetic Bragg peaks for phases A and B. The temperature of magnetic ordering was found to be $T_N=12.5\pm0.1$ K and $T_N=8.6\pm0.1$ K in phases A and B, respectively. This result has been obtained both by measurement in a double-axis mode and in a triple-axis mode with zero energy transfer.

It is apparent from the discussion above, that previously reported neutron scattering and magnetization measurements[17] were carried out on a different phase of $KNiCl_3$. Inelastic neutron scattering measurements (Figs. 1 and 2 of Ref. 17) were performed on crystal number 1 with phase A, while magnetization measurements (Figs. 3 and 4 of Ref. 17) were performed on a different small crystal corresponding to phase B. We remeasured the magnetization of both phases of $KNiCl_3$ using a Quantum Design SQUID magnetometer. A typical example of the temperature dependence of the magnetization at $H=0.75$ T is shown in Fig. 4. Both curves demonstrate well-pronounced changes of slope at the magnetic ordering temperature $T_N=12.6$ K and $T_N=8.7$ K, in good agreement with the neutron scattering results.

In conclusion, we have presented experimental data which unambiguously show the existence of two different low-temperature crystal and magnetic structures in the easy-plane triangular lattice antiferromagnet $KNiCl_3$. Three-dimensional x-ray or neutron diffraction measurements are needed to determine the precise crystal structure of both low-temperature phases.

New spin glass $Fe_{0.67}Cr_{1.33}Sn_{0.67}S_4$ with magnetic ions in tetrahedral and octahedral sublattices (abstract)

L. I. Koroleva, L. N. Lukina, and A. G. Odintsov
Department of Physics, M. V. Lomonosov Moscow State University, Moscow 119899, Russia

T. V. Virovets
Kurnakov Institute of General and Inorganic Chemistry, Moscow 117907, Russia

To date, spin glass state is observed in chalcogenide spinels with magnetic ions either in tetrahedral A sublattice or in octahedral B sublattice. The possibility of spin glass state in chalcospinels with magnetic ions in both of A and B sublattices is not evident because the intersublattice antiferromagnetic superexhange is more higher than intrasublattice ferromagnetic superexhange. In the present paper the magnetic and electrical properties of first produced spinel $Fe_{0.67}Cr_{1.33}Sn_{0.67}S_4$ are studied. This sample is p-type semiconductor. Here B sublattice is diluted of diamagnetic Sn^{4+} ions and Fe^{2+} ions deficiency exists in A sublattice. The isotherms of the magnetization σ are not saturated in investigation region of magnetic field $H \leqslant 35$ kOe and of temperatures $4.2 \leqslant T \leqslant 120$ K. At the same time, this sample possesses magnetic properties typical of spin glass. Thus a maximum on the temperature dependence of the magnetic susceptibility measured in a weak ac field is founded at the freezing temperature T_f. (The frequency region is $0.3 \leqslant \omega \leqslant 2$ kHz, $H_{\sim}=0.3$ Oe.) The maximum is lowered under a static magnetic field which is applied parallel to the ac field. Low-temperature magnetization in the weak field depends on the cooling process (with or without field). The $T_f(\omega)$ dependence obeys the power law and $T_f(H,T)$ dependence obeys the Almeida–Touless relation; these facts attest that phase transition spin glass–paramagnetic exists in this sample. This is a first spin glass among chalcospinels with magnetic ions in A and B sublattices. © *1996 American Institute of Physics.* [S0021-8979(96)63708-9]

Scaling of the thermoremanent relaxation in FeNiCr

D. Li and R. M. Roshko
Department of Physics, University of Manitoba, Winnipeg MB R3T 2N2, Canada

We present measurements of the relaxation of the low field thermoremanent magnetization of $Fe_{0.65}Ni_{0.24}Cr_{0.11}$ over four decades of observation time 1 s$<t\leq 10^4$ s, as a function of temperature T and system age t_w. The system orders ferromagnetically at $T_c\cong 110$ K and then, near $T_R\cong 50$ K collapses into a much less responsive low-temperature phase, with glassy, age-dependent dynamics appearing below $T_g\cong 22$ K. We have analyzed the data using a model of random traps developed by Bouchaud, according to which the relaxation curves for different t_w at a given temperature T will scale onto a universal curve when plotted as a function of t/t_w, provided that proper account is taken of the distribution of ergodic times $t_{\rm erg}$ possessed by a real system. With the assumption of a log-normal distribution $P(t_{\rm erg})$, we have calculated the nonuniversal correction-to-scaling factor explicitly, and we have shown that the data do indeed collapse remarkably well onto a universal curve, with a suitable choice of values for the two distribution parameters, and for the two relaxation function parameters. © *1996 American Institute of Physics.* [S0021-8979(96)03908-7]

Disordered materials are characterized by a very slow relaxation of their macroscopic observables (typically logarithmic, or stretched exponential, or weak power law) in response to a step-function excitation, and by the aging effect, which means that the relaxation response depends on the time that the system has spent in the glassy state at a temperature $T<T_g$ before it is probed. Recently, Bouchaud[1] has offered a phenomenological explanation for this behavior, which is based on the very general premise that the free energy landscape of a disordered material is very rugged, with many local metastable minima which temporarily trap the system as it evolves towards equilibrium. If the distribution of trapping times τ has the form $\psi(\tau)\sim\tau^{-(x+1)}$ with $x<1$, then the mean trapping time $\bar{\tau}=\int_{\tau_0}^{\infty}\tau\psi(\tau)d\tau$ diverges (τ_0 is a microscopic time), so that an infinite system will require an infinite time to explore all of its configuration space. Thus, its relaxation response will specifically depend on where it was trapped in configuration space when it was disturbed by the probing field.

In a finite system with S metastable states, a random walk analysis predicts that there will be a most probable longest trapping time encountered by the system, and this plays the role of an ergodic time $t_{\rm erg}=\tau_0 S^{1/x}$, after which the system is assumed to have reached equilibrium. If the wait time t_w between the temperature quench from above to below T_g and the application of the probing field is much less than the ergodic time $t_{\rm erg}$, the relaxation response is nonergodic and given by[1]

$$m(t,t_w)=m_0\exp\left(-\gamma\int_0^t t^{-x}(t+t_w)^{x-1}dt\right). \tag{1}$$

If $t_w\gg t_{\rm erg}$, the system is in equilibrium, and the relaxation response is very nearly the same function,[1,2] but with t_w replaced by $t_{\rm erg}$.

If the response of a real system was purely nonergodic then, for a given temperature T, the relaxation data for different t_w should scale onto a universal curve when plotted as a function of t/t_w, since the predicted response $m(t,t_w)/m_0$ in Eq. (1) depends only on the reduced variable t/t_w. However, if a macroscopic system was actually a collection of independent subsystems, with a distribution of sizes $P(S)$ and of ergodic times $P(t_{\rm erg})$, then departures from universality would be expected, due to that fraction of subsystems with $t_{\rm erg}<t_w$, for which aging has ceased.

In this paper, we present measurements of the relaxation of the low field thermoremanent magnetization in a sample of $Fe_{0.65}Ni_{0.24}Cr_{0.11}$ as a function of observation time t, wait

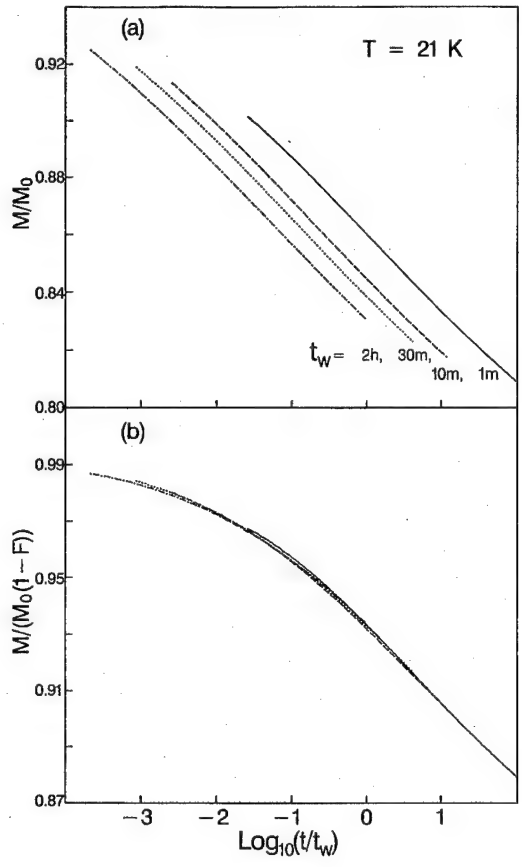

FIG. 3. (a) The thermoremanent relaxation $M(t)/M_0$ measured at $T=21$ K for several different values of the wait time t_w, plotted as a function of $\log_{10}(t/t_w)$. (b) The same data in (a) scaled along the vertical axis by the correction factor 1-F as described.

time t_w, and temperature T, and we show that, with only a few simplifying assumptions, the experimental systematics are remarkably consistent with Bouchaud's model of random traps.

An alloy of $Fe_{0.65}Ni_{0.35-x}Cr_x$ with $x=0.11$ was prepared by melting the appropriate amounts of 99.99% Fe foil, 99.995% Ni foil, and 99.99% Cr chunks, all supplied by Aldrich Chemical Company Inc., on the water-cooled copper hearth of an argon arc furnace, using a tungsten electrode and a titanium getter. The ingot was inverted and remelted several times to ensure homogeneity, then cold rolled into a thin sheet from which a sample of dimensions 10 mm×0.3 mm×0.05 mm was spark cut. The sample was sealed in a quartz tube under a partial atmosphere of argon, annealed for 4 days at 1000 °C, and rapidly quenched into water.

The measurements of the thermoremanent relaxation were performed on a custom-designed SQUID-based susceptometer which has been described in detail elsewhere in the literature.[3]

The system $Fe_{0.65}Ni_{0.24}Cr_{0.11}$ is a reentrant ferromagnet,[4] with a ferromagnetic Curie temperature $T_c \cong 110$ K and a reentrant temperature $T_R \cong 50$ K, the latter identified by a relatively abrupt drop in the low field, frequency dependent differential response function $\chi(\omega) \equiv \partial M/\partial H_a$ as the system is cooled through T_R.[4] Below a characteristic temperature $T_g \cong 22$ K, the relaxation response has age-dependent behavior typical of a glass; when the system is cooled in a field $H_c=1.0$ Oe from a paramagnetic reference temperature $T_{\rm ref}=140$ K above T_c to a temperature $T<T_g$ and held there for a time t_w before turning off the field, the thermoremanent relaxation curves exhibit an inflection point $t_{\rm infl}$ when plotted on a logarithmic time scale, which propagates towards longer observation times with increasing age t_w. The aging rate $d \log_{10} t_{\rm infl}/d \log_{10} t_w$ is temperature dependent, and decreases as $T \to T_g^-$. Figures 1(a), 2(a), and 3(a) show the measured thermoremanent decay, normalized to its value M_0 at $t=0$, and plotted versus $\log_{10}(t/t_w)$, for three temperatures $T=17$, 19, and 21 K, and several wait times $t_w=1$ min, 3 min, 5 min, 10 min, 15 min, 30 min, 1 h, and 2 h. The value of M_0 was determined by fitting the data to the superposition of a stretched exponential and a constant, and extrapolating to $t=0$.

If we interpret the decline in the aging rate, and the failure of the data in Figs. 1(a), 2(a), and 3(a) to scale onto a universal curve with $\log_{10}(t/t_w)$, as evidence of interrupted aging, then the magnetization $M(t)$ should be represented as a superposition of independent response functions each weighted according to a distribution $P(t_{\rm erg})$. If we further assume that the crossover from nonergodic to ergodic behavior occurs suddenly, which is equivalent to assuming that the most probable ergodic time $t_{\rm erg}=\tau_0 S^{1/x}$ is also the *only* ergodic time which occurs with any appreciable probability for

TABLE I. "Best fit" parameters for Eqs. (3) and (4).

T (K)	$\overline{\log_{10} t_{erg}}$	σ_{erg}	x	γ
17	2.0±0.2	2.0±0.3	0.10±0.05	0.0128±0.0010
19	1.0±0.3	2.0±0.3	0.60±0.10	0.0135±0.0010
21	0.0±0.3	2.0±0.3	0.83±0.10	0.0140±0.0010

any given subsystem, and that the crossover takes place when $t_w = t_{erg}$ (rather than when $t + t_w = t_{erg}$, as it does in the model), then each term in the superposition is either purely ergodic or purely nonergodic, and the total magnetization is given by

$$M_r(t) = M_0 \left[\int_0^{t_w} dt_{erg} P(t_{erg}) \exp\left(-\gamma \int_0^t t^{-x}(t + t_{erg})^{x-1} dt \right) + \int_{t_w}^{\infty} dt_{erg} P(t_{erg}) \times \exp\left(-\gamma \int_0^t t^{-x}(t + t_w)^{x-1} dt \right) \right]. \quad (2)$$

By factoring out the purely nonergodic t_w-dependent exponential, this equation can be recast as the product of a universal function $f(t/t_w)$ and a nonuniversal correction factor $1\text{-}F$ which describes deviations from t/t_w scaling:

$$M(t) = M_0 \underbrace{\exp\left(-\gamma \int_0^t t^{-x}(t + t_w)^{x-1} dt \right)}_{f(t/t_w)} \cdot \left\{ 1 - \underbrace{\int_0^{t_w} dt_{erg} P(t_{erg}) \left[1 - \exp\left(-\gamma \int_0^t t^{-x}(t + t_{erg})^{x-1} dt + \gamma \int_0^t t^{-x}(t + t_w)^{x-1} dt \right) \right]}_{F} \right\}. \quad (3)$$

Thus, a plot of $M(t)/[M_0(1-F)]$ should restore universality. In fact, with the choice of a log-normal distribution of ergodic times:

$$P(t_{erg}) = \frac{1}{\sqrt{2\pi t_{erg}^2 \sigma_{erg}^2}} \exp\left(-\frac{(\log_{10} t_{erg} - \overline{\log_{10} t_{erg}})^2}{2\sigma_{erg}^2} \right), \quad (4)$$

it is possible to explicitly calculate the correction factor in Eq. (3) numerically and, as Figs. 1(b), 2(b), and 3(b) show, to obtain remarkably good universal behavior using the "best-fit" parameters listed in Table I. Inspection of this table shows that (a) the width of the distribution of ergodic times is relatively large ($\sigma_{erg} \cong 2$) and temperature independent, (b) the mean of the logarithm of the ergodic time is relatively small ($\overline{\log_{10} t_{erg}} \leqslant 2$) and decreases with increasing temperature, which is consistent with the observed tendency of the system to age less and thus to approach equilibrium faster as T increases, (c) the parameter x, which describes the structure of configuration space, increases with increasing temperature and approaches unity as $T \to T_g^-$, which is more consistent with Derrida's model[5] of random energy levels than with the Sherrington and Kirkpatrick model[6] of random exchange bonds, in agreement with the conclusions reached by Bouchaud and co-workers[2] for more canonical spin glass systems. For our particular choice of distribution, the mean ergodic time $\bar{t}_{erg}$ is given by $\bar{t}_{erg} = \int_0^{\infty} t_{erg} P(t_{erg}) dt_{erg} = \exp(\overline{\log_{10} t_{erg}} / \log_{10} e + \sigma_{erg}^2 / 2(\log_{10} e)^2) / \log_{10} e$, which yields values of $\bar{t}_{erg}$ ranging from $\bar{t}_{erg}$ (17 K)$\sim 8\times 10^6$ s to $\bar{t}_{erg}$ (21 K)$\sim 5\times 10^4$ s, once again comparable to those deduced in Ref. 2.

^{7}Li nuclear magnetic resonance (NMR) spectra and relaxation rates in $Ni_{1-x}Li_xO$, for $0.01 \leq x \leq 0.46$ and for $20 \leq T \leq 550$ K are presented. For $x \leq 0.2$ the antiferromagnetic (AF) phase typical of NiO is still observed. The Neel temperatures $T_N(x)$, the temperature dependence of the field at the Li site, and the role of the extra holes in driving the correlated spin dynamics of Ni^{2+} are derived. In particular, from ^{7}Li relaxation rates W the hopping frequencies of the holes on the AF background and the energy gaps between itinerant and localized states are extracted. In the mixed regime ($x \geq 0.3$, $LiNiO_2$ structure-type) in which partial ordering on alternate Li^+ and Ni^{3+} layers occurs, ^{7}Li NMR data display the features typical of disordered paramagnets, consistent with a picture of random distribution of Ni^{3+} ($S=1/2$), Ni^{2+} ($S=1$) and of spin vacancies Li^+ ($S=0$). In particular, for $x=0.46$, on cooling, a paramagnetic-like divergence of the width and of the shift of the NMR line is observed while ^{7}Li W's indicate slowing down of the spin fluctuations. The fluctuation frequency decreases in the MHz range below a freezing temperature $T_f \simeq 40$ K. © *1996 American Institute of Physics.* [S0021-8979(96)41408-6]

I. INTRODUCTION

Among the transition metal oxides (TMOs), the antiferromagnetic (AF) NiO and its charge-doped derivates $Ni_{1-x}Li_xO$ play a key role in the studies of the correlated $3d$ electron systems.[1,2] For NiO it seems possible to assess that the holes compensating the Li^+ impurity charge are of $O(2p)$ character, with strong AF exchange interaction with localized Ni^{2+} ($S=1$) d electrons. On the basis of general aspects of t-J models and by extending the findings in other TMOs, the holes are expected to itinerate, although the impurity potential due to Li^+ tends to bind them in localized states.[2] In strongly doped compounds, $x \geq 0.3$, a sizeable distortion of the pseudocubic cell occurs and Li and Ni ions partially order on alternate layers normal to the $\langle 111 \rangle$ directions. The stoichiometric $LiNiO_2$ (thermodynamically unstable), with well separated layers of Ni^{3+} $S=1/2$ on a triangular lattice, has been considered a model system for frustrated AF.[3]

In this article, we report some results of a study carried out in $Ni_{1-x}Li_xO$ by means of pulsed ^{7}Li NMR. The NMR spectra convey information on the magnetic field $|\mathbf{h}_{AF}|$ at the Lithium site and on the sublattice magnetization $\langle \mu \rangle_{Ni}$ (average along the local quantization axis). The ^{7}Li relaxation rates W, due to the time dependent transverse components of the fluctuating part of the field, yield the hopping frequencies of the holes, the energy gap between localized and itinerant states, as it has been shown in $Cu_{1-x}Li_xO$.[4] In the disordered magnetic systems ($0.25 \leq x \leq 0.46$) the relaxation rates probe the cooperative freezing of the magnetic moments. A characteristic spin-fluctuation frequency is measured, leading to the activation energy E_{eff} and to the freezing temperature T_f below which a spin-glass-like phase is present.

II. EXPERIMENTAL RESULTS

The compounds have been prepared by the reactive system NiO/Li_2CO_3 heated up to 800 °C and annealed in alumina.[5] X-ray diffraction indicates a lattice parameter of the pseudo-cubic cell which decreases almost linearly with x, up to $x \simeq 0.2$. For $x \geq 0.3$ the quasi-cubic structure is lost and the expected sequence of Li and Ni layers with intercalated close packed oxygen layers is observed. Standard NMR techniques have been used for ^{7}Li spectra and to measure the relaxation times T_1 from the echo signals.[4] In the AF phases, the shape of the ^{7}Li line is controlled by the powder distribution of the field at the Li site of dipolar origin. The line width is $2\gamma |\mathbf{h}_{AF}|$, thus yielding the temperature dependence of the AF field (see Fig. 1). The transferred hyperfine field $\Sigma_i A \langle \mathbf{S}^{(i)} \rangle$ causes a shift K. In nominally $LiNiO_2$, the hyperfine field A has been estimated to be equal 350 G/μ_B.[6] It should be stressed that for AF cubic symmetry of Ni^{2+} ions around the reference ^{7}Li nucleus, one has $h_{AF}=0$ and $K=0$.

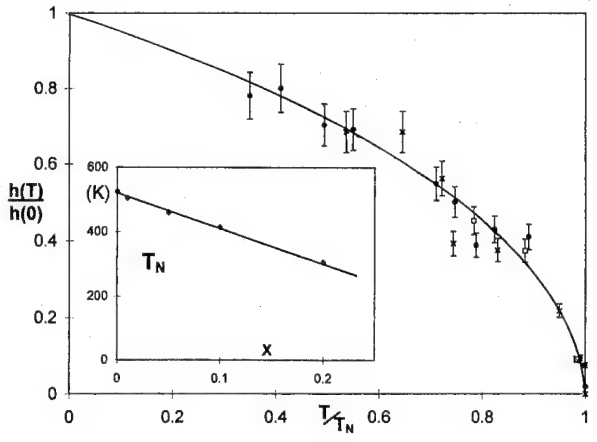

FIG. 1. Temperature dependence of the AF field $|h_{AF}|$ at the Li site for $x=0.05$(□), $x=0.1$(●), and $x=0.2$(X). The solid line shows the best fit behavior according to the MFA law $h_{AF} \propto (T_N - T)^{\beta}$, with $\beta=0.5$. It is noted that the extrapolated value of the field $h_{AF}(T \to 0)$ equals 800 G for $x=0.05$ and 1400 G for $x=0.1$. In the inset the Neel temperatures $T_N(x)$, as obtained from the extrapolation of the line width and from the concurrent peaks in the relaxation rate (see text) are shown.

 0021-8979/96/79(8)/6621/3/$10.00

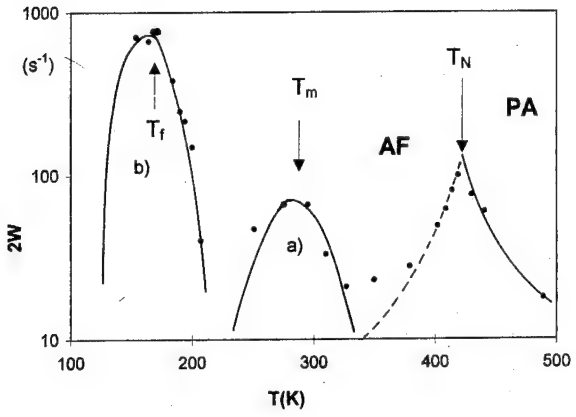

FIG. 2. ^{7}Li relaxation rate as a function of temperature in $Ni_{0.9}Li_{0.1}O$. The Neel temperature (Fig. 1) is shown. The curve (a) is the theoretical behavior for the contribution due to hole diffusion [Eq. (2) in the text] and it corresponds to $E_g \simeq 3000$ K and $\tau_0 \simeq 2\times10^{-13}$ s rad^{-1}. Curve (b) shows the behavior expected from the freezing of the spin fluctuations for localized magnetic moments superimposed to the AF matrix. The dotted line below T_N is the sketchy behavior of W from two-magnons relaxation in conventional AFs (approximately of the form $W \propto T^3$).

The static and the dynamical effects of the quadrupole interaction on the ^{7}Li Zeeman levels can be neglected[4] and the relaxation process is driven by the time dependent part of the electron nucleus Hamiltonian. One has

$$\frac{1}{T_1} = 2W = \frac{\gamma^2}{2} \int \langle h_+(0) h_-(t) \rangle \exp[-i\omega_L t] dt, \qquad (1)$$

where $h_\pm$ are the transverse components of the effective field $\mathbf{h}(t)$ at the Li site. The time dependence of $\mathbf{h}$ is due either to the diffusion of the extra hole that locally destroys the AF order or to the fluctuations of localized magnetic moments (e.g., Ni^{3+}) anomalous with respect to the AF matrix.[4] The typical behavior of the ^{7}Li relaxation rate observed for $x \leqslant 0.2$, is shown in Fig. 2. The behavior of W in quasistoichiometric $LiNiO_2$ ($x=0.46$) (Fig. 3) is analogous to the one in disordered magnets, with the progressive increase of W on cooling, indicating freezing of spin fluctuations.

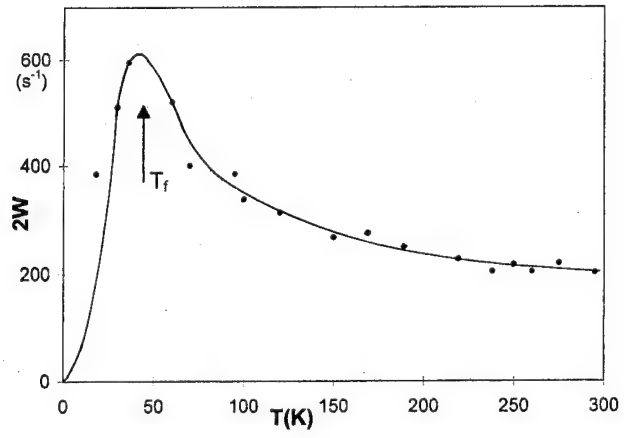

FIG. 3. ^{7}Li $2W$ in $Li_{0.92}Ni_{1.08}O_2$ (the sample closest to the fully stoichiometric $LiNiO_2$). The solid line corresponds to the best fit of the data according to a law of the form $2W \propto \Gamma_{SF}/(\Gamma_{SF}^2+\omega_L^2)$, for $\Gamma_{SF}=\Gamma_0 \exp[-E_{eff}/T]$, with $E_{eff}=84$ K and $\Gamma_0 \simeq 10^9$ rad s^{-1}. $\omega_L=\gamma H_0$, with $H_0=1.1$ T.

III. ANALYSIS OF THE RESULTS AND SUMMARIZING REMARKS

For $x \leqslant 0.2$ the Neel temperature decreases (Fig. 1), with initial suppression rate $B=-[T_N(0)]^{-1}(dT_N(x)/dx)$ around $B \simeq 2.2$. This value is about two times larger than the one in Mg-doped NiO.[7] The difference is likely to be due to the fact that while for Mg the spin vacancy is localized, the somewhat equivalent magnetic polaron associated to the extra hole is itinerant in Li-doped NiO. It is noted that in both cases one has a practically linear decrease of T_N on increasing x, for $x \leqslant 0.2$. The onset of the order parameter, the sublattice magnetization $\langle \mu \rangle_{Ni}$ to which h_{AF} is proportional, is qualitatively consistent with a critical exponent $\beta=0.5$. The absolute value of h_{AF} for $T \to 0$ is x dependent, since breaking of the AF symmetry is required to have $h_{AF} \neq 0$ (see caption to Fig. 1).

The behavior of ^{7}Li W (Fig. 2) for $T \geqslant T_N$ can be justified by considering that the AF symmetry of the critical fluctuations is broken by one or more Li^+-induced spin vacancy. Thus transverse components $h_\pm$ [see Eq. (1)] are generated and instead of an antidivergence of W, as detected for AF symmetry,[8] on has W diverging for $T \to T_N^+$. The absolute value of W is consistent with the slowing down of dipolar field fluctuations driven by the exchange Heisenberg frequency $\omega_{exch}=[J^2 8zS(S+1)/3]^{1/2}/\hbar$, by using for the exchange constants the values $J_1=-34$ K (for the nearest neighbors, $z=12$) and $J_2=202$ K for the next nearest neighbors.[9]

In the AF phase [region (a) in Fig. 2], instead of the two-magnons relaxation mechanism, a contribution to W approximately of the form

$$W = \gamma^2 C^2 x \frac{\tau_h}{1+\omega_D^2 \tau_h^2}. \qquad (2)$$

and due to the diffusion of the holes,[4] is detected. C is of the order of the dipolar field induced at the Li site when the hole locally anneals the AF spin configuration. τ_h is the mean time interval between consecutive passages of the holes and it is written $\tau_h=\tau_0/n_h$, $n_h=x \exp[-E_g/T]$ being the fraction of the mobile holes, with E_g gap between itinerant and localized states.

At lower temperatures [region (b) in Fig. 2] the hole is localized and a relaxation driven by the spin fluctuations of extra magnetic moments (Ni^{3+} and the related spin texture in the AF background) occurs. One can write $W=D\Gamma_{SF}/(\Gamma_{SF}^2+\omega_L^2)$ where D is a constant depending on the hole concentration and on the dipolar field and Γ_{SF} a characteristic spin fluctuation frequency.

From the analysis of the results along the lines outlined above, one can extract quantitative information, that we summarize in the following. From W in the region (a) of Fig. 2 one derives $E_g \simeq 4000$ K for $x=0.05$ (results not reported) and $E_g=3000$ K for $x=0.1$. $T_m=285$ K corresponds to the temperature at which the hopping frequency τ_h^{-1} is about $\omega_L=18$ MHz (2π) and can be considered as freezing temperature for charge fluctuations. The values for E_g are close to the ones estimated for the hopping of the polarons from

resistivity and/or dielectric data.[10] While for isolated polarons the barrier is almost 1 eV, it decreases with increasing x.

For $T \ll T_m$ the extra magnetic moments related to Ni^{3+} ions act like magnetic impurities in driving a strong relaxation mechanism. One can extract the barrier for the cooperative freezing: $E_A \simeq 100$ K for $x=0.01$ and $E_A \simeq 300$ K for $x=0.05$ (results not reported). It should be remarked that the divergence of the relaxation rate appears to shift towards higher temperatures on increasing the magnetic field. Thus the increase of T_1^{-1} in the region *b*) of Fig. 2 is likely to reflect a field-induced paramagnetic-like behavior in the Ni^{2+} AF with random Ni^{3+} ions.

In mixed systems ($0.3 \leqslant x \leqslant 0.5$) the relaxation process is a complicated one, in view of nonequivalent Li sites and of the disordered character of the planes with Ni^{2+} and Ni^{3+} ions.[3] ^{7}Li W's indicate relaxation mechanism and spin dynamics similar to the ones in spin glass and/or superparamagnetic domains systems. The results are rather well fitted by a temperature activated effective frequency, with barrier $E_{\text{eff}}=84$ K, implying spin fluctuation frequencies in the MHz range below $T_f \simeq 40$ K. Consistency with the occurrence of a frozen spin state, as inferred from neutron diffuse scattering,[11] is thus found.

Susceptibility and ^{89}Y nuclear magnetic resonance in $Y_{1-x}Ca_xVO_3$

INFM-Department of Physics "A. Volta" and Sezione INFN, University of Pavia, I-27100 Pavia, Italy

P. Ghigna
Department of Chemical Physics, University of Pavia, I-27100 Pavia, Italy

A. Lascialfari
Department of Chemistry, University of Firenze, I-50144 Firenze, Italy

Temperature-dependent (10–300 K) field-cooled (FC) and zero-field-cooled (ZFC) susceptibilities, and ^{89}Y NMR spectra and relaxation in $Y_{1-x}Ca_xVO_3$ with $0 \leqslant x \leqslant 0.9$ are reported. In the paramagnetic phase (PA) of YVO_3 and for $T \geqslant 120$ K the susceptibility χ is of antiferromagnetic (AF) type, with no field dependence. Around the Neel temperature $T_N^{(1)} = 113 \pm 1$ K a field-dependent ferromagnetic behavior is observed under FC condition. Below $T_N^{(2)} \simeq 77$ K (AF phase with AF interplane coupling) strong difference is present between FC and ZFC χ's. For $T \rightarrow T_N^{(1)+}$ the ^{89}Y NMR line shows marked broadening and no measurable shift, consistent with a dominant dipolar contribution in the nucleus–electrons interaction. The ^{89}Y relaxation rate T_1^{-1}, related to the correlated spin dynamics of V^{3+} $\mathbf{S}(t)$, seems to indicate that the interplane ferromagnetic symmetry of the spin fluctuations is quenched in strong fields. The peculiar findings for χ and T_1 could result from a field-dependent weak ferromagnetism of Dzyaloshinsky–Moriya character. In $Y_{1-x}Ca_xVO_3$, χ and T_1^{-1} decrease on increasing x, still preserving the qualitative behavior as for $x=0$. For $x \simeq 0.6$ (Ca concentration which drives the transition to the metallic phase) the marks of the PA–AF transition are practically suppressed and behaviors characteristic of correlated metals are observed.
 [S0021-8979(96)00708-9]

I. INTRODUCTION

The magnetic properties of highly correlated d-electron systems are presently of great interest, high-temperature superconductivity having recalled attention towards the insulator-metal (IM) transitions driven by carrier doping. YVO_3 is a typical Mott–Hubbard antiferromagnetic (AF) insulator, with $V^{3+} 3d^2 S=1$ magnetic ions. As recently observed by neutron scattering,[1] YVO_3 undergoes a second-order phase transition ($T_N^{(1)} \simeq 114$ K) to an AF phase, with intraplane AF order and interplane ferromagnetic (FE) order (C type). A first-order phase transition at $T_N^{(2)} \simeq 77$ K leads the system to a G-type phase, with AF order also among planes. Y^{3+} ions can be substituted by Ca^{2+} and for $x \rightarrow 1$ in $Y_{1-x}Ca_xVO_3$ the nominal valence of vanadium is $4^+(3d^1)$. Resistivity measurements and optical spectra[2] have shown that, for $x_C \simeq 0.5$, a hole-doped-induced IM transition occurs.

In this article the main results of a study carried out by means of magnetic susceptibility χ and ^{89}Y NMR and T_1 relaxation measurements are presented. χ has been studied from $x=0$ up to $x=0.9$, under field-cooled (FC) and zero-field-cooled (ZFC) conditions. As regards NMR, ^{51}V spectra in the AF phase of YVO_3 have been reported, while for $x<0.6$ ^{51}V Knight shift and T_1 support the picture of a metallic phase.[3] A ^{51}V NMR study has been carried out in $La_{1-x}Sr_xVO_3$.[4] No ^{89}Y NMR investigations seem to have been performed. ^{89}Y is an attractive probe to study magnetic properties and the correlated V^{3+} spin dynamics: the absence of quadrupole interaction ($I=1/2$) and the lattice position makes this nucleus sensitive to the symmetry of the interplane spin correlations and to the wave vector of the critical fluctuations.

II. EXPERIMENTAL RESULTS AND DISCUSSION

The samples were prepared by heating at 1200 °C in Ar–H atmosphere the stoichiometric mixture of Y_2O_3, V_2O_5, and $CaCO_3$. X-ray diffraction indicated single phase samples over all the composition range. At $T \simeq 300$ K the resistivity was observed to decrease from 6×10^3 Ω cm in YVO_3 to about 2×10^{-3} Ω cm for $x \simeq 0.6$, in agreement with previous results.[2] The dc magnetic measurements were made with a superconducting quantum interference device (SQUID).

In pure YVO_3 [see Fig. 1(a)], from the peak in the ZFC χ in $H=0.1$ T one derives $T_N^{(1)} = 113 \pm 1$ K, in agreement with the estimate from Y NMR in a field of 5.9 T (see below). The FC susceptibility around T_N in a field of 0.1 T is about three times larger than in 0.5 T, an indication of anomalous saturation or of field-induced diamagnetic contribution causing an apparent decrease of the paramagnetic χ. Figure 1(b) shows how the FC temperature behavior of χ for $H=0.5$ T in $Y_{1-x}Ca_xVO_3$ changes in crossing the IM transition. For $x=0.6$ the ferromagneticlike term around $T_N^{(1)}$ is almost suppressed. Below $T \simeq 50$ K Curie-like terms seem present, possibly due to isolated magnetic defects, or double-exchange (V^{3+}–V^{4+}) effects.[5] For $x=0.9$ and high temperatures one derives a Pauli-like susceptibility $\chi_P \simeq 2.5 \times 10^{-3}$ cm^3/mol, larger than $\chi_P \simeq 1 \times 10^{-3}$ cm^3/mol for $x=0.6$, indicating a possible presence oxygen deficiencies. $CaVO_3$, in fact, was shown to become insulating by annealing the sample in air.[6]

The ^{89}Y NMR relaxation rates ($H_0=5.9$ T, Fig. 2) are related to the time dependence of the hyperfine field $\mathbf{h}(t)$ at the Y site:

$$T_1^{-1} = \tfrac{1}{4}\gamma^2 [J_+(\omega_L) + J_-(\omega_L)], \tag{1}$$

 0021-8979/96/79(8)/6624/3/$10.00

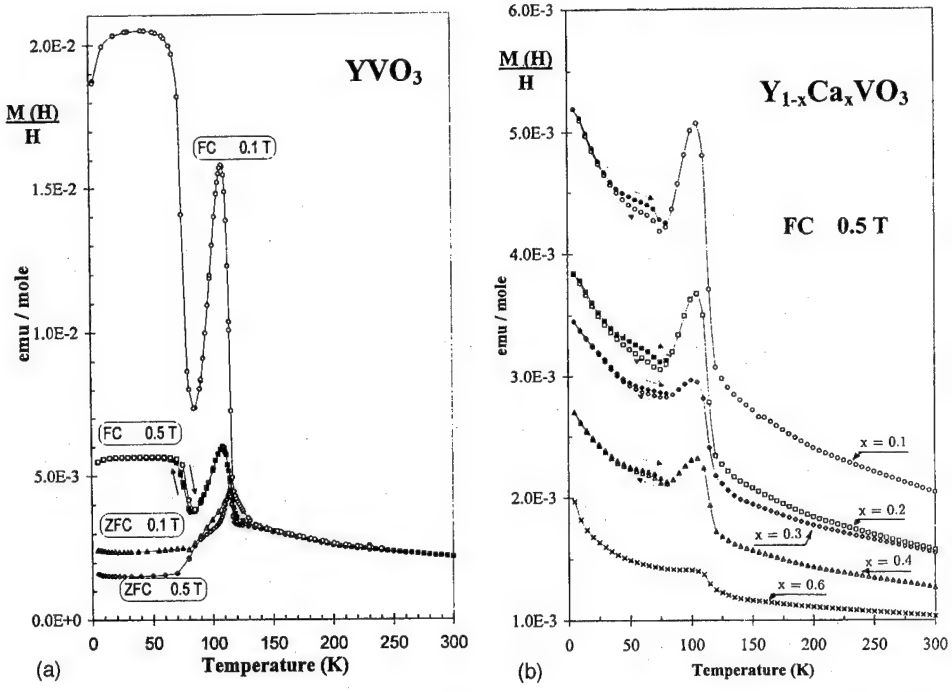

FIG. 1. (a) Field-dependent susceptibility in YVO_3 as a function of temperature. The arrows evidence the thermal hysteresis observed below the transition temperature $T_N^{(2)} \simeq 77$ K, in the AF–AF phase (see text). The divergence for FC in 0.1 T is qualitatively of the form predicted for Dzyaloshinsky–Moriya interaction.[8] (b) FC magnetic moment, in $H=0.5$ T, as a function of temperature in $Y_{1-x}Ca_xVO_3$ for $x=0.1$ (○ and ●), $x=0.2$ (□ and ■), $x=0.3$ (◇ and ◆), $x=0.4$ (△ and ▲), and $x=0.6$ (x) [where no thermal hysteresis was observed]. For $x \leqslant 0.4$ differences between the values at $H_0=0.1$ and 0.5 T similar to the ones in pure YVO_3 are observed.

where $J_\alpha = \int \langle h_\alpha(0) h_\alpha^*(t) \rangle e^{-i\omega t} dt$ $(\alpha = x \pm iy, z)$ are the spectral densities while

$$\mathbf{h} = \sum -A_i \mathbf{S}_i + B_i (\mathbf{r}_i \cdot \mathbf{S}_i) \mathbf{r}_i , \tag{2}$$

where $A_i = \gamma_e \hbar / d_i^3 + C/\gamma$ and $B_i = 3\gamma_e \hbar / d_i^5$. C is the transferred scalar interaction and d_i the distance of the Y nucleus from the i-th V ion. On approaching $T_N^{(1)}$ a marked increase in the linewidth is observed. The lack of measurable shift implies that C in Eq. (2) is negligible, the dipolar terms A and B in powdered samples practically causing a broadening proportional to $\langle S \rangle = \chi_A H_0$ and thus tracking the atomic susceptibility. For $x \leqslant 0.5$, the temperature behavior of T_1^{-1} is similar to the one for $x=0$, with decrease of the peak around $T_N^{(1)}$.

The peculiar magnetic properties pointed out in rare-earth (RE) vanadates,[4,7] are evidenced for YVO_3 in the data for χ [see Fig. 1(a)]. While for $T \geqslant 130$ K one has a Curie–Weiss field-independent susceptibility, below T_N χ depends on the cooling conditions in a way similar to the one in $LaVO_3$,[4,7] attributed to canted spin configuration and/or ferromagnetism. An effect characteristic of YVO_3 is the ferromagnetic-type FC divergence for $T \simeq T_N^{(1)}$, possibly due to a Dzyaloshinsky–Moriya interaction $D \cdot \mathbf{S}_i \times \mathbf{S}_j$. In this case, in fact, the susceptibility in a polycrystalline sample, namely $\chi = (2/3)\chi_\perp + (1/3)\chi_\parallel$, near T_N deviates from the Curie–Weiss law. The susceptibility perpendicular to the easy axis displays a divergence of the form[8] $\chi_\perp \propto (T - T_O)/(T - T_N)$ with $T_O = JzS(S+1)/3K_B$, J exchange coupling constant and z number of nearest neighbors. T_N becomes $T_N = T_O[1 + (D/J)^2]^{1/2}$. T_N is slightly affected by charge doping, up to $x=0.4$ (where T_N is around 100 K). In the metallic phase the Pauli-like part of χ is almost an order of magnitude larger than in other vanadates and for or $x=0.9$, in particular, it appears field dependent. An interpretation of these peculiarities has to be delayed after a complete phase diagram for samples close to $CaVO_3$ is available.

The ^{89}Y relaxation rates [see Eq. (1)] can be related to the correlated spin dynamics through the collective spin components $\mathbf{S_q}$ and the decay rate $\Gamma_\mathbf{q}$ of the normal excitations. For localized moments and for fast spin fluctuations ($\Gamma_\mathbf{q} \gg \gamma H_0$) one can write

$$T_1^{-1} = \gamma^2 \sum_\mathbf{q} H_q^2 |S_q|^2 / \Gamma_\mathbf{q} , \tag{3}$$

where H_q^2 results from the Fourier transform of the factors A and B in Eq. (2).

For $T \gg T_N$ the correlation functions are q-independent and Eq. (3) can be written $T_1^{-1} \simeq \frac{1}{2} n \gamma^2 h_e^2 / \omega_{\text{exch}}$, where $h_e^2 = (h_x^2 + h_y^2)$ comes from the dipolar field at the Y site, $n=8$ is the number of $n.n.$ ions (for which a common distance $d \simeq 3.3$ Å will be assumed), and ω_{exch} is the exchange frequency. For $h_e \simeq 3 \times 10^3$ G (for $\mu = 1.6\ \mu_B$)[1] and $\omega_{\text{exch}} = [\frac{3}{2} zS(S+1)]^{\frac{1}{2}} K_B T_N / \hbar \simeq 6 \times 10^{12}$ rad s^{-1}, one obtains $T_1^{-1} \simeq 12$ s^{-1}. The experimental data at $T \simeq 300$ K is likely to reflect a certain degree of AF correlation, which is expected to decrease the relaxation rate. In fact, to analyze T_1^{-1} vs T the complete q-dependence should be used. In particular, $H_\mathbf{q}^2$ strongly depends on the symmetry of the critical fluctuations. Here we only emphasize the following. For symmetry corresponding to the AF–AF phase one would have $H_{\text{AF-AF}}^2 = 0$

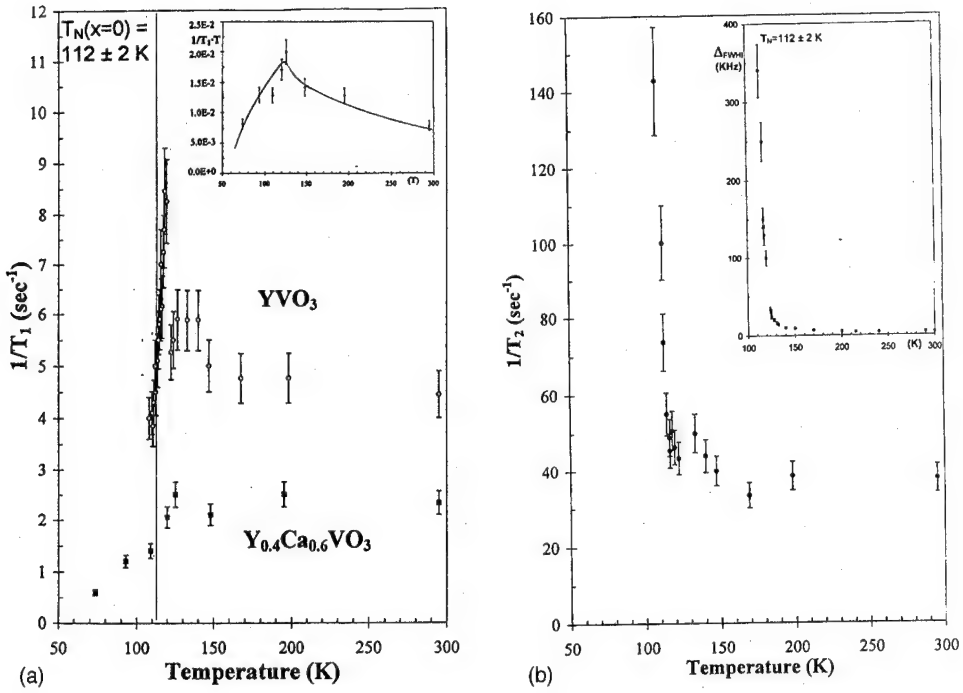

FIG. 2. (a) ^{89}Y NMR relaxation rate T_1^{-1} as a function of temperature, in YVO_3 (○) and in $Y_{0.4}Ca_{0.6}VO_3$ (■), in H_0=5.9 T. In the inset the temperature behavior of $(T_1T)^{-1}$ for x=0.6 is reported, with the solid line as a guide for the eye. (b) ^{89}Y spin–spin relaxation rate, from the decay of the echo signal, as a function of temperature in pure YVO_3. The decay of the echo amplitude is described by a Gaussian law for $T \geq 150$ K, while it turns to a Lorentzian form for temperature around $T_N^{(1)}$. In the inset the width Δ of the ^{89}Y NMR line, in the paramagnetic phase, is shown. No temperature-dependent shift is detected.

and on approaching $T_N^{(1)+}$ from above the relaxation rate would decrease.[9] On the contrary, in correspondence to the interplane FE symmetry $H^2_{\text{AF–FE}}$ in Eq. (3) is different from zero and one should observe a divergent behavior of T_1^{-1} around T_N. The lack of a marked divergence in T_1^{-1} indicates that a strong field quenches the ferromagnetic correlations in the spin fluctuations that is somewhat consistent with the finding for χ in 0.5 [see Fig. 1(a)]. In the ordered phase, for AF–FE configuration, from a lattice sum of the dipolar terms the field at the Y site is evaluated in the form $\mathbf{h}_{\text{AF–FE}} = 1.9S_x - 1.6S_y - 0.23S_z$ (kG/μ_B), S_α being the components of a given V^{3+} spin with respect to the crystalline axes. The random orientation of $\mathbf{h}_{\text{AF–FE}}$ with respect to $\mathbf{H}_0$ causes broadening of the ^{89}Y NMR line over more than one MHz. The experimental detection of such a broadening (results not reported) confirms that the intermediate phase is of C type.

In $Y_{0.4}Ca_{0.6}VO_3$, just above the carrier concentration driving the IM transition, T_1^{-1} is practically constant down to 130 K and then it decreases. In free-electron metals one should have $T_1^{-1} \propto \chi_P^2 T \propto \rho^2(E_F)T$ [$\rho(E_F)$ density of states at Fermi level] and absolute value decreased with respect to the one for localized spins. These conditions are not verified for x=0.6: the Korringa relation is not obeyed and $(T_1T)^{-1}$ shows a maximum at $T^* \simeq 130$ K [see inset in Fig. 2(a)]. These findings indicate strong magnetic correlations among carriers, a situation reminiscent of the one in superconducting cuprates,[10] where T^* is often considered the mark of a spin pseudo-gap opening. In the sample at x=0.9, ^{89}Y T_1^{-1} has been found to decrease and, according to the ^{51}V NMR data,[3] the Korringa relation is obeyed. However, the role of the oxygen stoichiometry for $x \simeq 1$ has to be clarified.

By summarizing, our susceptibility measurements point out peculiar magnetic properties of yttrium vanadates. In particular, a divergence (of ferromagnetic type) in FC χ is observed around T_N, possibly due to Dzyaloshinsky–Moriya interaction. The divergence is suppressed by increasing the field. ^{89}Y NMR yields valuable information on the AF's fields and on the symmetry of the critical fluctuations. Again, an effect of the external field in quenching the spin fluctuations of FE symmetry appears to occur. In $Y_{1-x}Ca_xVO_3$ for x=0.6, in the metallic state, both susceptibility and T_1 measurements indicate the persistence of strong magnetic correlations among carriers.

Spin glass behavior of amorphous $Fe_5(InTe_4)_3$

Jian H. Zhang, Damon Williams, and Cuihong Tao
Department of Chemistry, Xavier University of Louisiana, New Orleans, Louisiana 70125

Charles J. O'Connor
Department of Chemistry, University of New Orleans, New Orleans, Louisiana 70148

The amorphous phases of $Cr_5(InTe_4)_3$ and $Fe_5(InTe_4)_3$ have been prepared via the precipitation reaction of the Zintl polyanion $InTe_4^{-5}$ with Cr^{3+} and Fe^{3+} in aqueous solution, respectively. Their magnetic and conducting properties have been examined as a function of temperature. The high-temperature susceptibility of $Cr_5(InTe_4)_3$ follows the Curie–Weiss law with $\theta = -30.2$ K and $C = 1.65$ emu/mole Cr atom. $Cr_5(InTe_4)_3$ has a conductivity of $1.07\times10^{-3}\ \Omega^{-1}\ cm^{-1}$ at 300 K and is a semiconductor with $Ea = 0.20$ eV. $Fe_5(InTe_4)_3$ exhibits relatively high conductivity due to partial delocalization of electrons. Its conductivity is $7.41\ \Omega^{-1}\ cm^{-1}$ at 300 K, and shows little temperature dependence. $Fe_5(InTe_4)_3$ obeys the Curie–Weiss law at high temperatures with $\theta = -26.3$ K and $C = 1.60$ emu/mole Fe atom, and undergoes a transition to a spin glass state at 6.0 K. The spin glass state has been characterized by an analysis of the field and temperature dependence of the thermal remanent magnetization and isothermal remanent magnetization. The hysteresis loops measured at 2.0 K under field-cooling and zero-field-cooling conditions reveal the presence of a small unidirectional exchange interaction. © *1996 American Institute of Physics.*

I. INTRODUCTION

In previous communications, we described the synthesis and characterization of a series of ternary metal chalcogens of the formula $M_5(InTe_4)_2$, where M is a transition metal.[1,2] The preparation of the ternary metal chalcogens involves a metathesis reaction between a Zintl phase material (K_5InTe_4) and a divalent transition metal chloride. The Zintl phase of matter can be described as a polar metallic alloy in which the bonds have a substantial amount of ionic character due to the large difference in electronegativity of the metals or metalloids. The ionic character of the Zintl phase, i.e., K_5InTe_4 in this case, allows for the solvation of saltlike ions ($InTe_4^{-5}$) in polar solvents such as water. In the presence of a metal cation of sufficient electron affinity, an insoluble intermetallic solid forms due to the transfer of electrons from the active polyanion ($InTe_4^{-5}$) to the transition metal. The rapid precipitation between the polyanion and the transition metal often results in an amorphous product.

These ternary metal chalcogens display a variety of interesting magnetic and electronic conducting properties. For instance, $Fe_5(InTe_4)_2$ undergoes double magnetic transitions: a transition from paramagnetic to weak ferromagnetic at 32 K, and a second transition to a spin glass state at 13 K.[1] It was also observed that the magnetic and conducting properties in this series of intermetallic materials are correlated with the ability of the precursor transition metal cations to be reduced by the Zintl polyanion.[2] To continue the search for the novel magnetic materials, we have extended our study to include trivalent transition metals and rare-earth metals. In this paper, we report the synthesis of two new amorphous phases, $Fe_5(InTe_4)_3$ and $Cr_5(InTe_4)_3$, and a study of their electronic conducting and magnetic propertied, in particular, the spin glass behavior in $Fe_5(InTe_4)_3$ through measurements of ac and dc susceptibility and time-dependent magnetization effects.

II. EXPERIMENTAL DETAILS

The Zintl phase material, K_5InTe_4, was prepared using a solid-state reaction and purified in an argon filled glovebox as described previously.[1] $Cr_5(InTe_4)_3$ and $Fe_5(InTe_4)_3$ were prepared by the reaction of K_5InTe_4 with $FeCl_3$ and $CrCl_3$ in degassed water at ambient temperature. In a typical preparation, a 30 mL solution of 0.05 M K_5InTe_4 was slowly added to a 25 mL solution of 0.1 M $FeCl_3$ or $CrCl_3$ while stirring. A fine black precipitate was immediately formed, separated by suction filtration, washed with water and acetone, and dried under vacuum. The product was recovered with percent yield greater than 95%. Both solids are amorphous in structure as confirmed by their x-ray diffraction (XRD) patterns obtained with a XDS 2000 Scintag diffractometer.

Resistivity was measured on pressed pellets over the temperature range 100–300 K using the four-probe van der Pauw technique.[3] Magnetic measurements were performed on a Quantum Design MPMS-5S SQUID susceptometer. The temperature dependence of the dc susceptibility (M/H) was measured at a fixed field of 1 kG using the temperature cycling, following the usual zero-field cooling (ZFC) and field-cooling (FC) procedures. For $Fe_5(InTe_4)_3$, the thermal remanent magnetization (TRM), isothermal remanent magnetization (IRM), and hysteresis loop were measured. In the TRM measurement, the specimen was cooled in an applied magnetic field to temperatures below the spin glass freezing temperature, then the field was switched off, and the remanent magnetization was measured. In the IRM measurement on the other hand, the specimen was cooled in a zero field to temperatures below the spin glass freezing temperature, exposed to an applied field for a certain time, and then the applied field was quenched and the remanent magnetization was measured.

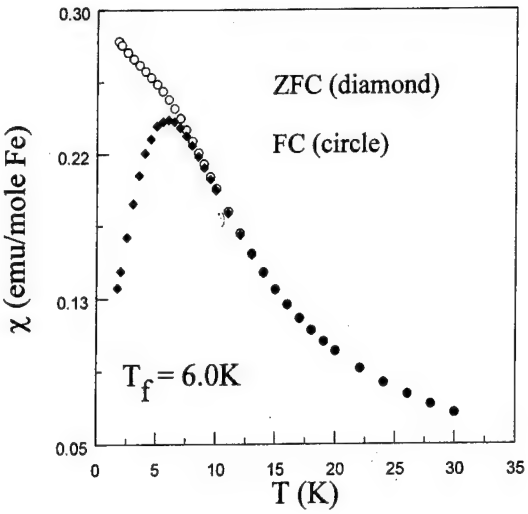

FIG. 2. The temperature dependence of dc susceptibilities as measured at 1.0 kG for $Fe_5(InTe_4)_3$.

III. RESULTS AND DISCUSSION

The conductivity (σ) for $Fe_5(InTe_4)_3$ is only slightly affected by temperature and, for example, σ is 7.41 Ω^{-1} cm^{-1} at 300 K and 2.92 Ω^{-1} cm^{-1} at 100 K. For $Cr_5(InTe_4)_3$, σ is 1.07×10^{-3} Ω^{-1} cm^{-1} at 300 K and highly temperature dependent. A least-squares fit of the linear portion in a plot of $\log\sigma$ vs $1/T$ to the relationship $\sigma = C\exp(-Ea/k_BT)$, where σ is specific conductivity, gives an activation energy (Ea) of 0.20 eV.

The high-temperature magnetic data indicate that both $Cr_5(InTe_4)_3$ and $Fe_5(InTe_4)_3$ exhibit strong antiferromagnetic interactions. A Curie–Weiss fit of the susceptibilities above 100 K for $Cr_5(InTe_4)_3$ gives $\theta = -30.2$ K and $C = 1.65$ emu K/mole Cr atom. A Curie–Weiss fit of the susceptibilities above 200 K for $Fe_5(InTe_4)_3$ gives $\theta = -46.3$ K and $C = 1.60$ emu K/mole Fe atom. The effective moment at room temperature is $3.64\mu_B$/Cr, that is, close to the spin-only value of $3.87\mu_B$ for Cr^{3+}. Thus, the electrons are completely localized in $Cr_5(InTe_4)_3$. The effective moment at room temperature is $3.57\mu_B$/Fe significantly lower than the spin-only value of $5.92\mu_B$ for Fe^{3+}, indicating some degree of electron delocalization. This is consistent with its relatively high conductivity.

The susceptibility of $Fe_5(InTe_4)_3$ deviates gradually from the Curie–Weiss law with decreasing temperature due to the development of ferromagnetic correlations between the dominant antiferromagnetic clusters. As a result, the susceptibilities between 10 and 100 K are well fit to the Curie law. The competition between ferromagnetic and antiferromagnetic interactions ultimately gives rise to a spin glass state in $Fe_5(InTe_4)_2$ at low temperatures. Figure 1 shows both in-phase and out-of-phase components of ac susceptibility of $Fe_5(InTe_4)_2$ measured at 25 Hz and zero magnetic field. Usually, a sharp cusp at a well-defined temperature called the freezing temperature T_f is observed in ac susceptibility curve of the classic spin glasses, i.e., the first row transition metals in the noble metal hosts.[4] In our case, a round peak was observed. The reason for the difference might be that the disorder in classic spin glasses is produced only by random occupation of crystal sites by transition metal impurities, and thus the RKKY interaction among the magnetic impurities is solely responsible for the frustration necessary for a spin glass to exist. However, the source of the frustration in the amorphous phase under study is likely due to a combination of bond disorder and topological disorder. The extrapolation around the spin glass transition gives T_f of 6.0 K. From the dc susceptibility shown in Fig. 2, it is seen that the ZFC curve with a maxima at 6.0 K is almost identical to the ac susceptibility curve. The FC susceptibility does not reach a plateau below T_f as seen for many spin glass systems,[4] but instead continue to increase with decreasing temperature. In addition, the FC and ZFC susceptibility curves merge at a temperature higher than T_f. These may imply the occurrence of the significant ferromagnetic component in the solid.

Among the most diagnostic experiments for the characterization of a spin glass state is the analysis of the field dependence of the IRM and TRM. The field dependence of both TRM and IRM measured at 2.0 K is illustrated in Fig. 3. The hump at 5.0 kG in the TRM curve is characteristic of a spin glass state and has been observed in many systems.[4] This TRM maximum is time dependent, and may be explained by the cluster model. According to the cluster model, the spins are correlated into "magnetic clusters" of different size at temperatures well above the freezing temperature, and then, the freezing process can be thought of as resulting from a distribution of temperatures at which the different magnetic clusters are no longer able to overcome an energy barrier and are therefore blocked. Aharoni and Wohlfarth[5] have successfully interpreted the anomalous TRM maximum using the physical idea of a blocking process in effective magnetic clusters in the cluster model along with a time delay inherent in the measurement. The cluster model also explains the occurrence of a round peak in the ac curve instead of a sharp cusp. Since a rather sharp cusp is predicted only if all the clusters have the same blocking temperature. A distribution

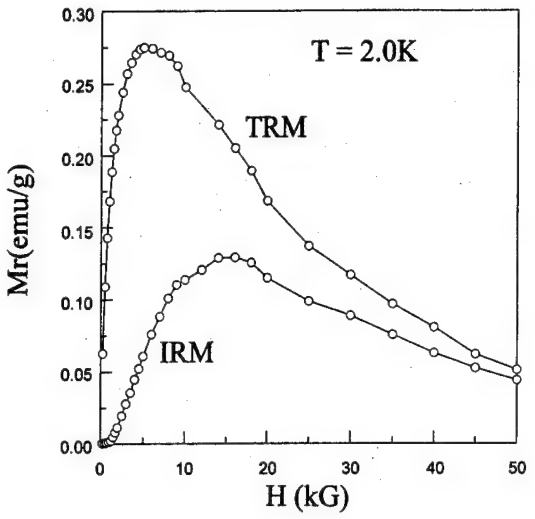

FIG. 3. The field dependence of the remanent magnetizations for $Fe_5(InTe_4)_3$. The solid lines are guides to the eye.

of blocking temperatures results from the distribution of particle size; thus smooths out the sharp cusp.[6]

For a spin glass state at weak fields, the TRM measurements give large remanence relative to the IRM, while at strong fields the TRM and IRM converge to the same saturation remanence as seen in Fig. 3. The effect seen for the TRM is greatly enhanced by performing the experiment at lower temperatures, whereas the IRM is little affected by the temperature as shown in Fig. 4. The TRM and IRM curves merge at a temperature higher than T_f. The remanence and irreversible behavior of a spin glass can also be seen in its

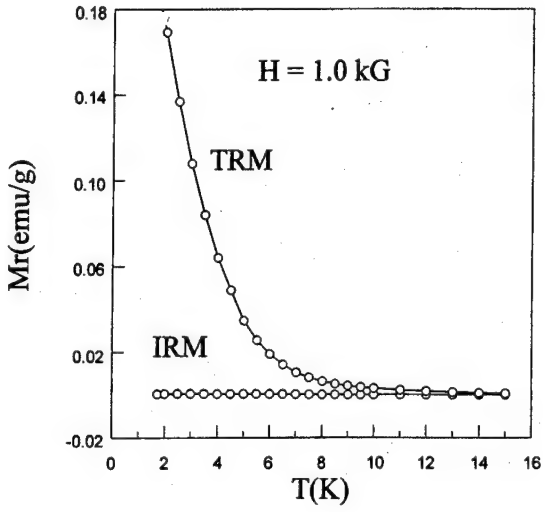

FIG. 4. The temperature dependence of the remanent magnetizations for $Fe_5(InTe_4)_3$. The solid lines are guides to the eye.

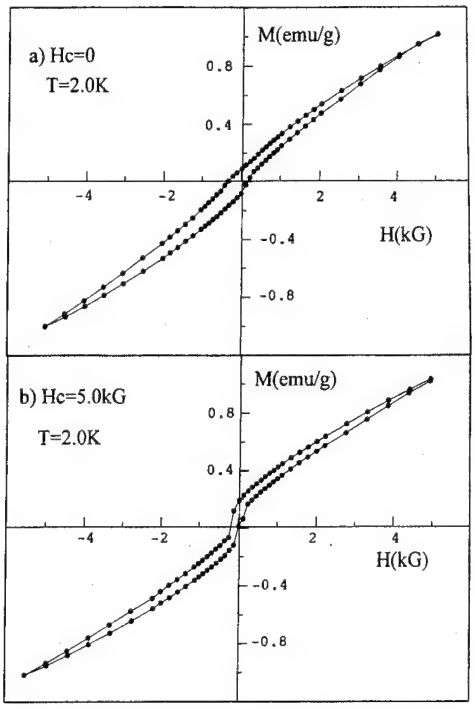

FIG. 5. Hysteresis loops of $Fe_5(InTe_4)_3$ as cooled to 2.0 K (a) at a zero field and (b) at a field of 5.0 kG.

hysteresis loop below the freezing point. Figure 5 shows the hysteresis loops of magnetization between ±5.0 kG obtained after zero field cooling and field cooling to 2.0 K, respectively. For the zero-field-cooled sample, the loop is rather flat and smooth. While for the field-cooled sample the loop consists of sharp steps due to the reversal of the magnetization in a very short time and at a very small oppositely directed field. The field-cooled loop exhibits a small displacement due to the presence of a small unidirectional exchange interaction in the material.

In summary, we have synthesized and characterized the amorphous $Cr_5(InTe_4)_3$ and $Fe_5(InTe_4)_3$. $Cr_5(InTe_4)_3$ is a semiconductor and exhibits strong antiferromagnetic couplings between localized moments. $Fe_5(InTe_4)_3$ exhibits strong antiferromagnetic couplings at high temperatures and undergoes a transition to a spin glass state at 6.0 K.

Order-parameter fluctuations in the frustrated Heisenberg model on the square lattice

Shu Zhang and Gerhard Müller
Department of Physics, The University of Rhode Island, Kingston, Rhode Island 02881-0817

The $T=0$ dynamics of the two-dimensional $s=1/2$ Heisenberg model with competing nearest-neighbor (J_1) and next-nearest-neighbor (J_2) interactions is explored via the recursion method, specifically the frequency-dependent fluctuations of the order parameters associated with some of the known or suspected ordering tendencies in this system, i.e., Néel, collinear, dimer, and chiral order. The results for the dynamic structure factors of the respective fluctuation operators show a strong indication of collinear order at $J_2/J_1 \gtrsim 0.6$ and a potential for dimer order at $0.5 \lesssim J_2/J_1 \lesssim 0.6$, whereas the chiral ordering tendency is observed to be considerably weaker.
 [S0021-8979(96)00808-5]

The impact of quantum fluctuations on the zero-temperature phase diagram of a quantum many-body system tends to be strongest if that system contains competing interactions. A particular, sometimes exotic phase may be stabilized by quantum fluctuations in the presence of interactions that frustrate each other's ordering tendencies. The two-dimensional (2D) Heisenberg antiferromagnet with nearest-neighbor (nn) and next-nearest-neighbor (nnn) coupling on the square lattice,

$$H=J_1\sum_{\mathbf{r}} \mathbf{S}_{\mathbf{r}}\cdot(\mathbf{S}_{\mathbf{r}+\hat{\mathbf{x}}}+\mathbf{S}_{\mathbf{r}+\hat{\mathbf{y}}})+J_2\sum_{\mathbf{r}} \mathbf{S}_{\mathbf{r}}\cdot(\mathbf{S}_{\mathbf{r}+\hat{\mathbf{x}}+\hat{\mathbf{y}}}+\mathbf{S}_{\mathbf{r}+\hat{\mathbf{x}}-\hat{\mathbf{y}}}), \tag{1}$$

has been a prominent object of study in this context.[1]

The Néel long-range order (LRO) present in the ground state of the nn model disappears at some critical coupling ratio, $J_2/J_1 \simeq 0.4$, and is replaced, at sufficiently large J_2/J_1, by Néel LRO within each of the two nnn sublattices. The latter is preceeded, at $J_2/J_1 \gtrsim 0.65$, by collinear LRO, which breaks the (discrete) rotational symmetry of H on the lattice but not yet its (continuous) rotational symmetry in spin space. The Néel and collinear order parameters (OPs) are described by the operators

$$O_N=\frac{1}{N}\sum_{\mathbf{r}} (-1)^{x+y}N_{\mathbf{r}}, \quad O_C=\frac{1}{N}\sum_{\mathbf{r}} C_{\mathbf{r}}, \tag{2}$$

where $N_{\mathbf{r}}=S^z_{\mathbf{r}}$, $C_{\mathbf{r}}=\mathbf{S}_{\mathbf{r}}\cdot(\mathbf{S}_{\mathbf{r}+\hat{\mathbf{x}}}+\mathbf{S}_{\mathbf{r}-\hat{\mathbf{x}}}-\mathbf{S}_{\mathbf{r}+\hat{\mathbf{y}}}-\mathbf{S}_{\mathbf{r}-\hat{\mathbf{y}}})$.

At intermediate coupling ratios, $0.4 \lesssim J_2/J_1 \lesssim 0.65$, the Néel and collinear ordering tendencies keep each other at bay and thus make the frustrated ground state susceptible to different kinds of ordering potentialities. Dimer order,[2,3] twist order,[4] and chiral order[5] have been proposed in this context. The dimer and chiral OPs considered here are defined by the following expressions in terms of spin operators:

$$O_D=\frac{1}{N}\sum_{\mathbf{r}} (-1)^{x}D_{\mathbf{r}}, \quad O_\chi=\frac{1}{N}\sum_{\mathbf{r}} \chi_{\mathbf{r}}, \tag{3}$$

where $D_{\mathbf{r}}=\mathbf{S}_{\mathbf{r}}\cdot\mathbf{S}_{\mathbf{r}+\hat{\mathbf{x}}}$, $\chi_{\mathbf{r}} = Z_{\mathbf{r},\mathbf{r}+\hat{\mathbf{x}},\mathbf{r}+\hat{\mathbf{x}}+\hat{\mathbf{y}}} - Z_{\mathbf{r},\mathbf{r}+\hat{\mathbf{x}}+\hat{\mathbf{y}},\mathbf{r}+\hat{\mathbf{y}}}$, $Z_{\mathbf{i},\mathbf{j},\mathbf{k}} = i(S^+_{\mathbf{i}}S^-_{\mathbf{j}}-S^-_{\mathbf{i}}S^+_{\mathbf{j}}+S^+_{\mathbf{j}}S^-_{\mathbf{k}}-S^-_{\mathbf{j}}S^+_{\mathbf{k}}+S^+_{\mathbf{k}}S^-_{\mathbf{i}}-S^-_{\mathbf{k}}S^+_{\mathbf{i}})$. They probe the long-range phase coherence of singlets stacked in columns along the y axis and the handedness of the spin configuration on a plaquette, respectively, in the ground-state wave function $|G\rangle$. Whether any one of these types of LRO is, in fact, realized, or whether a ground state with short-range correlations of the resonating-valence-bond type,[6,7] for example, is stabilized, has not been determined for certain.

The absence or presence of a specific type of LRO determines whether the associated OP correlation function decays to zero or not. In the finite-cluster data, the relevant information on the asymptotic behavior is best captured by the expectation value of the squared OP. The problem here is to find a meaningful reference point for any enhancement in that quantity.[3]

An alternative avenue to comparing the different ordering tendencies in the spin-frustrated ground state of (1) is to explore the dynamic (i.e., frequency-dependent) fluctuations of any proposed OP. The recursion method[8] in conjunction with recently developed techniques of continued-fraction analysis[9,10] is very suitable for that purpose. Here the dynamical information is derived from the finite-size ground-state wave function. No excited states have to be computed. This is an important advantage for the study of systems with complicated spectra and with potential OPs that have widely varying symmetry properties, as is the case here.

We investigate the fluctuations of the four OPs defined in (2) and (3) as they manifest themselves in the dynamic structure factors

$$S_{AA}(\mathbf{q},\omega)=\int_{-\infty}^{+\infty} dt e^{i\omega t}\langle F^A_{\mathbf{q}}(t)F^A_{-\mathbf{q}}\rangle, \tag{4}$$

where $F^A_{\mathbf{q}}=N^{-1/2}\Sigma_{\mathbf{r}}e^{i\mathbf{q}\cdot\mathbf{r}}A_{\mathbf{r}}$ is the fluctuation operator associated with a given OP, and $A_{\mathbf{r}}$ stands for $N_{\mathbf{r}}$, $C_{\mathbf{r}}$, $D_{\mathbf{r}}$, or $\chi_{\mathbf{r}}$, as defined above.

The recursion algorithm in the present context is based on an orthogonal expansion of the wave function $|\Psi^A_{\mathbf{q}}(t)\rangle = F^A_{\mathbf{q}}(-t)|G\rangle$. It produces (after some intermediate steps) a sequence of continued-fraction coefficients $\Delta^A_1(\mathbf{q})$, $\Delta^A_2(\mathbf{q})$, ... for the relaxation function

$$c^{AA}_0(\mathbf{q},z)=\cfrac{1}{z+\cfrac{\Delta^A_1(\mathbf{q})}{z+\cfrac{\Delta^A_2(\mathbf{q})}{z+\ldots}}}, \tag{5}$$

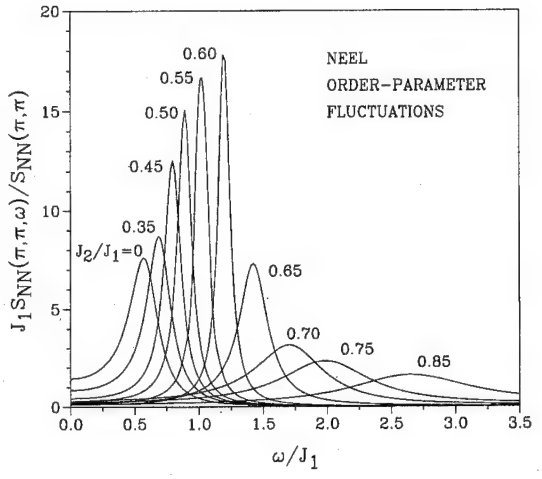

FIG. 1. $T=0$ dynamic structure factor (4) normalized by its integrated intensity for the Néel fluctuation operator $F_{\mathbf{q}}^{N}$ at $\mathbf{q}=(\pi,\pi)$ of the Hamiltonian (1) at various values of the coupling ratio J_2/J_1, obtained via strong-coupling continued-fraction reconstruction from the coefficients $\Delta_1,\ldots,\Delta_6$ and a Gaussian terminator as explained in Refs. 9 and 10.

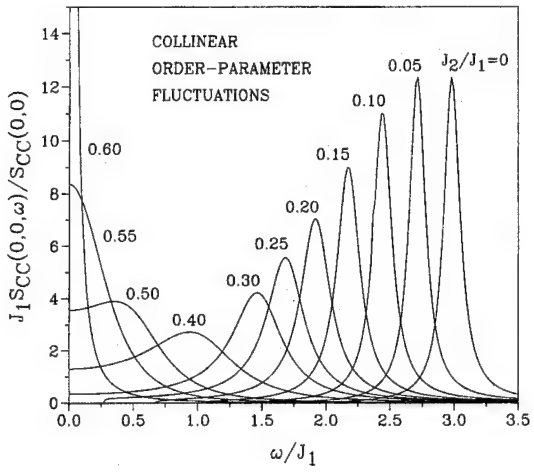

FIG. 2. $T=0$ dynamic structure factor (4) normalized by its integrated intensity for the collinear fluctuation operator $F_{\mathbf{q}}^{C}$ at $\mathbf{q}=(0,0)$ of the Hamiltonian (1) at various values of the coupling ratio J_2/J_1, obtained via strong-coupling continued-fraction reconstruction from the coefficients $\Delta_1,\ldots,\Delta_6$ and a Gaussian terminator.

which is the Laplace transform of the symmetrized correlation function $\Re\langle F_{\mathbf{q}}^{A}(t)F_{-\mathbf{q}}^{A}\rangle/\langle F_{\mathbf{q}}^{A}F_{-\mathbf{q}}^{A}\rangle$. The $T=0$ dynamic structure factor is then obtained from (5) via

$$S_{AA}(\mathbf{q},\omega)=4\langle F_{\mathbf{q}}^{A}F_{-\mathbf{q}}^{A}\rangle\Theta(\omega)\lim_{\varepsilon\to 0}\Re[c_0^{AA}(\mathbf{q},\varepsilon-i\omega)], \quad (6)$$

where $\langle F_{\mathbf{q}}^{A}F_{-\mathbf{q}}^{A}\rangle=S_{AA}(\mathbf{q})$ is the integrated intensity.[11]

All the results presented here are for clusters of $N=4\times4$ sites with periodic boundary conditions. Extreme care must be exercised in separating finite-size effects from properties that reflect the physics of the infinite system. This distinction can be made with more confidence for coupling ratios $J_2/J_1\lesssim0.7$ than at $J_2/J_1>0.7$, where the gradual decoupling of the two *nnn* sublattices causes a crossover in the finite-size effects.

The Néel OP fluctuations are probed by the dynamic structure factor $S_{NN}(\mathbf{q},\omega)$ at the wave vector $\mathbf{q}=(\pi,\pi)$. This quantity is shown in Fig. 1 for various coupling ratios. The presence of Néel LRO at $J_2/J_1=0$ implies that $S_{NN}(\pi,\pi,\omega)$ is governed by a zero-frequency peak. Quantum fluctuations split the ground-state level for finite N. In a 4×4 cluster the finite-size gap is known to be of magnitude $\Delta E/J_1\simeq0.57$.[10] The peak position of the curve for $J_2/J_1=0$ must be interpreted with this fact in mind.

What are the effects of the *nnn* coupling on the Néel OP fluctuations? For $0\leqslant J_2/J_1\lesssim0.4$, i.e., over the estimated range of the Néel phase, we observe only small changes in peak position and line shape. Then the Néel OP fluctuations begin to change rapidly in two stages:

(i) Over the range $0.4\lesssim J_2/J_1\lesssim0.6$, the peak position moves to higher frequencies at an accelerated rate, the linewidth shrinks, and the integrated intensity (not shown) drops to 32% of its value at $J_2/J_1=0$. This signals the presence of some non-Néel type ordering tendency which supports well-defined Néel modes at increasingly high frequencies.

(ii) At $J_2/J_1\gtrsim0.6$ the linewidth of $S_{NN}(\pi,\pi,\omega)$ grows rapidly, while the peak position moves further up and the integrated intensity continues to fade away quickly. As the two *nnn* sublattices begin to decouple, the system ceases to support well-defined Néel modes.

The dynamic structure factor $S_{CC}(0,0,\omega)$, which describes the collinear OP fluctuations, is shown in Fig. 2. At $J_2/J_1=0$, we observe a fairly sharp collinear mode at $\omega/J_1\simeq3.0$. As the Néel ordering tendency weakens with increasing J_2/J_1, the collinear mode shifts to lower frequencies, while its line shape broadens considerably. The width reaches a maximum at $J_2/J_1\simeq0.4$. Between here and $J_2/J_1\simeq0.55$, where the competing dimer and chiral ordering tendencies are at their peak, the collinear mode moves to $\omega=0$, and the integrated intensity more than triples in relation to its value at $J_2/J_1=0$. In the interval $0.55\lesssim J_2/J_1\lesssim0.7$, the function $S_{CC}(0,0,\omega)$ transforms into a narrow

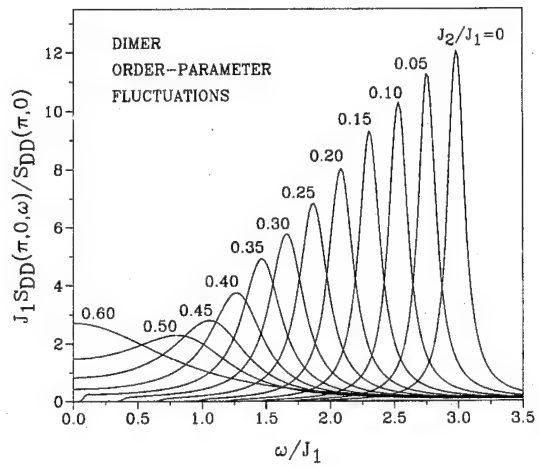

FIG. 3. $T=0$ dynamic structure factor (4) normalized by its integrated intensity for the dimer fluctuation operator $F_{\mathbf{q}}^{D}$ at $\mathbf{q}=(\pi,0)$ of the Hamiltonian (1) at various values of the coupling ratio J_2/J_1, obtained via strong-coupling continued-fraction reconstruction from the coefficients $\Delta_1,\ldots,\Delta_6$ and a Gaussian terminator.

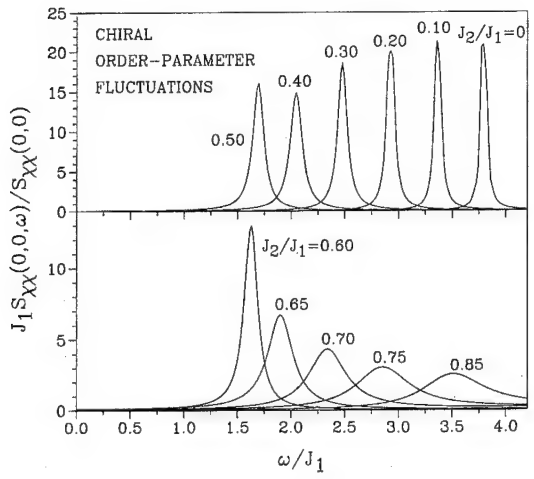

FIG. 4. $T=0$ dynamic structure factor (4) normalized by its integrated intensity for the chiral fluctuation operator $A_{\mathbf{q}}^{\chi}$ at $\mathbf{q}=(0,0)$ of the Hamiltonian (1) at various values of the coupling ratio J_2/J_1, obtained via strong-coupling continued-fraction reconstruction from the coefficients $\Delta_1,\ldots,\Delta_6$ and a Gaussian terminator.

central peak, and $S_{CC}(0,0)$ increases by another factor of $\simeq 1.6$. This clearly reflects the onset of collinear LRO in the infinite system.

The dimer OP fluctuations as described by the dynamic structure factor $S_{DD}(\pi,0,\omega)$ and shown in Fig. 3 resemble those of the collinear OP with respect to line shape and peak position for as long as the Néel ordering tendency is perceptible in the ground state ($J_2/J_1 \lesssim 0.4$). Both modes become soft and very broad at $J_2/J_1 \simeq 0.55$, but then they part company. While the collinear mode has been observed to transform into a high-intensity narrow central peak, the dimer mode, which has reached its maximum intensity here ($\simeq 1.8$ times its value at $J_2/J_1=0$), broadens further and loses intensity very rapidly. It literally dissolves as the inter-sublattice correlations begin to weaken at $J_2/J_1 \gtrsim 0.7$. Nevertheless, the softness of the dimer OP fluctuations at $J_2/J_1 \simeq 0.55$ in the 4×4 cluster is consistent with dimer LRO in the infinite system.

The chiral OP fluctuations are based more significantly on intra-sublattice correlations than the dimer OP fluctuations and, therefore, evolve differently. This is illustrated in Fig. 4. At $J_2/J_1=0$ the dynamic structure factor $S_{\chi\chi}(0,0,\omega)$ exhibits a sharp mode at $\omega/J_1 \simeq 3.8$. At $J_2/J_1 \simeq 0.55$, the peak position has moved down to $\omega/J_1 \simeq 1.6$, while the linewidth has increased only slightly, and the integrated intensity has grown to a maximum value of $\simeq 2.3$ times its value at $J_2/J_1=0$. Then the peak position starts to move back out to higher frequencies, the line shape begins to broaden, but less so compared to that of the dimer fluctuations, and the integrated intensity drops rapidly. The minimum gap of the chiral mode is perhaps too large to be entirely attributable to a finite-size effect, which would indicate that the observed chiral ordering tendency does not turn into chiral LRO as $N\rightarrow\infty$.

The ϵ-MnZn alloy (disordered hcp structure) containing 15 at. % Mn seems to be ferromagnetic below about 200 K; the magnetization σ in a field H of 9.5 kOe amounts to 26 emu/g at a temperature T of 4.2 K. The σ vs T curve in lower H, however, shows a maximum, suggesting mictomagnetism. This is verified by the existence of a hump on the ac susceptibility χ_{ac} vs T curve. The σ versus concentration curve shows a maximum at 15 at. % Mn. The χ_{ac} vs T curves for the 12 at. % Mn alloy show a cusp at 45 K in addition to the hump between 80 and 180 K, suggesting a spin glass state. Both the cusp and the hump are suppressed by a dc magnetic field applied parallel to the ac field. The micromagnetic behavior becomes more pronounced for the Mn richer alloys which show only the hump in the χ_{ac} vs T curve. The σ vs T curves exhibit a magnetic field cooling effect below a freezing temperature T_f. The values of T_f for the alloys containing 20, 30, and 45 at. % Mn are 38, 50, and 75 K, respectively. Although the antiferromagnetic interaction predominates in the Mn rich alloys, a long-range antiferromagnetic order may not be expected because of the random distribution of Mn moments. The 25 at. % Mn alloy shows strong ferromagnetism, if the atomic ordering in the hcp lattice is realized. [S0021-8979(96)04008-1]

I. INTRODUCTION

The ϵ phase (disordered hcp structure) in the Mn–Zn alloy system is stable at high temperatures in a rather wide composition range (13–55 at. % Mn)[1] and can be retained at room temperature by water quenching. A few decades ago, the ferromagnetism of this phase was found by Nowotny *et al.*[2] The present authors[3] have reported that the magnetic susceptibility of this phase at high temperatures obeys the Curie–Weiss law; the extrapolated Curie temperature is positive for the alloys with less than 20 at. % Mn and negative for those with more than 25 at. % Mn. It has also been clarified[4] that the ϵ-MnZn alloys containing about 25 at. % Mn become strongly ferromagnetic at room temperature if annealed at 100 °C for several days. The ferromagnetism is due to the formation of the ordered hcp structure of $D0_{19}$ type. Since the $D0_{19}$ type phase (ϵ' phase) is merely metastable, more prolonged annealing gives rise to the transformation to the antiferromagnetic Cu_3Au type phase (α' phase). In the present work, more detailed magnetization and ac-susceptibility measurements for the quenched ϵ-MnZn alloys were made at temperatures down to 4.2 K.

II. EXPERIMENT

Samples of the Mn–Zn alloys containing 8–50 at. % Mn were prepared by the following procedures. Electrolytic Mn (99.9%) and pure Zn (99.9%) were mixed, sealed in an evacuated quartz tube, melted at about 900–1100 °C, and quenched in water. The ingot was sealed in a quartz tube and annealed at the stable temperature of the ϵ-MnZn phase (about 440–600 °C) for more than 3 days. Powder samples for x-ray diffraction experiments and small pieces (10–500 mg in weight) for magnetization measurements were prepared by filing and cutting, respectively. In order to remove the stress caused by filing and cutting, these samples were annealed again at the stable temperature of the ϵ-MnZn phase for several hours and then quenched in water. The magnetization was measured by a Faraday type magnetic balance in a field up to 10 kOe. The ac-susceptibility measurements were made using a standard double coil in an ac driving field of 3.9 Oe rms and 80 or 160 Hz. Various dc magnetic fields between 0 and 800 Oe were applied parallel to the ac field.

III. EXPERIMENTAL RESULTS AND DISCUSSION

The x-ray diffraction lines for the well-annealed powder samples are very sharp, indicating that the samples are quite homogeneous and stress-free. No appreciable impurity phases were observed except for the alloys containing less than 10 at. % Mn. The ϵ-phase region is somewhat wider than that of the current phase diagram.[1] The hexagonal lattice constants a and c at 20 °C are shown in Fig. 1(a). Figure 1(b) shows the effective magnetic moment and the extrapolated Curie temperature determined by the magnetization measurement in the paramagnetic region.

Figure 2 shows the temperature dependence of magnetization in various applied fields for the alloys containing 10–15 at. % Mn. These data were taken with increasing temperature after cooling to 4.2 K in zero field. The 15 at. % Mn alloy seems to show a typical ferromagnetism with the Curie temperature of about 200 K and the saturation magnetization of 26 emu/g (1.79 μ_B per Mn atom). In lower fields, however, the magnetization σ vs temperature T curve shows a maximum at about 90 K. The 10 and 12 at. % Mn alloys show a similar behavior. Both the Curie temperature and the saturation magnetization decrease with decreasing Mn concentration. The maximum in the σ vs T curve is sometimes

observed in mictomagnetism or cluster spin glass owing to the existence of antiferromagnetic interactions.

Figure 3 shows the ac susceptibility χ_{ac} vs T curve for these alloys, which was measured during heating after zero-field cooling. A hump is observed between the Curie temperature and 80 K, the latter corresponding to the onset of mictomagnetism or cluster spin glass. In addition to the hump, a cusplike peak is observed at 36 and 45 K for the 10 and 12 at. % Mn alloys, respectively, suggesting the existence of a spin glass state. Both the cusp and the hump are

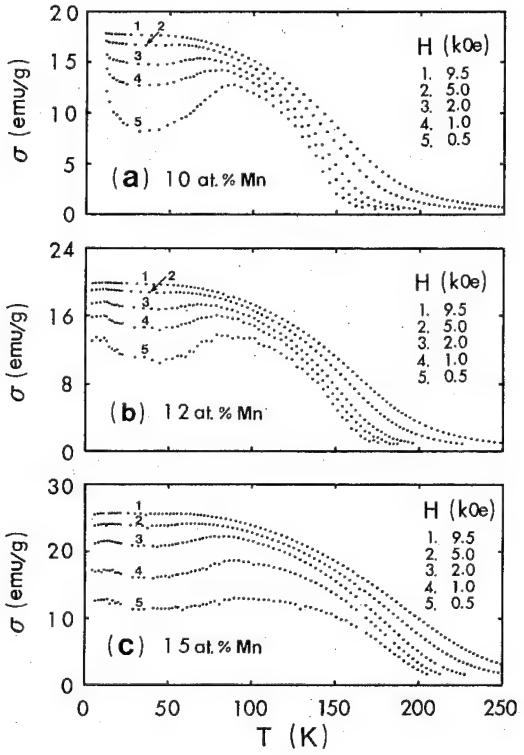

FIG. 2. Temperature T dependence of magnetization σ in various magnetic fields H for ϵ-MnZn alloys containing 10–15 at. % Mn.

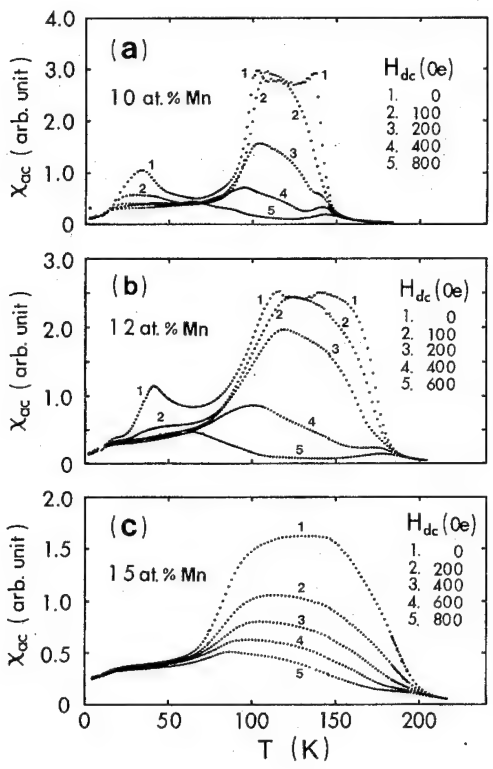

FIG. 3. Temperature T dependence of ac-susceptibility χ_{ac} in various dc fields H_{dc} parallel to the ac field for ϵ-MnZn alloys containing 10–15 at. % Mn.

suppressed by a dc magnetic field applied parallel to the ac field. This effect is more remarkable for the cusp than for the hump. The cusp is not observed for the Mn-richer alloys which, on the other hand, show more pronounced mictomagnetism owing to the enhancement of the antiferromagnetic interaction.

Figure 4 shows the σ vs T curves for the alloys containing 20–45 at. % Mn. The magnetization was measured in 9.5 kOe during heating after cooling from about 80 to 4.2 K in 9.5 kOe (curves denoted as I) or in zero field (curves denoted as II). The so-called magnetic cooling effect appears below a freezing temperature T_f. The values of T_f for the alloys containing 20, 30, and 45 at. % Mn are 28, 50, and 75 K, respectively. The maximum in the σ vs T curve even appears at the field of 9.5 kOe. The maximum values of magnetization are plotted against the Mn concentration in Fig. 5, together with the magnetization values at 4.2 K.

Although the antiferromagnetic interaction predominates in the alloys containing more than 30 at. % Mn, a long-range antiferromagnetic order may not be expected because of the random distribution of Mn moments. Instead, the cluster spin glass may occur.

We have re-examined the strong ferromagnetism of the ordered hcp phase (ϵ' phase). The ϵ phase alloys were annealed at 100 °C for a long time. The magnetization of 25 at. % Mn alloy at room temperature showed a maximum (26 emu/g) for the annealing time of 50 h, and then gradually decreased owing to the transformation to the nonferromagnetic α' phase. The results are in qualitative agreement with those of the earlier work.[4]

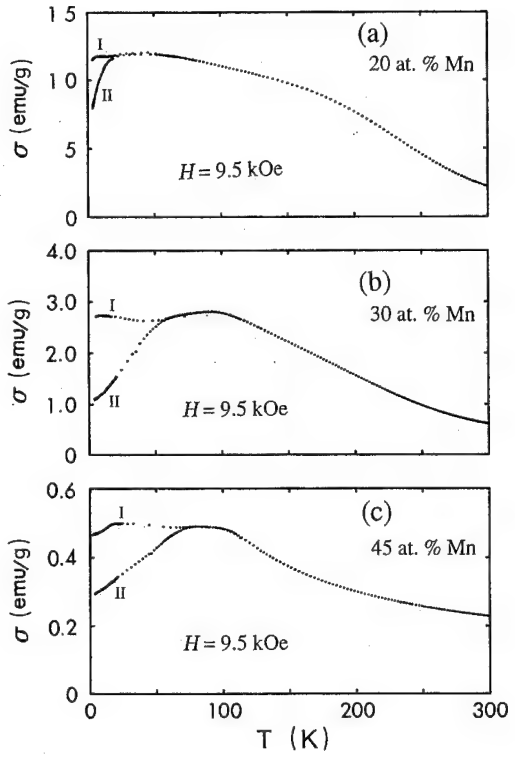

FIG. 4. Temperature T dependence of magnetization σ measured during heating in a field of 9.5 kOe for ϵ-MnZn alloys containing 20–45 at. % Mn. Curves denoted as I and II were obtained after the cooling from about 80 to 4.2 K in 9.5 kOe and in zero field, respectively.

Even the 13 at. % Mn alloy is affected by the prolonged annealing at 100 °C. The ferromagnetic Curie temperature of the annealed alloy was about 250 K, being higher than that of the as-quenched alloy. The difference is thought to be caused by an atomic short-range order which may enhance

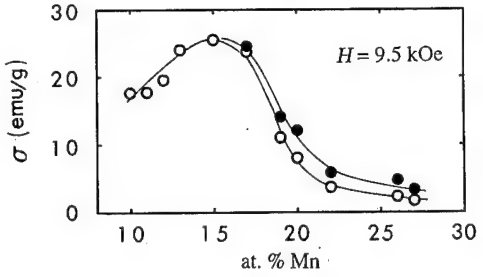

FIG. 5. Concentration dependence of magnetizations σ in a field of 9.5 kOe. Open circles show the magnetization at 4.2 K, and closed circles show the maximum magnetization in the σ vs T curve.

the tendency to ferromagnetism. Since the short-range order might exist to some extent even in the as-quenched alloy, it would be difficult to determine the Curie temperature of the "ideally disordered" ϵ-MnZn alloys.

IV. CONCLUSIONS

The ϵ-MnZn alloys containing less than 20 at. % Mn show typical ferromagnetism near the Curie temperature and cluster spin glass at low temperatures. Furthermore, the alloys containing 10–12 at. % Mn show a cusp in the ac susceptibility versus temperature curve at a lower temperature. On the other hand, the Mn-richer alloys show more pronounced mictomagnetism. The so-called magnetic cooling effect is observed even for the alloys containing 45 at. % Mn.

The spin dynamics of geometrically frustrated pyrochlore antiferromagnets $Y_2Mo_2O_7$ and $Y_2Mo_{1.6}Ti_{0.4}O_7$ have been investigated using muon spin relaxation. In $Y_2Mo_2O_7$ a dramatic slowing down of the Mo^{4+} spin fluctuations occurs as one approaches the spin freezing temperature T_F of 22 K from above. At lower temperatures the spins freeze into a disordered magnetic state similar to that found in a spin glass but with a small residual muon spin relaxation rate at low temperatures. This residual relaxation rate is larger in $Y_2Mo_{1.6}Ti_{0.4}O_7$ where $T_F=15$ K. These results suggest that there is a nonzero density of states for magnetic excitations in these systems near zero energy.
 [S0021-8979(96)05808-4]

Recently, there has been considerable interest in the behavior of geometrically frustrated antiferromagnets in which the natural antiferromagnetic coupling between ions is uniformly frustrated by the geometry of the lattice. This is unlike the random frustration occurring in conventional disordered spin glasses. In three dimensions, the most well studied systems are pyrochlores, where magnetic ions occupy a lattice of corner sharing tetrahedra. Monte Carlo simulations[1] have shown that Heisenberg spins on a lattice of corner sharing tetrahedra have a classical ground state with a macroscopic degeneracy, since the lowest energy spin configuration requires only that $\Sigma_{i=1}^{4}\mathbf{S}_i=0$ for each tetrahedron. Villain argued the classical ground state is a cooperative paramagnet,[2] with only short range spin-spin correlations and no ordering for $T>0$ K. However, additional factors such as magnetic anisotropy, further nearest neighbor exchange and thermal fluctuations[3] can lift the degeneracy. A variety of magnetic ground states have been observed in different pyrochlores. These include a non-collinear long range order (LRO) in which the spins on each tetrahedron point away from the center and a dense spin glass where the moments are frozen with no LRO.

Bulk magnetic susceptibility measurements on the pyrochlores $Y_2Mo_2O_7$[4] and $Y_2Mo_{1.6}Ti_{0.4}O_7$ show a cusp-like behavior at T_F with strong irreversibilities below $T_F=22$ K and 15 K, respectively, typical of conventional spin glasses. Strong diffuse scattering, indicating the presence of short range correlations, has been observed in wide angle neutron scattering measurements on the isostructural compound $Tb_2Mo_2O_7$.[5,6] No LRO is observed below T_F.

We report on the results of an investigation of the low temperature magnetic properties of $Y_2Mo_2O_7$ and $Y_2Mo_{1.6}Ti_{0.4}O_7$ using muon spin relaxation. Below T_F a large static internal magnetic field develops which has a very broad distribution, such that no coherent muon spin precession is observed. At the same time, the muon spin relaxation rate $1/T_1$ decreases according to a power law with decreasing temperature. The most remarkable feature in the data is the

 0021-8979/96/79(8)/6636/3/$10.00

presence of a residual spin relaxation rate in both samples at low temperatures, which is evidence for a nonzero density of magnetic states near zero energy. These results may be compared with μSR experiments on conventional spin glasses AuFe and CuMn.[7]

Pyrochlores crystallize with a fcc structure containing eight formula units per conventional unit cell and space group $Fd\bar{3}m$. The ions on the 16d site form a network of corner sharing tetrahedra; the 16c sites constitute an identical sublattice, displaced by (1/2,1/2,1/2). Mo^{4+} ions occupy the 16c site, while the Y^{3+} ions occupy the 16d site. The Mo^{4+} ion has a magnetic moment of $\sim 1\mu_B$, whereas Y^{3+} and Ti^{4+} are diamagnetic. The oxygen vacancy concentration, which is likely the main source of crystalline disorder in these materials, is below the limit of 1% detectable by neutron and x-ray diffraction.

The μSR measurements on pressed polycrystalline pellets were made at TRIUMF in a ^{4}He gas flow cryostat for temperatures above 2K and in an Oxford Instruments model 400 top loading dilution refrigerator (DR) for lower temperatures. In a μSR experiment the observed quantity is the time evolution of the muon spin polarization, which depends on the ensemble averaged distribution of internal magnetic fields and their temporal fluctuations. The present measurements were made in a small external field directed along the initial polarization direction (longitudinal field) to reduce sensitivity to small random static nuclear magnetic dipolar fields in the sample, sample holder and cryostat. Details on the μSR technique may be found elsewhere.[8]

Figure 1(a) shows several typical μSR spectra of $Y_2Mo_2O_7$ in a longitudinal applied field of 0.02 T. Above T_F=22 K the observed spin relaxation is attributed to rapid fluctuations of the internal magnetic field due to Mo^{4+} moments in the paramagnetic phase. When $\nu \gg \Delta$ (defined below) the relaxation function [see $P_z(t)$ in Fig. 1] for each magnetically equivalent site i can be described by a single exponential $e^{-\lambda_i t}$ with a relaxation rate[8]:

$$\lambda_i = \frac{4\pi\Delta_i^2 \nu_i}{\nu_i^2 + 2\nu_L^2}, \tag{1}$$

where $\Delta_i = \gamma_\mu B_i$ is the gyromagnetic ratio of the muon ($2\pi \times 135.54$ MHz/T) times the rms internal magnetic field B_i at site i. ν_i is the fluctuation rate of the internal field, and $\nu_L = \gamma_\mu B_{\text{ext}}$ is the Larmor frequency of the muon in the external magnetic field. Note that λ_i is only weakly dependent on the applied field provided $\nu_i \gg \nu_L$; this is consistent with the absence of any observed field dependence above T_F. Just above T_F, $P_z(t)$ deviates somewhat from a single exponential [see for example T=27.5 K spectrum in Fig. 1(a)] and is better described by a stretched exponential form $e^{-(\lambda t)^\beta}$ with β near 0.4. In conventional spin glasses in the limit of rapid spin fluctuations, a square root exponential relaxation is a natural consequence of the large number of magnetically inequivalent sites arising from the broad distribution of distances to the magnetic moments. In a system of dense moments such as $Y_2Mo_2O_7$ it is still possible to have multiple sites and multi-exponential behavior, but the ratio of amplitudes for the various components and the corresponding relaxation rates are temperature independent. The data for $Y_2Mo_2O_7$ near T_F could not be fit with this latter restriction, indicating that the observed non-exponential behavior possibly originates from a distribution of correlation times τ_i associated with different finite spin clusters. Similar behavior has recently been observed in other dense spin glasses AgMn and AuFe.[9] μSR spectra for $Y_2Mo_{1.6}Ti_{0.4}O_7$ are shown in Fig. 1(b), where the diamagnetic Ti^{4+} ions are substitutional impurities on the B site, introducing random disorder into the system.

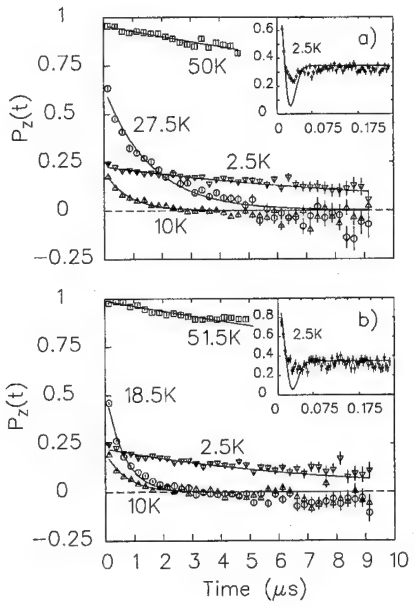

FIG. 1. Long-time dependence of the muon polarization, $P_z(t)$. Solid lines are best fits to the data. The inset shows the short-time behavior at T=2.5 K for (a) $Y_2Mo_2O_7$ and (b) $Y_2Mo_{1.6}Ti_{0.4}O_7$.

The muon spin polarization function below T_F (see insets in Fig. 1) is characterized by rapid depolarization of 2/3 of the initial polarization in the first 0.05 μs, followed by slow relaxation of the remaining 1/3 component. This is a characteristic signature of a highly disordered magnetic state in which the moments are quasi-static on the timescale of the muon lifetime. For example, the muon polarization function for a single magnetic site with a Gaussian distribution of static internal fields is given by a Kubo-Toyabe function.[8] The curves in the insets of Fig. 1 show a fit of the early time data at 2.5 K to this function, modified slightly to include the small external field of 0.02 T. This does not change the form of the function appreciably provided B_{ext} is much less than B_i. Note that the 2.5 K spectrum for $Y_2Mo_2O_7$ was taken with better statistics. The best fit to the data corresponds to an average field strength $\sqrt{8/\pi}\Delta/\gamma_\mu = 0.105(5)$ T for both compounds. The dip in $P_z(t)$ at 0.032 μs is not however as deep as predicted by the Kubo-Toyabe function, indicating the distribution of internal fields is more complicated than a single Gaussian.

Muon spin relaxation results from the exchange of energy with magnetic excitations. A first order process, in which the muon absorbs or creates an excitation with an energy equal to the muon Zeeman energy, is normally suppressed in conventional long range ordered systems, since it

requires excitations at energies less than the smallest gap. In a second order process (Raman magnon scattering) involving inelastic scattering of an excitation, application of Fermi's Golden rule gives:

$$1/T_1 \propto \int_0^\infty dE n\left(\frac{E}{k_B T}\right)\left[n\left(\frac{E}{k_B T}\right)+1\right]M^2(E)\rho^2(E), \qquad (2)$$

where the muon Zeeman energy has been neglected, $\rho(E)$ is the density of states and $M(E)$ is the matrix element for inelastic scattering of an excitation of energy E causing a muon spin flip. In a spin glass, $n(E/k_BT)$ is the probability distribution for the intravalley excitations, assumed to be Bose, within one of a macroscopic number of metastable states or "valleys." The power law behavior of $1/T_1$ is primarily determined by the energy dependence of $\rho(E)M(E)$, as intervalley transitions are thought to be important only in the mK range.[10] For example, an energy gap in $\rho(E)$ generally leads to an exponential variation of $1/T_1 \sim T\exp(-E_g/k_bT)$ at low temperatures, where T is much less than E_g/k_b. If $\rho(E)$ and $M(E)$ have power law dependences with powers l and m, respectively, then Eq. (2) implies $1/T_1$ varies as $T^{2(l+m)+1}$. The low temperature linear specific heat observed in $Y_2Mo_2O_7$ (Ref. 4) suggests $\rho(E)$ is flat or at least weakly dependent on energy.

Figure 2(a) shows the average muon spin relaxation rate in $Y_2Mo_2O_7$ obtained from fits to a single exponential relaxation function over a restricted time interval of 0.05 to 6 μs. There is a sharp rise in the average $1/T_1$ as one approaches T_F=22 K from above. This is attributed to critical slowing down of the Mo^{4+} fluctuations. Below T_F, $1/T_1$ decreases gradually as the magnetic excitations freeze out. The curve in Fig. 2(a) shows the best fit of the data below 12 K to a simple power law form, $\lambda = \lambda_0 + AT^n$, with exponent n=2.1(3). A similar analysis of the $Y_2Mo_{1.6}Ti_{0.4}O_7$ data below 12 K yields a value of n=2.03(6), as illustrated in Fig. 2(b). The spin freezing temperature, as seen by a peak in $1/T_1$, occurs at ~15 K in this sample. The muon spin depolarization rate is roughly temperature independent below 1 K, but at a higher value of ~0.05 μs^{-1}, as compared to 0.02 μs^{-1} in $Y_2Mo_2O_7$. The small but finite residual relaxation at the lowest temperatures implies there is an appreciable density of excitations close to zero energy. We suggest that the mechanism giving rise to temperature independent muon spin depolarization is enhanced by the addition of random disorder. However, the power law behavior is unaffected within the accuracy of the measurements.

Computer simulations by Ching *et al.*[11] on insulating Heisenberg spin glasses $Eu_xSr_{1-x}S$ (x=0.54 and 0.40) have indicated the density of states $\rho(\epsilon)$ may be peaked at low energies. The geometrically frustrated kagomé lattice system $SrCr_8Ga_4O_{19}$ has also recently been studied using μSR. Dynamic spin fluctuations are observed without static freezing, even at 100 mK, well below T_F = 3.5 K.[12]

In summary the data for $Y_2Mo_2O_7$ and $Y_2Mo_{1.6}Ti_{0.4}O_7$ are consistent with spin glass behavior as shown by:

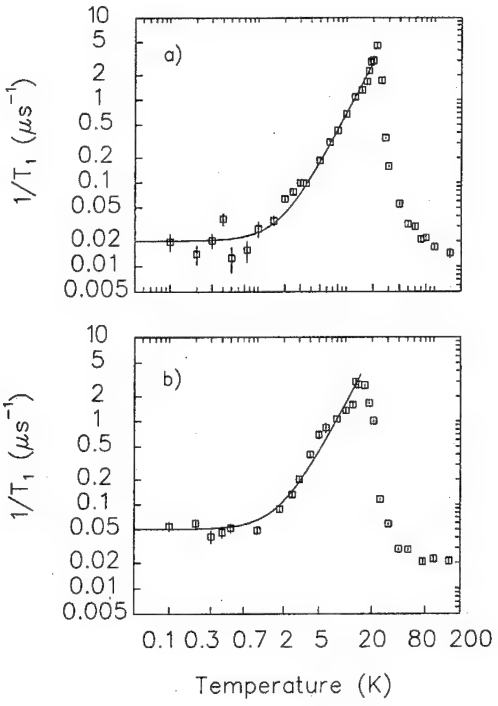

FIG. 2. Dynamical relaxation rate $1/T_1$ vs temperature for (a) $Y_2Mo_2O_7$ and (b) $Y_2Mo_{1.6}Ti_{0.4}O_7$in a longitudinally applied field of 0.02 T. The solid line is the best fit to the data assuming a power law functional form.

(1) the critical slowing down of the spin fluctuations and nonexponential muon spin relaxation near T_F,
(2) a broad distribution of static internal fields below T_F and
(3) the weak power law behavior in $1/T_1$ below T_F.

In both systems there appears to be a residual relaxation which persists down to very low temperatures. This indicates there is a nonzero density of states for magnetic excitations close to zero energy.

Quarternary giant magnetoresistance random access memory

Zhigang Wang and Yoshihisa Nakamura
Research Institute of Electrical Communication, Tohoku University, Sendai 980, Japan

We designed a quarternary memory using weakly coupled giant magnetoresistance (GMR) multilayers based on the fact that there are four stable states when the applied field is zero. Compared with conventional binary memory, the major advantage of the quarternary GMR memory is that we can simply double its capacity. This design's feasibility has been proved by experiments.
 [S0021-8979(96)13608-1]

I. INTRODUCTION

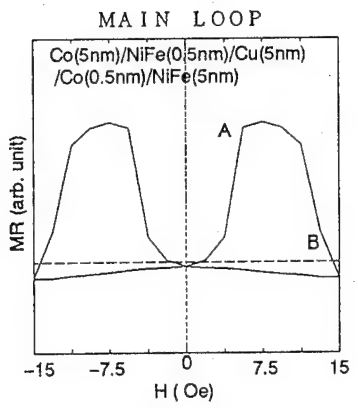
The discovery of giant magnetoresistance (GMR) in magnetic multilayers has led to a large number of studies[1–3] on the giant magnetoresistance system for application. Usually, devices exhibiting giant magnetoresistance are under consideration and development as magnetic field sensors, for instance, in read-back magnetic heads used in magnetic recording technology. Differing from these studies for sensing purposes, we found a storage mechanism in GMR materials and succeeded in fabricating a binary GMR memory.[4] Moreover, the fact that the magnetizations in two ferromagnetic layers of weakly coupled multilayer act independently makes it possible to realize a quarternary data storage by making use of the four combinations of magnetizations. The different coercivities between the two ferromagnetic layers can be just employed to magnetize or remagnetize the two layers, respectively. In this article, we will discuss the mechanism, design, and experimental results of the quarternary GMR memory.

II. QUARTERNARY STORAGE MECHANISM

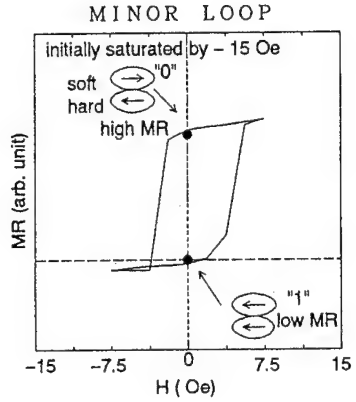
From the viewpoint of application, weakly coupled GMR multilayer,[5,6] with two ferromagnetic components possessing different coercivities, is a hopeful candidate because of its low switching field (smaller than 10 Oe) and relatively large magnetoresistance (MR) ratio (4%–17%). We made samples of Co (5 nm)/NiFe (0.5 nm)/Cu (5 nm)/Co (0.5 nm)/NiFe (5 nm) by rf sputtering. The thinner NiFe and Co layers were formed to enhance interfacial scattering, which increases the MR ratio two times as large as that of Co (5 nm)/Cu (5 nm)/NiFe (5 nm), and the sandwich structure is comprised of two ferromagnetic components: the hard component Co (5 nm)/NiFe (0.5 nm) and the soft component Co (0.5 nm)/NiFe (5 nm). Uniaxial anisotropy, important both for memory storage and for the way that a bit is selected, is induced by a magnetic field of 15.5 Oe applied in the plane of the films during sputtering. Thereafter, an ac magnetic field anneal (300 °C×80 Oe×2 h) was executed and it was found that the ac magnetic thermal treatment helps to increase the slope of the $R(H)$ curve.

The resistance-field transfer curves $R(H)$ of these samples under exciting field of various strength were investigated. The applied magnetic field is along the plane of the samples. The switchings of the double ferromagnetic layers with different coercivities gives rise to the "double-hump" shaped curve of the main loop depicted in Fig. 1(a), where the applied field is between ±15 Oe. From Fig. 1(a) we can observe two obvious switching points: point A corresponds to the switching field (about 5.5 Oe) of the soft component and point B corresponds to the switching field (about 14 Oe) of the hard component. Figures 1(b) and 1(c) illustrate the $R(H)$ response's minor loop for the same sample operating in the mode in which only the soft component is switched by limiting an applied field between ±7.5 Oe. In Fig. 1(b) the element is initially saturated to the "negative" direction by a field of −15 Oe, while in Fig. 1(c) it is initially saturated to the "plus" direction by +15 Oe.

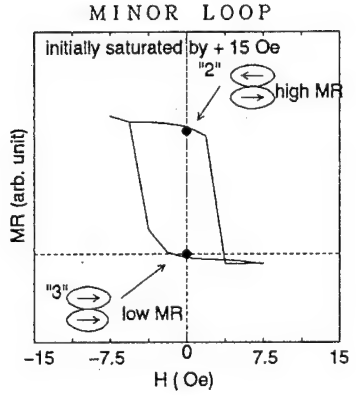
Theoretical analysis[7] indicates that the minor loop is primarily determined by the hysteresis of the soft component. But we found that these minor loops were shifted since the initially polarized hard component blocks the spins of the soft component through the ferromagnetic exchange interaction. In this case, the exchange field is about 1.5 Oe, smaller than the coercivity (4 Oe) of the soft component. So that the remanent state of the soft component cannot be influenced, although the exchange field is present. For this reason this type of GMR material is called weakly coupled. It is apparent that the soft component will act independently as long as the exchange field is smaller than its coercivity, and the lower the exchange field becomes the more stable the working point is. In fact, the exchange field will decrease with increasing Cu's thickness but, unfortunately, the MR ratio will also decrease with increasing Cu's thickness. We have to balance these two requirements and we found that for a Cu thickness of about 5 nm, the MR change ratio stays large and the exchange field is still relatively small. As a result, there are four stable states for the sample we used when the applied field is zero, which correspond to four combinations of



(a)Main loop in which the applied field is between ±15 Oe.



(b)Minor loop in which the applied field is between ±7.5 Oe but the sample is initially saturated by the field of −15 Oe.



(c)Minor loop in which the applied field is between ±7.5 Oe but the sample is initially saturated by the field of +15 Oe.

FIG. 1. Quarternary storage mechanism.

magnetizations, as shown in Fig. 1. In GMR multilayers the resistance is lower when alternate magnetizations are parallel than when they are antiparallel. This rule is also shown in the same figure.

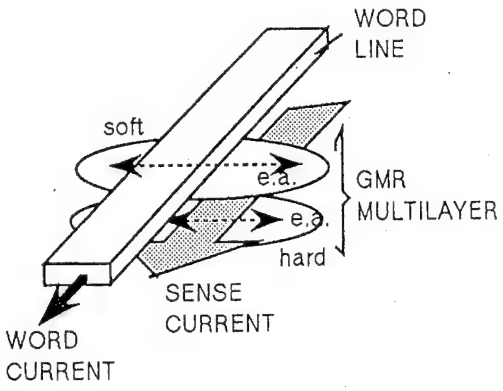


FIG. 2. Schematic diagram for quarternary memory cell.

The above description gives a quarternary storage mechanism. For any uniaxial anisotropic ferromagnetic film, there are two stable states: the magnetization will tend to point in one of two easy directions, and the fact that the magnetizations in two ferromagnetic layers act independently in weakly coupled sandwiches makes it possible to use these directions to represent a quarternary data.

III. EXPERIMENTAL RESULTS

We have fabricated a one-bit quarternary GMR memory cell with a storage/sense line and a word line on to neoceramic substrate. Its schematic diagram is illustrated in Fig. 2. A brief outline of the fabrication method is given in the following. The material of the storage/sense line was the GMR multilayer, as described in the above section. This sandwiches were patterned into a rectangular shape whose size is 5 μm×10 μm by optical lithography and ion milling techniques. The storage/sense line was covered with a 0.5 μm thick SiO_2 layer, which served as an insulator, and a Cr (10 nm)/Cu (1000 nm)/Cr (30 nm) multilayer was deposited onto the SiO_2 and patterned into the word line. Contact holes were etched in the SiO_2 by a lift-off technique, followed by the structuring of electrodes for the storage/sense line. The use of the Cr/Cu/Cr structure was to make mechanically strong contacts. The word line was parallel to the storage/sense line, and both of them were orthogonal to the easy axis because the preferred easy axis is chosen to lie along the transverse direction of the GMR stripe. A combination of a sense current flowing along the GMR line itself (the sense current is assumed to pass primarily through the intermediate layer Cu because of its high conductivity), together with an exciting current flowing along the word line, make it possible for a 2D selective storage/sense function to be realized.

The different coercivities of the two ferromagnetic layers can be used to polarize the two layers, separately. In our experiments, we first use a strong magnetic field of 15 Oe to polarize the hard component whose switching field is 14 Oeand then use a weak field of 7.5 Oe to polarize the soft

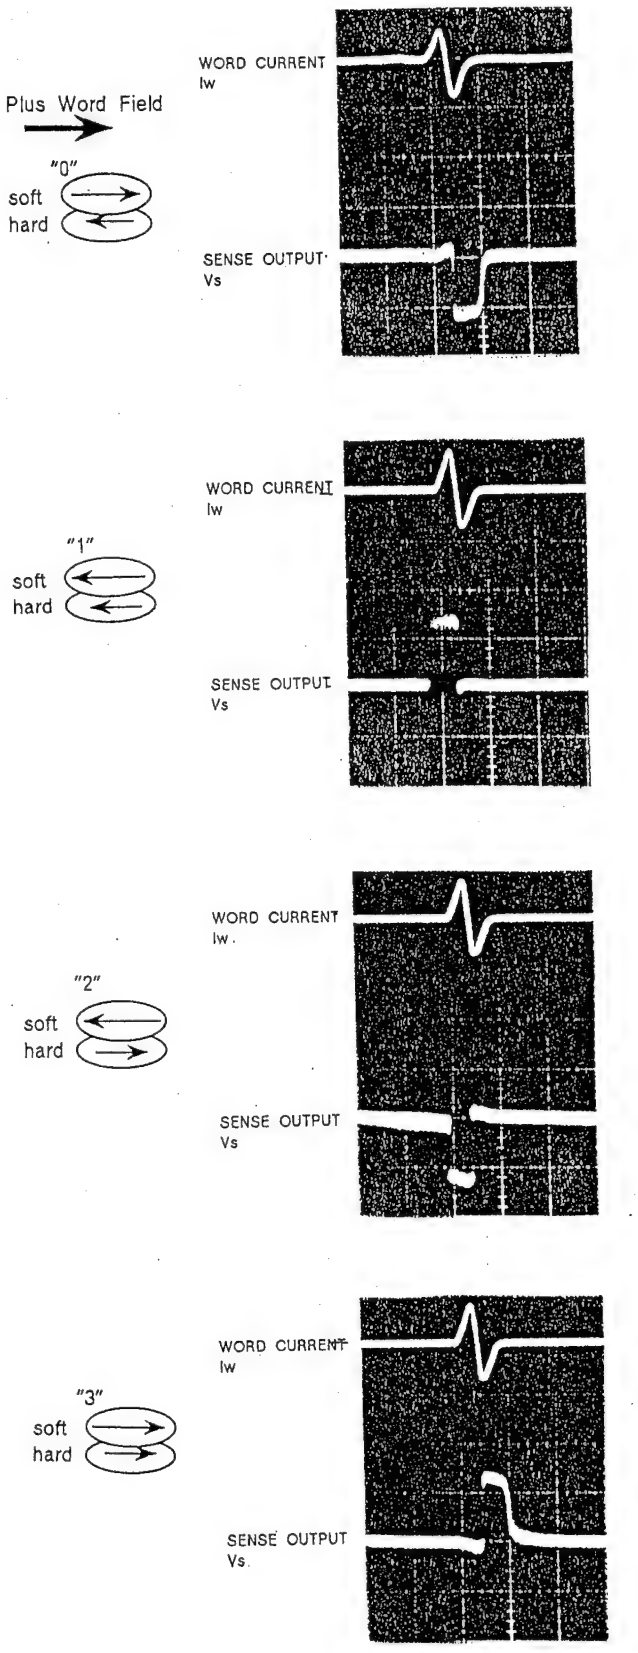

FIG. 3. Reading timing sequences. The vertical scale for sense voltage output Vs is 5 mV/div.

component. (In this mode the remanent magnetization of the hard component cannot be altered but the soft component can be switched since its switching field is about 5.5 Oe.)

For reading method, a bipolar excitation pulse current was used, and the strength of the corresponding magnetic field is limited to be smaller even than the coercivity of the soft component to confirm a nondestructive readout (NDRO) capability. It is easy to understand that the magnetization parallel to the excitation field could not rotate while the magnetization anti-parallel could. When a bipolar pulse word current Iw passes through the word line, a voltage-pulse combination should appear across the GMR line, in which a plus pulse corresponds to increasing resistance, and a minus pulse corresponds to decreasing resistance, and zero voltage corresponds to no resistance change. Figure 3 is the measured result, in which four kinds of pulse combinations corresponding to the remanent states arise, and therefore data readout can be performed by monitoring these pulse combinations against the plus–minus word current (field). The word current Iw is 15 mA and the sense current is 5 mA. The voltage difference between plus and minus pulses is 12 mV. Furthermore, the continuous test indicates that a stable readout waveform can be held for a long time. That is to say, this element has NDRO ability, and an additional rewrite operation after reading is not needed.

IV. CONCLUSIONS

We succeeded in fabricating a quarternary memory cell. In this structure, the multilayer is used not only for data storing but also for data sensing. The major advantage of the quarternary GMR memory is that we can simply double its capacity compared with conventional binary memory. NDRO capability was also confirmed.

Important factors included in nondestructive readout of GMR MRAM (abstract)

Y. Nakamura and Z. Wang
Research Institute of Elect. Communication, Tohoku University, Sendai 980, Japan

We proposed a new type of magnetoresistive random access memory (MRAM) using a weakly coupled GMR effect. It operates on the general principle of storing a binary digit in hard component and sensing its remanent state by switching the soft component in such a way that the magnetic state of the hard component is unaltered.[1] It is believed that this structure could have nondestructive readout (NDRO) characteristics. However, in experiments we found that NDRO was not always achieved; i.e., NDRO was dependent on the polarity of the excitation field. We take an example for mode "0" (corresponding to a + remanent state). Although tests involving 3×10^8 plus excitation pulses indicated that the element was still stable, stability against minus disturb pulses could not be expected. The remanent state of 0 was degrading gradually and was finally destroyed after nenormous numbers of readout switching. An analytical model, in which the hard component follows the Rayleigh law, can explain the above phenomenon. It is because the irreversible magnetization processes cause disturbed states (0′ or 1′). Obviously the worst case for mode 0 is being excited by continous minus pulses whereas the worst case for mode 1 is being excited by continous plus pulses. We think that two methods will be effective to eliminate the unstability. One is to obtain a rectangular hysteresis loop for the hard component. The other is to imporve the excitation method, for example, to employ bipolar pulses for excitation signals. [S0021-8979(96)46708-4]

Material grooving has been proposed as a possible technique for stabilizing magnetic domains in a thin film. Grooving changes the local properties of the material, and can change the stability range of domains in the vicinity of a groove.[1] In this work, the effects of material grooving on the collapse fields of magnetic domains were simulated, measured, and interpreted magnetostatically for thin, epitaxial $(YBiGdHoCa)_3(FeGeSi)_5O_{12}$ and $(YBiSmLuCa)_3(FeGaSi)_5O_{12}$ garnet films which were 2 μm thick. The domain collapse field (H_{co}) was simulated with a recently developed computer code based on a simplified model of domain structure.[2] Simulation results indicated that H_{co} varied linearly with groove depth (δ) increasing for groove widths (ω) <20 μm, and decreasing for $\omega>20$ μm. As groove widths increased, H_{co} is a maximum when ω is near the domain diameter. These trends correspond to the effect induced by the demagnetizing fields from the groove bottom and edges, respectively. The grooved film is modeled as an ungrooved film of reduced film thickness upon which were placed two semi-infinite magnetized film layers separated by ω. Experimental measurement of H_{co} was performed by magneto–optic observation on an array of grooves at pitches of 4–8 μm. δ from 0.2–0.6 μm, and ω from 1.2 to 2.6 μm. The experimental data were in good agreement with the simulated values and magnetostatic interpretation. [S0021-8979(96)46808-8]

Fundamental studies of stripe-domain chopping in the presence of magnetic fields

K. J. Fogarty, K. Matsuyama, and H. Asada
Electrical Engineering Department, Kyushu University 36, Fukuoka, Japan

W. W. Clegg
Electrical Engineering Department, Manchester University, Manchester, United Kingdom

The effects of externally uniform applied orthogonal and parallel in-plane magnetic fields on the stripe-chopping characteristics and negative vertical Bloch line replication probability have been studied experimentally and by numerical simulation on a 5 μm bubble film. The orthogonal and parallel in-plane fields on the stripe domain were varied from -50 to 50 Oe and -9 to 9 Oe, respectively, to represent actual working device parameters. The numerical simulation results agree with the experimental data, confirming the suppression of horizontal Bloch line nucleation by the external-uniform in-plane fields and the in-plane field components of the chopping conductor.
 [S0021-8979(96)13708-8]

The chopping detection of vertical Bloch lines (VBL) is the major impediment for all of the VBL memory processes, yet full fundamental studies have never been performed in terms of large uniform-orthogonal in-plane fields and the probability of the chopped parts of an $S=0$ stripe domain still being an $S=0$ state for positive and negative in-plane fields. Nakada *et al.*[1] showed that the cause and the reproducibility can be understood in the relation of the in-plane wall magnetization to the in-plane field components of the chopping conductor (CC). The in-plane field parallel to the in-plane wall magnetization increases the Bloch line (BL) nucleation velocity,[2] effectually reducing the presence of the horizontal Bloch lines (HBLs). However, the in-plane field orthogonal to the stripe domain wall changes the critical velocity for BL instability and the actual position of the critical point itself.[2,3] The critical points are Bloch-line nucleation centers. It is this changing of the critical point that should aid the suppression of the HBLs in the chopping process.

The film characteristics are as follows: $4\pi Ms=187$ G, $\alpha=0.11$, $Ku=8200$ erg/cm^3, $\gamma=1.76\times10^7$/(Oe s), $A=1.88\times10^{-7}$ erg/cm, and $h=4.12$ μm. Figure 1 shows a schematic of the chip configuration. The stripe domain is stabilized in a loop conductor field of 6.4 Oe and a mid-range external bias field of 58 Oe.[4] The CC is 1.8 μm above the bubble garnet with a gap, width, and thickness of 4, 6, and 1.01 μm, respectively. The externally applied orthogonal, Hy, and parallel, Hx, in-plane field ranges applied to the stripe domain are -50 to 50 Oe and -9 to 9 Oe, respectively. The stripe domain is chopped with a triangular pulse of fixed rise and fall times of 100 ns, and at the threshold current value (100–110 mA) that successfully chops the stripe domain for each in-plane field value. The chopped parts of the initial $S=0$ stripe domain to the left and to the right of the CC are rocked[5] and their rocking states determined as being $S=0$, positive or negative. The minimum number of repetitions that were made to show the probability of specific chopping characteristics was 30.

The simulation method used is that used by Fujita *et al.*[6] which is a (q,ϕ) model of a side view through the film thickness. To show the physical effects of the in-plane field components of the CC on the wall structure, the wall structures at 0, ±1, and ±2 μm, from the center of the CC were simulated. The material parameters for the simulation are the actual physical characteristics of the 5 μm $(YSmLuCa)_3(GeFe)_5O_{12}$ garnet film as given above.

Considering the positive $(+ve)$ Hx simulation conditions (with reference to Fig. 1), generally the dynamic HBLs are formed at the bottom and the top surface of the left-hand side (LHS) and the right-hand side (RHS) Bloch walls, respectively. This is due to the gyrotropic force induced by the chopping field, as shown in Fig. 2, for curves 3a and 3b. Lines 3a and 3b, etc., in Fig. 2, are the magnetization structures of the RHS and LHS Bloch walls, respectively. However, due to the CC being located on the bottom surface, HBLs will normally be formed from here, and the HBL will generate more easily on the LHS of the CC as the in-plane field component here is opposite to the in-plane wall magnetization, reducing the Bloch line nucleation velocity, as suggested in curves 2a and 2b. The application of the Hy field to the stripe domain changes the static wall profiles as reported by Kosiński *et al.*,[3,7,8] but the wall profiles are different for each wall as their surface magnetizations are opposite to each other, therefore their respective critical points will change, as in curves 1a and 1b. The critical points for lines 1a and 1b, are the two depths from each film surface at which, because of the planar components of demagnetizing or external fields, the wall structure changes from truly

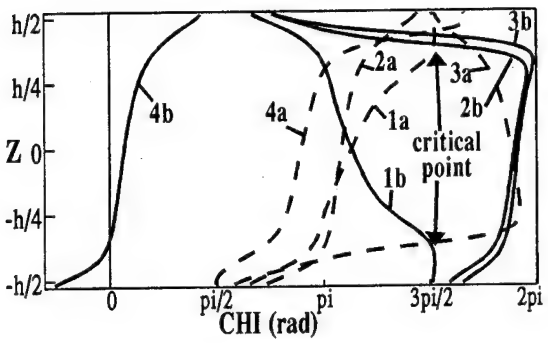

FIG. 2. Wall-magnetization distributions for the RHS and LHS Bloch walls. For all of the curves, $Hx=3$ Oe. $Hy=10$ Oe, curves 1a and 1b: $t=0$ s, at the center of the CC. $Hy=10$ Oe, curves 2a and 2b and curves 3a and 3b: $t=135$ ns, -1 μm and -2 μm from the center of the CC, respectively. $Hy=-50$ Oe, curves 4a and 4b: $t=135$ ns, -2 μm from the center of the CC.

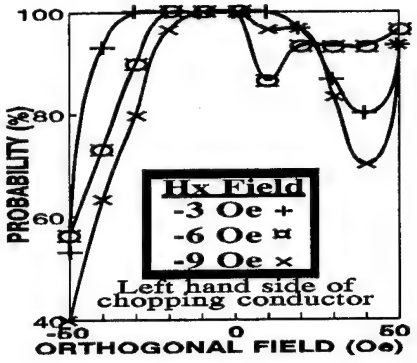

FIG. 4. Bubble $S=0$ probability for $-ve$ Hx field range on the good side.

Bloch wall to Néel type. A $+ve$ Hy field will push the critical point on the bottom surface of the LHS Bloch wall away from the surface, whereas on the upper surface the critical point will be pushed into the top surface. The opposite effect occurs in the RHS Bloch wall, and vice-versa for the negative $(-ve)$ Hy field. It is the movement of the position of the critical point into and away from the surface magnetization that causes the suppression and the acceleration of the HBL generation, respectively. Also, if the $\pm\pi/2$ magnetization around the Bloch loop is parallel to Hy, the Bloch loop should effectively sweep its area out faster. Curve 4b shows punch through from the top surface to the bottom surface due to the wall's stored momentum and the critical point's position.

Bearing in mind the above, the simulations show that at the time when the chopping current is at its peak from the start of the simulation (relaxation time of 10 ns+100/0.8 =135 ns),[12] a $-ve$ Hy field causes a complete HBL suppression even on the LHS of the CC. At $Hy=0$ Oe and $Hx=3$ Oe, HBLs are formed only on the LHS of the CC due to the gyrotropic force and the in-plane field components, but as Hy becomes more positive, the HBL nucleation is accelerated and slowly sweeps out from the LHS to the RHS of the CC, though the HBL does not actually punch through. A HBL does not appear on the RHS until $Hy=30$ Oe. As Hx increases, it reduces the effective in-plane field component of the LHS of the CC causing a slight HBL suppression at the lower Hy field values. Therefore, with a HBL being present, it will change the chopping characteristics and the S states of the bubbles. For $-ve$ Hx fields, which would invert the Bloch wall in-plane magnetization due to the $-ve$ VBLs switching their stripe domain head positions, the shape and principal behavior of the wall structure is the same for opposite Hy field values.

Figure 3 shows the simulated threshold values of Hy for the presence/absence of HBLs as a function of distance from the center of the CC for six values of Hx, showing all of the physical characteristics of the above explanation. For the $+ve$ Hx field values, below each line, there are no HBLs and vice-versa for the $-ve$ Hx field values. Point symmetry is shown in the figure for $+ve$ and $-ve$ Hx.

Referring to Fig. 1, the RHS of the CC, the in-plane wall magnetization and the direction of Hx, this is referred to as the "good" side where no errors should occur[1] and the LHS is the "bad" side. The reverse is realized for the $-ve$ Hx field.

Figures 4 and 5 show the percentages of success for the LHS and RHS $S=0$ bubbles after chopping, for the $-ve$ and $+ve$ Hx fields, respectively. The best of the error-free

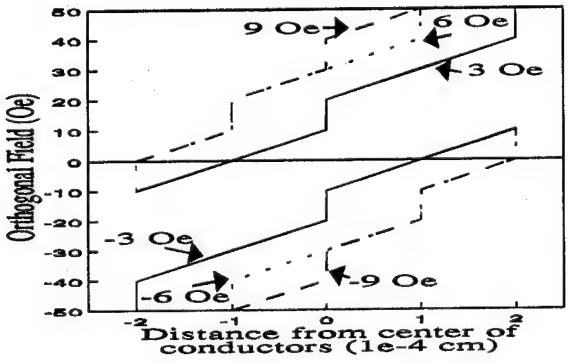

FIG. 3. Simulated threshold values of Hy for the presence/absence of HBLs as a function of distance from the center of the CC for six values of Hx.

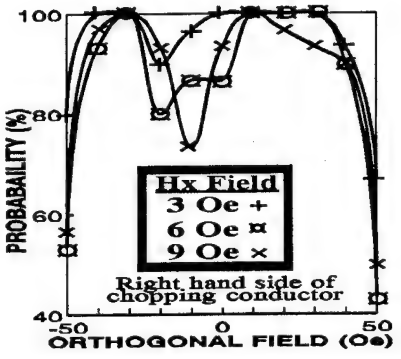

FIG. 5. Bubble $S=0$ probability for $+ve$ Hx field range on the good side.

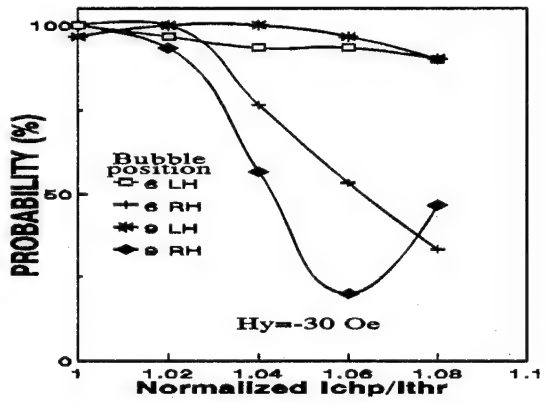

FIG. 6. Effects of larger currents on bubble probability on the LHS and RHS of the CC at $Hy=-30$ Oe for $Hx=6$ Oe and 9 Oe.

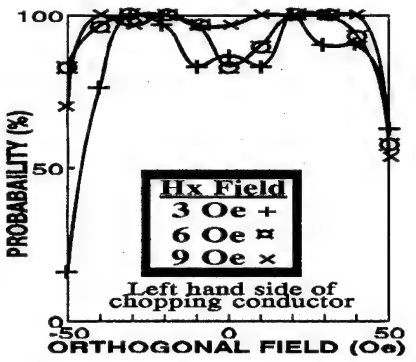

FIG. 7. Bubble $S=0$ probability for $+ve$ Hx field range on the bad side.

chopping is seen in the Hy ranges -30 to 10 Oe for Hx equal to -3 Oe, and 0 to 30 Oe for Hx equal to $+3$ Oe, due to the suppression of the dynamic HBL formation by the in-plane field components of the CC. Figures 4 and 5 also show a mirror symmetrical effect for the opposite in-plane fields. In Fig. 5, in the Hy range 0 to -20 Oe, they form various minimums but, at -30 and -40 Oe, the bubble percentages are between 90% and 100%, indicating HBL suppression. For the $-ve$ Hx and $-ve$ Hy field values, as Hx increases in magnitude, the $S=0$ bubble percentage starts to decrease. Similarly, Fig. 5 depicts the same effect for the $+ve$ Hy and $+ve$ Hx field values. Iwata *et al.*[9] also found that as Hx is applied, the experimental results gradually deviate from the theory, but we are unable to propose a cause of this. The origin may be due to the cubic anisotropy of the garnet. The large minimums in the figures occur for the current being too large, but these are the threshold values which consistently chop the stripe domain. Figure 6 shows these effects on the $S=0$ bubble percentage at $Hy=-30$ Oe and $Hx=6$ Oe and 9 Oe as a function of current. The minimum threshold currents (I_{thr}) at $Hy=-30$ Oe and 30 Oe, are 100 and 108 mA, respectively. The simulations showed total HBL suppression for the different currents for the RH bubbles (the good side), but experimentally the $S=0$ bubble percentage decreases drastically as the current increases. The experimental and simulation results are comparable at $Hy=30$ Oe for the RH bubbles, since the simulation showed no HBLs on the RHS, and yet the LH $S=0$ bubble percentage is greater than that for all of the RH bubbles. The reason may be that as the chopping current increases, increasing the effective $+ve$ Hx in-plane field at the RHS part of the CC, it induces the same errors that are due to a large Hx. Also, a larger chopping current would increase the wall velocity and the gyrotropic force causing the HBLs to generate faster, though the simulations did not show this. The strong effective Hx field and the large Hy field could flip the VBL magnetization, or Bloch point (BP) injection might occur after chopping. An analogy for the BP injection can be made with the experiment of Beaulieu *et al.*[10] on the contracting movement of the domain heads of the chopped parts of the stripe domain to the Hy field. The experiment in Ref. 10 has the in-plane field applied perpendicular to the gradient drive field that is rocking the bubble and induces bubble state conversion via BP injection. The velocities of the stripe domain heads are not known, and therefore a relation with the Bloch line nucleation velocity[11] cannot, at this stage, be made. Figure 7 shows a very good $S=0$ bubble percentage for the supposedly bad side of the CC for increasing Hx and Hy fields, confirming the suppression of the HBLs as shown by the simulations.

Although there remain discrepancies at high values of planar fields, thus requiring further work, the broad results of numerical simulations are borne out by experimental results.

The Japanese government is thanked for the award of a Monbusho scholarship to enable K.F. to further his research studies in Japan.

Micromagnetic study on write operation in submicron magnetic random access memory cell

H. Asada, K. Matsuyama, and K. Taniguchi
Department of Electrical Engineering, Kyushu University 36, Fukuoka 812, Japan

In a spin-valve random access memory, the binary bit states of the storage cell are determined by the magnetization direction in the free magnetic layer. The write operation of a submicron memory cell element has been studied by a micromagnetic computation based on an energy minimization scheme, which aids in the chip design. The magnetization of the binary bit states in the element was found to take a single domain structure having the opposite direction of the long-axis component. The mean long-axis component of magnetization of each binary state was ± 0.97 without external fields. The selective switching of the bit state in the element was performed by the write currents applied into the two level conductors overlying the element for various conditions. The influence of the write currents to the neighboring element on a two-dimensional memory array with a 1×1 μm pitch was also simulated, in order to confirm the selective switching of the memory element. It was found that the selective write current amplitude decreased with an increasing assist current amplitude and the range was extended by the large difference of the transverse magnetic field between the selected and neighboring element. The effect of the exchange interaction from the pinned magnetic layer on the write operation was also discussed. © *1996 American Institute of Physics.* [S0021-8979(96)16808-X]

I. INTRODUCTION

Using a giant magnetoresistance material, a nonvolatile random access memory has been proposed.[1,2] In the memory cells proposed by D. D. Tang *et al.*,[2] the binary states of the storage cell are determined by the magnetization direction in the free magnetic layer, which offer a static signal depending upon the magnetoresistive variation caused by the parallel and antiparallel states between both the pinned and the free magnetic layers. The write operation of the bit information is performed by applying the pulse currents into the two-dimensional array of conductors overlying the storage cell. Micromagnetic simulation is useful to investigate the bit states before and after applying the write currents, which aids in the chip design and development of the memory operation. Two-dimensional micromagnetic simulation results of the bit state change performed by the uniform in-plane fields have been reported.[3]

In the present work, the write operation of a submicron memory cell element has been studied by the micromagnetic computation representing a three-dimensional magnetization direction, based on an energy minimization scheme, for various cases. The effect of an uniform in-plane field, which corresponds to the exchange interaction from the pinned magnetic layer, on the write operation has also been studied.

II. RESULTS AND DISCUSSION

A schematic memory bit cell configuration assumed in the simulation is illustrated in Fig. 1. Since the storage cell was constituted with a noncoupled spin valve film, the magnetization state in the free layer was computed by the micromagnetic simulation representing a three-dimensional magnetization direction. A memory cell element of 0.5×0.25 μm^2 size was discretized into a two-dimensional array ($32\times16\times1$) of a tetragonal grid, assuming that the magnetization distribution was uniform through the thickness of the material due to the negligible film thickness. For calculating the magnetization distribution of each grid, the total magnetic energy, written as the sum of the exchange, anisotropy and demagnetizing energy terms, was minimized by using the conjugate gradient method.[4] The following standard material parameters for permalloy were assumed as the free magnetic layer; saturation induction $4\pi M = 10^4$ G, uniaxial anisotropy $K_u = 10^3$ erg/cm^3 ($H_k = 2.5$ Oe), exchange constant $A = 10^{-6}$ erg/cm and film thickness $h = 50$ Å. The selective write operation was performed by applying the pulse currents into the two level conductors overlying the element, which consist of the write and assist conductors located along the short- and long-axis direction of the element, respectively. The magnetization direction in the free magnetic layer is determined by the direction of the longitudinal component of the magnetic field generated by the write current, I_w. The write conductor width and thickness were 0.7 and 0.3 μm, respectively, and the assist conductor width and thickness were 0.5 and 0.3 μm, respectively. The spacer thickness between the free magnetic layer surface and the conductors were 0.1 μm for the first layer and 0.5 μm for the second layer. The switching of the bit state is performed by the magnetization rotating towards the opposite state by the longitudinal magnetic field from the write current, I_w, with the assistance of the transverse magnetic field from the assist current, I_a.

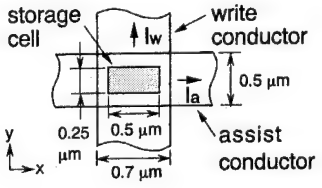

FIG. 1. Schematic memory cell element.

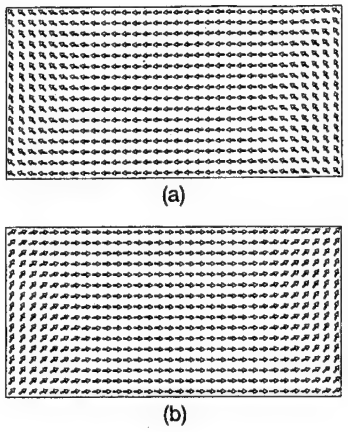

FIG. 2. Magnetization states in the free magnetic layer of each binary state after applying the (a) positive and (b) negative write currents.

Figure 2 shows the simulation results of the magnetization direction in the element without external magnetic fields after applying (a) positive and (b) negative currents into the write conductor. The arrows indicate the magnetization direction on each calculation grid. The easy axis direction of anisotropy was along the long-axis direction of the element. As shown in the figures, though the magnetization around the long-axis edges inclines due to the demagnetizing field, the long-axis component of each magnetization for (a) and (b) are opposite to each other. Both magnetization states take the single domain structure, which is suitable for the binary bit states of the storage cell. The relative amount of the exchange energy compared to that of the magnetostatic energy becomes dominant in the fine pattern with the thin film thickness. The mean long-axis component of each binary state, which contributes to the magnetoresistive variation, is ± 0.97.

For estimating the amplitudes of the write currents, the bit state switching from the magnetization direction as shown in Fig. 2(a) to that in Fig. 2(b) by the uniform transverse and longitudinal fields were computed. Figure 3 shows the threshold amplitude of the longitudinal field, H_l, with various transverse fields, H_t. The H_l value, needed to switch the bit state, decreases with increasing H_t, which enables the selective switching. However, the gradient of the threshold

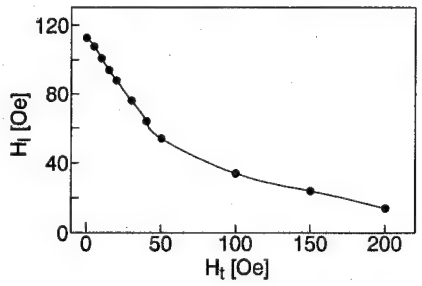

FIG. 3. Threshold amplitude of the longitudinal magnetic field, H_l, for the state switching as a function of the transverse field, H_t.

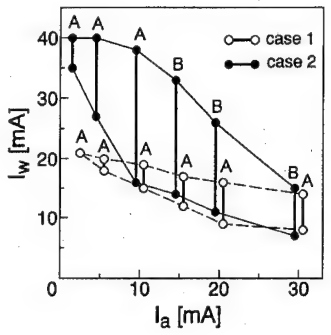

FIG. 4. Dependence of the write current range, I_w, of the selective switching upon the assist current, I_a, for both the case 1 (first layer, write conductor; second layer, assist conductor) and case 2 (first layer, assist conductor; second layer, write conductor).

curve, H_l/H_t, decreases with increasing H_t. The gradients are 1.2 at $H_t=30$ Oe and 0.2 at $H_t=100$ Oe.

The selective write operation was studied by calculating the bit state switching under the application of the write currents. We also simulated the influence of the write currents to a neighboring element on a two-dimensional memory array with 1×1 μm pitch, which achieves a density of 10^8 bit/cm^2, in order to confirm the selective switching of the memory element. The dependence of the selective write current range, I_w, upon the assist current, I_a, is shown in Fig. 4. Open circles connected with the line indicate the selective switching range when the write and assist currents were applied into the first and second conductor layers (case 1), respectively. In this case, the averaged longitudinal magnetic fields due to I_w over the different memory elements are 5.2 Oe/mA in the selected element and 0.55 Oe/mA in the neighboring element aligned in the long-axis direction. The averaged transverse magnetic fields due to I_a are 2.9 Oe/mA in the selected element and 0.94 Oe/mA in the neighboring element aligned in the short-axis direction. Closed circles also indicate the selective switching range when the write and assist currents were applied into the second and first conductors (case 2). The marks A and B in the figure indicate the error modes of the upper threshold for the selective switching, which were limited by the occurrence of the switching in the neighboring element aligned in the short-axis (mark A) and long-axis (mark B) directions, respectively. For case 1, the lower threshold of I_w decreases and the current range increases with increasing I_a. Below $I_a=20$ mA, though the lower threshold of I_w for case 2 is higher than that for case 1, the current range for case 2 is fairly larger due to the improvement of the upper threshold. These results show that the selective switching current range is extended by the large difference of the transverse component of the magnetic field between the selected and neighboring elements. For case 2, however, the abrupt degradation of the upper threshold was observed for I_a greater than 15 mA caused by the occurrence of error B, where the large amplitude of the transverse magnetic field was generated. The obtained current ranges are $I_w=15-19$ mA at $I_a=10$ mA and $I_w=9-16$ mA at $I_a=20$ mA for case 1, and $I_w=16-38$ mA at $I_a=10$ mA and $I_w=11-26$ mA at $I_a=20$ mA for case 2.

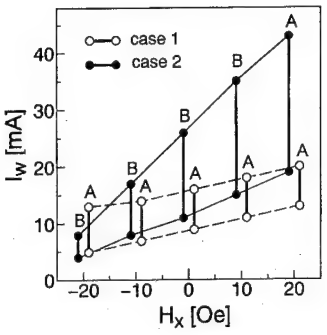

FIG. 5. Dependence of the write current range, I_w, of the selective switching upon the uniform longitudinal magnetic field, H_x, for both the case 1 (first layer, write conductor; second layer, assist conductor) and case 2 (first layer, assist conductor; second layer, write conductor).

We also investigated the influence of the direction and amplitude of the anisotropy to the selective switching. It was found that the I_w amplitude can decrease without any degradation of the range for each I_a, when the easy axis direction of the anisotropy was assumed along the short-axis direction of the element. Furthermore the amplitude of anisotropy increased.

In order to study the effect of the exchange interaction from the pinned magnetic layer on the write operation, we simulated the bit state switching by the write currents under the conditions of an uniform in-plane field, H_x, along the long-axis direction for simplification of the exchange interaction. Simulation results are as shown in Fig. 5. The open and closed circles connected with the line indicate the selective switching range of I_w for case 1 and case 2, respectively, which are the same as in Fig. 4. The assist current, I_a, was 20 mA. When the magnetization directions of the free and pinned layers are parallel to each other, this defines the positive H_x field direction, which suppresses the bit state switching. And for the negative H_x field direction, the magnetization directions are antiparallel to each other, which supports the switching. For case 1, the I_w amplitude varied as 2 mA per 10 Oe, and the current ranges for each H_x are the same. The influence of H_x to the bit state switching in the neighboring element aligned in the long-axis direction is significantly larger than that in the neighboring element aligned in the short-axis direction. Therefore, for case 2, the effect of H_x on the upper threshold of I_w, which is limited by the occurrence of error B, is much stronger, as clearly seen in the figure. The most serious case for the selective switching is the parallel state in the selected element and the antiparallel state in the neighboring element. The selective current ranges decrease to $I_w = 11-14$ mA for case 1 and $I_w = 15-17$ mA for case 2 with the exchange interaction field of 10 Oe, which corresponds to the common I_w ranges at $H_x = \pm 10$ Oe as in the figure.

III. CONCLUSIONS

The write operation in a submicron memory cell has been investigated by the micromagnetic computation. The magnetization of the binary bit states in the free magnetic layer was found to take a single domain structure having the opposite long-axis component. The selective switching was performed by write currents applied into the two level conductors overlying the element. It was found that the selective write current amplitude decreased with increasing assist current amplitude and the range was extended by the large difference of the transverse field amplitude between the selected and neighboring elements. However, the large amplitude of the transverse magnetic field from the assist current caused the abrupt degradation of the upper threshold for the selective switching. The effect of the exchange interaction from the pinned magnetic layer on the write operation was studied and clarified.

Analytical model in a weakly coupled sandwich for memory purposes

Zhigang Wang[a] and Yoshihisa Nakamura
Research Institute of Electrical Communication, Tohoku University, Sendai 980, Japan

A simple analytical model explains giant magnetoresistive properties in a weakly coupled sandwich with two magnetic components. The model describes in detail a new storage mechanism in which the minor loop's slope depends on its past magnetic histories. A new type of solid-state giant magnetoresistance memory based upon this mechanism has been realized by experiments. Furthermore, some important factors included in nondestructive readout capability are also analyzed by this model. © *1996 American Institute of Physics.* [S0021-8979(96)13808-4]

I. INTRODUCTION

Results obtained on giant magnetoresistance (GMR) materials show increases in magnetoresisce of a factor of 10 over conventional anisotropic magnetoresistance materials. Many devices based on giant magnetoresistance are under consideration and development for reproductive heads for use in magnetic tape and disk devices. In addition, a storage mechanism in GMR materials itself has been found recently and the feasibility of a new type of solid-state memory using weakly coupled GMR effect has been examined by experiments.[1]

The present study presents a simple analytical model for the field dependence of the GMR effect in both full-field and small-field cases. The model permits a determination of the ferromagnetic coupling energy through conducting spacers. The model is essentially an extension of Stoner–Wohlfarth theory with an included small-field hysteresis property for the hard magnetic component in the form articulated by Rayleigh. The model also simply presents a description of the above-mentioned new storage mechanism. The so-called "distortion" phenomenon, which can be observed in the experimental transfer curves, can be explained confidently with the present model.

II. MODEL DESCRIPTION

We established an engineering model to demonstrate the giant magnetoresistive properties in a weakly coupled sandwich. The model is based on the coherent rotation and uniaxial anisotropy assumptions. Because of the flux closure configuration of the sandwich, the demagnetizing field perpendicular to the length is strongly reduced compared to those obtained from a single layer structure. As a result, multiple magnetic domain formation could be reduced and the sandwich structure will behave more in the manner of a single domain ferromagnetic layer. Hence the consideration that the switching characteristics of the films behave like a single domain is reasonable. We consider two ferromagnetic components of identical thickness having the uniaxial anisotropy (Ku_1 and Ku_2) with easy axes parallel to each other, as shown in Fig. 1. The angles of the magnetizations with respect to the easy axis are θ_1 and θ_2, and the angle of applied field is ϕ. In this calculation the applied field was held constant at an angle of 45° for the consideration of 2D memory cell selection application.[1,2] The parameters are taken as experimentally measured:[3] the anisotropic fields of the soft and the hard magnetic component are assumed as 8 and 28 Oe, respectively; the exchange coupling between the two components is assumed as ferromagnetic (parallel) coupling and its value is 2 Oe (in fact the exchange field is a function of spacer thickness and the exchange field of 2 Oe corresponds to the spacer thickness=4 nm according to the experiments). Please note that the coupling's value is so weak that it is even less than the soft component's coercivity (theoretical value is 4 Oe). For this reason this type of GMR is named as a weakly coupled one. The angles of the magnetizations in two layers are chosen such that they minimize the energy function[4] which covers the anisotropy and external field terms in the two components, respectively, and the ferromagnetic exchange term between the two components. The total energy per unit volume may then be expressed as

$$E=(\tfrac{1}{2})(E_1+E_2)+A_{12}\cos(\theta_1-\theta_2), \tag{1}$$

where $E_i=Ku_i\sin^2\theta_i-M_iH\cos(\phi-\theta_i)$, $i=1$ for the soft component and $i=2$ for the hard. A_{12} is the exchange constant and Mi is the saturation magnetization ($M_1=1000$ emu/cm^3 and $M_2=500$ emu/cm^3).

The resistance is calculated by

$$GMR(H)=G^*\sin^2\frac{\theta_1(H)-\theta_2(H)}{2}, \tag{2}$$

where G is the coefficient of the GMR effect.

We calculated the resistance versus applied field $R(H)$ transfer curves under excitating field with various strength. The switching of the double ferromagnetic layers with different coercivities gives rise to the "double-hump" shaped

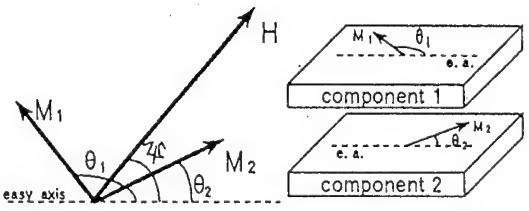

FIG. 1. The analytical model is based on the coherent rotation and uniaxial anisotropy assumptions. The angles of the magnetizations with respect to the easy axis are θ_1 and θ_2, and the angle of applied field is ϕ.

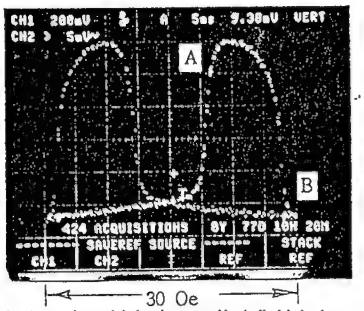
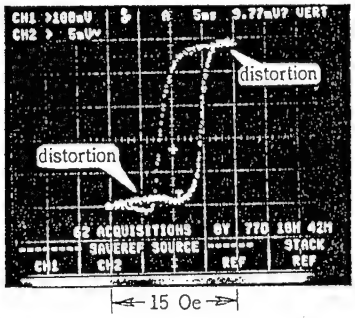
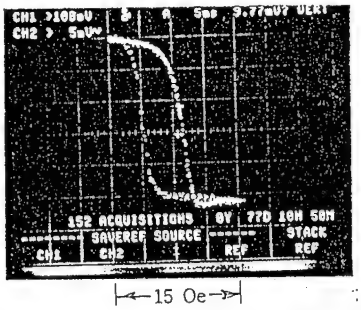
FIG. 2. The calculated resistance vs applied field $R(H)$ transfer curves under excitating field with various strength. In main loop of (a), the applied field was varied between ±15 Oe. In minor loops of (b) and (c), only the soft component is switched by applying a field between ±7.5 Oe. The initial saturated states in (b) and (c) are different as indicated in the figure.



(a)Main loop in which the applied field is between ±15 Oe.



(b)Minor loop in which the applied field is between ±7.5 Oe but the sample is initially saturated by the field of −15 Oe.

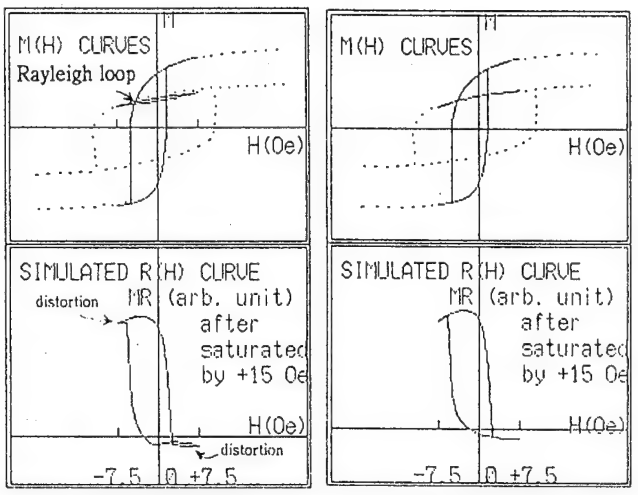


(c)Minor loop in which the applied field is between ±7.5 Oe but the sample is initially saturated by the field of +15 Oe.

FIG. 3. Experimental results of Co (5 nm)/NiFe (0.5 nm)/Cu (4 nm)/Co (0.5 nm)/NiFe (5 nm). The measurement conditions are indicated in the figure.

main loop depicted in Fig. 2(a), where the applied field was varied between ±15 Oe. The two switching thresholds at point A and point B correspond to the magnetization reversals of the soft and the hard component, respectively. The magnetization in the soft component rotates in weak field below point A while that of the hard is not saturated up to point B. The sharp increase of resistance starts when the magnetization of the soft component begins to rotate (below A). The maximum of resistance is observed at the A where the direction of the soft component's magnetization has just reversed. With further increasing of the field (exceeding A), the direction of the hard component's magnetization also turns to the field direction and subsequently the resistance gradually decreases.

Figures 2(b) and 2(c) illustrate the $R(H)$ response's minor loops operating in the mode in which only the soft component is switched by applying a field between ±7.5 Oe. In



(a) with Rayleigh loop. (b) without Rayleigh loop.

FIG. 4. Comparison of $R(H)$ curves with and without Rayleigh loop. The calculation conditions are indicated in the figure.

Fig. 2(b) the element is initially saturated to the "negative" direction by a field of -15 Oe while in Fig. 2(c) it is initially saturated to the "plus" direction by $+15$ Oe. In these minor loops of small-field GMR response one can expect a shift since the initially saturated hard component blocks the spins of the soft component through the ferromagnetic exchange interaction. Figures 2(b) and 2(c) also illustrate a possible storage mechanism. The slope of the small-field response $R(H)$ (minor loop) depends on its past magnetization history. After being magnetically saturated to the negative direction the response's slope will be positive, whereas after being saturated to the plus direction the slope will be negative. Based on this property, data readout will be performed by monitoring the polarity of the voltage signal against the unipolar excitation field.

III. DISCUSSIONS

The above calculated $R(H)$ curves gives a good agreement with the experimental results shown in Fig. 3. The sample is Co (5 nm)/NiFe (0.5 nm)/Cu (4 nm)/Co (0.5 nm)/NiFe (5 nm), in which the thinner NiFe and Co layers were formed to enhance interfacial scattering.

The measured $R(H)$ curves shown in Fig. 3 illustrate the phenomenan known as distortion. It can be explained confidently with the present model. Under small-field excitation, the soft component is switched but the magnetization in the hard component should rotate along a loop in the following form articulated by Rayleigh:[5]

$$M_1 = a_1 H^2 + b_1 H + c_1, \tag{3}$$

$$M_2 = a_2 H^2 + b_2 H + c_2, \tag{4}$$

where a_i, b_i, and c_i are Rayleigh constants. As shown in Fig. 4(a), the distortion happens to the simulated $R(H)$ as expected. On the other hand, if neglecting the hysteresis,

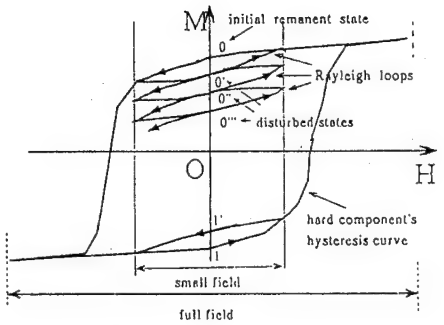


FIG. 5. The hard component's hysteresis curve with small-field Rayleigh loops. The remanent state will be degrading gradually along a series of half Rayleigh loops, whereas the rehabilitation function will be achieved along the whole Rayleigh loop.

simulations without the Rayleigh loop could not give rise to the distortion phenomenon, as shown in Fig. 4(b). In conclusion, the hard component's small-field response should be characterized by Rayleigh law.

The existence of Rayleigh loop in the hard component will be harmful to our memory design. This memory operates on the general principle of storing a binary digit in the hard component and sensing its remanent state by switching the soft component in such a way that the magnetic state of the hard component is unaltered. Initially, it was believed that this design should have a nondestructive readout (NDRO) characteristic. However, experiments indicated that NDRO was not always achieved; i.e., NDRO was dependent on the polarity of the excitation field. Consider the mode of "0" (corresponding to the + remanent state). Experimental tests involving 3×10^8 plus excitation pulses indicated that the readout wave form was still stable. However, stability against minus disturb pulses could not be achieved. We can use our model to explain the reason. Because irreversible magnetization processes (Rayleigh loop) exist, a disturbed states ($0'$ or $1'$) will possibly be caused, as shown in Fig. 5. For the mode of "0," the worst case is being excited by continuous minus pulses, whereas for "1" the worst case is being excited by continuous plus pulses. The remanent state will be degrading gradually along a series of half Rayleigh loops and finally destroyed after enormous numbers of readout switching. We think that two methods will be effective to eliminate the unstability. One is to select the hard materials with rectangular hysteresis loop. The other is to regrade the excitation method, for example, to employ bipolar exciting pulses with rehabilitation function. As shown in Fig. 5, stability against bipolar disturb pulses could be achieved because the hard component should rotate along the whole Rayleigh loop.

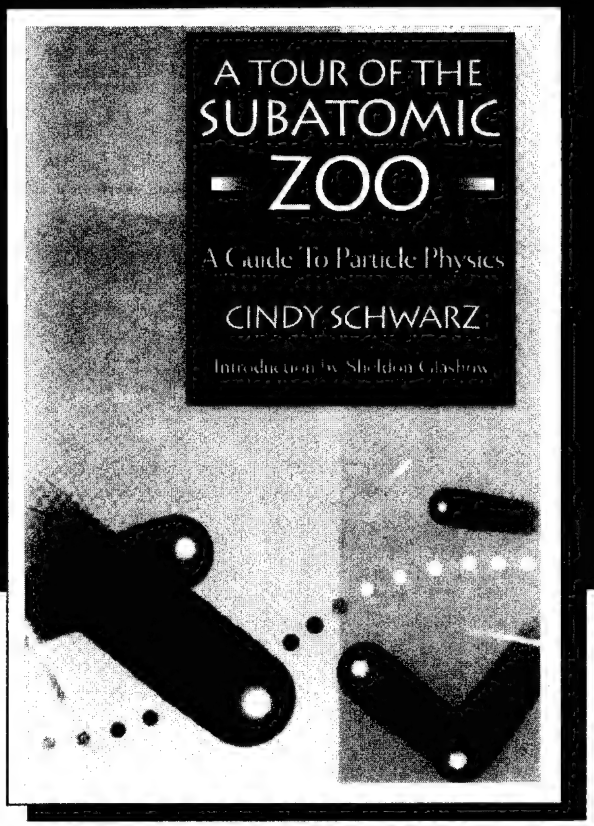
A TOUR OF THE SUBATOMIC —ZOO—

A Guide to Particle Physics

Cindy Schwarz, *Vassar College*



"A great little book, and if every physics textbook were like this, physics classrooms would be crowded."

—Scitech Book News

With hardly a mathematical formula, Ms. Schwarz clearly explains the substance of elementary particle physics. The book guides readers through the subatomic "zoo," populated by some of the most dramatic discoveries of modern science—notably, quarks, leptons, and the basic forces that govern their interactions.

Most important, this tour is conducted in terms that are easily understood—even by those who have no prior particle physics background. Each chapter in this book begins with an overview of concepts and ends with a summary and self-tests to help readers gauge their understanding.

If you're involved in teaching science to the non-scientist, think about using this book. It's been used successfully to introduce future lawyers, politicians, and parents to the ideas, terminology, and techniques of high energy physics and it's given them a unique historical perspective on the field.

1992, 128 pages, illustrated
ISBN 0-88318-954-2, paper
$25.00 ***Members $20.00**

*Members of AIP Member Societies are entitled to a 20% discount.

ORDER FORM

❑ **Yes!** Please send me ___ copy(ies) of ***A Tour of the Subatomic Zoo*** by Cindy Schwarz (ISBN 0-88318-954-2) at **$25.00 per copy ($20.00 for Members.)**

Shipping: $2.75 first book ($7.50 foreign), $.75 each additional book.

METHOD OF PAYMENT

❑ Check enclosed (payable in U.S. dollars to the **American Institute of Physics** and drawn on a bank in the United States).

❑ Charge my credit card: ❑ AMEX ❑ VISA ❑ MasterCard

Cardholder name (please print)_____

Acct. No. _____ Exp. Date _____

Signature _____

(Credit card orders not valid without signature)

Name_____

Organization_____

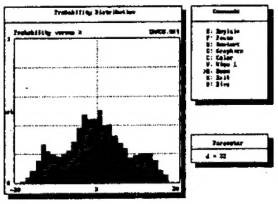
We Put the World of Physics Right at your Fingertips

Explore the science of physics with interactive educational software

Chaos Data Analyzer

by J. C. Sprott
University of Wisconsin,
G. Rowlands
University of Warwick



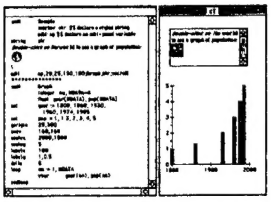
Pc

Fourteen analytical tools search for chaotic behavior in real world data and determine the properties of the underlying equations. Performs time series analysis.

$99.95; $299.95 (10-copy lab pack)

cT

by D. Andersen,
B. Sherwood,
J. Sherwood,
K. Whitley
Carnegie Mellon



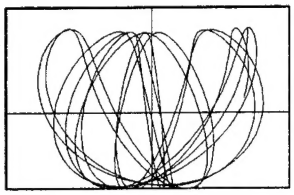
Pc Ma

cT programming language offers instant portability between Macintosh and MS-DOS computers. For expert and novice programmers.

$175 (PC or Mac), $525 (10-copy lab pack); $275 (PC/Mac combo), $825 (lab pack)

ODE Workbench

by Juan Aguirregabiria
University of the
Basque Country



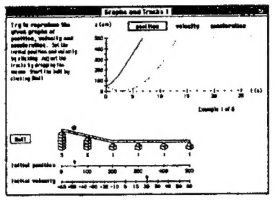
Pc

Computational tool for solving ordinary differential equations. Features user-defined graphical output for extended exploration and visualization.

$54.95; $164.95 (10-copy lab pack)

Graphs & Tracks

by David Trowbridge
Microsoft
Corporation



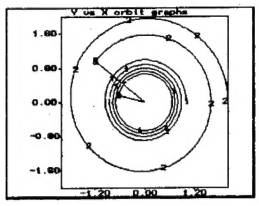
Pc Ma

Goal-oriented simulation underscores the connection between animated motion and graphs using an inclined track and ball scenario.

$79.95; $239.95 (10-copy lab pack)

Dynamic Analyzer

by Roger Sipson
Moorhead State
University



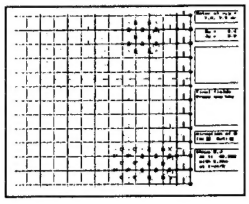
Pc

Interact with 22 common linear and nonlinear physical systems and view the results simultaneously in graphs and animations. Over 30 different scenarios are included.

$74.95; $224.95 (10-copy lab pack)

Maxwell

by Pieter Visscher
University
of Alabama



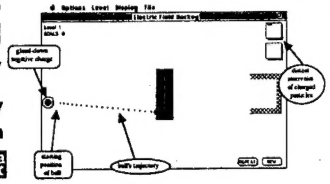
Pc

Displays time evolution of electromagnetic fields. Helps create an intuitive understanding of electrodynamics with a variety of configurations and devices.

$69.95; $209.95 (10-copy lab pack)

Electric Field Hockey

by Ruth W. Chabay
Carnegie Mellon



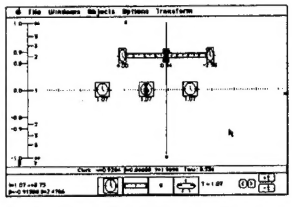
Pc Ma

Unique simulation game instills intuitive understanding of the Coulomb force, the superposition of forces, and frictionless motion.

$59.95; $179.95 (10-copy lab pack)

Spacetime

by Edwin F. Taylor
Massachusetts
Institute of
Technology



Pc Ma

Introduction to the study of special relativity. Explore time dilation, Lorentz contraction, the twin paradox, and the Doppler shift.

$59.95; $179.95 (10-copy lab pack)

PAS offers a diverse selection of more than 30 peer-reviewed titles, so there is something for everyone—students, teachers, and scientists!

PHYSICS ACADEMIC SOFTWARE

Act Now Order Today!

Order by check, credit card (MC, Visa, AmEx), or institutional purchase order. Just call or write:

The Academic Software Library
Box 8202
North Carolina State University
Raleigh, NC 27695-8202

For shipping & handling in the U.S., Mexico, & Canada add $3.50 for first package and $.75 for each additional package. All other foreign orders will be shipped air mail. Add $12.50 for first package and $4.00 for each additional package. Allow 2 weeks for delivery.

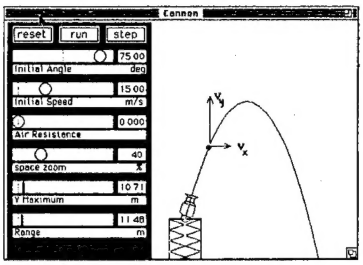
Make an Introduction That Leaves a Lasting Impression

Introductory Physics Software for your Classroom and Lab

Objects In Motion



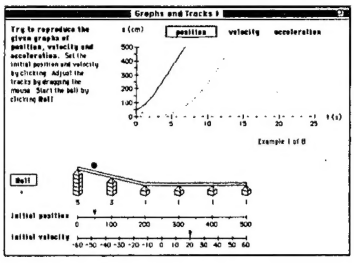
Peter Cramer

Case Western Reserve

Your students will learn the notion behind the motion with Objects In Motion, a collection of six interactive simulations—Cars, Cannon, River, Planet, Circle, and Collider—that focuses on the physics of moving objects and teaches the concepts underlying kinematics, rotational motion, uniformly accelerated motion, conservation laws, Galilean relativity, Kepler's laws, scattering, and vector superposition.

$84.95; $254.95 (10-copy lab pack)

Graphs & Tracks



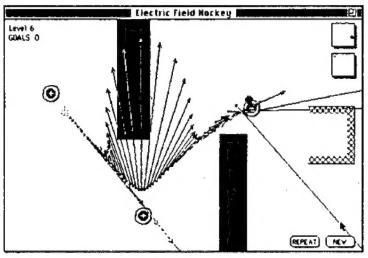
David Trowbridge

Microsoft Corporation

Put your students on the right track with Graphs & Tracks, a goal-oriented simulation tutorial that underscores the connection between animated motion and graphs. In Part I, students set up a ball on an inclined set of tracks and try to reproduce the motion indicated on a given set of graphs. In Part II, they roll the ball on the tracks and sketch the subsequent motion with a graph-drawing editor.

$79.95; $239.95 (10-copy lab pack)

Electric Field Hockey



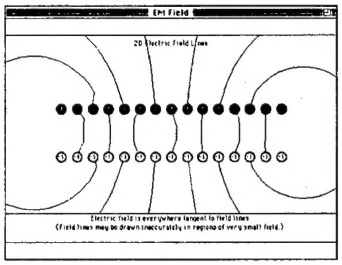
Ruth Chabay

Carnegie Mellon

By combining serious learning with serious fun, Electric Field Hockey instills an intuitive understanding of the Coulomb force, the superposition of forces, and frictionless motion. This computer-simulated game challenges students to move a charged ball around various barriers and into a goal. Because you can show the resultant force acting on the ball, Electric Field Hockey is a powerful tool for demonstrating the superposition of forces.

$59.95; $179.95 (10-copy lab pack)

EM Field



David Trowbridge

Microsoft Corporation

Bruce Sherwood

Carnegie Mellon

Get your students charged up about electricity and magnetism with EM Field! This interactive software will help them visualize electric fields produced by point and line charges and magnetic fields produced by current-carrying wires and gain an intuitive, physical feel for fields. Unique features include the ability to explore Gauss's law and Ampere's law.

$69.95; $209.95 (10-copy lab pack)

A publishing project of the American Institute of Physics in cooperation with the American Physical Society and the American Association of Physics Teachers

AMERICAN INSTITUTE OF PHYSICS 500 Sunnyside Boulevard, Woodbury, NY 11797-2999

The American Institute of Physics (AIP) is a not-for-profit membership corporation chartered in New York State in 1931 for the purpose of promoting the advancement and diffusion of the knowledge of the science of physics and its application to human welfare. In order to achieve our purpose, we serve the sciences of physics and astronomy by serving the member societies, by serving individual scientists, and by serving students and the general public.

As leading scientific publishers, the American Institute of Physics and its Member Societies publish more than one-quarter of the world's research literature in all areas of physics including: general physics, applied physics, chemical physics, geophysics, plasmas and fluids, medical physics, nuclear and particle physics, astronomy, electronics, engineering, crystallograhy, instrument science, materials science, mathematics, acoustics, rheology, optics, and vacuum science. AIP publishes its own archival and translation journals, and provides publishing services to member and other organizations.

Member Societies

The American Physical Society
Judy Franz, Executive Officer
One Physics Ellipse
College Park, MD 20740-3844

Optical Society of America
David W. Hennage, Executive Director
2010 Massachusetts Avenue, N.W.
Washington, DC 20036

Acoustical Society of America
Charles Schmid, Executive Director
500 Sunnyside Blvd., Woodbury, NY 11797-2999

The Society of Rheology
Andrew M. Kraynik, Secretary
Department 1512
Sandia National Labs.
Albuquerque, NM 87185

American Association of Physics Teachers
Bernard V. Khoury, Executive Officer
One Physics Ellipse
College Park, MD 20740-3845

American Crystallographic Association
William L. Duax, Executive Officer
P.O. Box 96, Endicott Station
Buffalo, NY 14205-0096

American Astronomical Society
Peter B. Boyce, Executive Officer
1630 Connecticut Avenue, N.W.
Washington, DC 20009

American Association of Physicists in Medicine
Sal Trofi, Executive Director
One Physics Ellipse
College Park, MD 20740-3846

American Vacuum Society
William D. Westwood, Secretary
Bell–Northern Research, Ltd.
P.O. Box 3511, Station C
Ottawa, Ontario K1Y 4H7, Canada

American Geophysical Union
A. F. Spilhaus, Jr., Executive Director
1630 Connecticut Avenue, N.W.
Washington, DC 20009

Affiliated Societies

American Institute of Aeronautics and Astronautics, American Meteorological Society, American Nuclear Society, ASM International, Astronomical Society of the Pacific, Division of Physical Chemistry of ACS, Engineering Information, Inc., The Geological Society of America, Instrument Society of America, International Association of Mathematical Physicists, International Centre for Diffraction Data, Materials Research Society, Microscopy Society of America, Nuclear and Plasma Sciences Society of IEEE, Physics/Astronomy Section of the Council on Undergraduate Research, Physics Section of AAAS, Society for Applied Spectroscopy, SPIE—The International Society for Optical Engineering.

Corporate Associates: Approximately 175 leading corporations, by their membership, participate in and contribute to the support of AIP.

Also Available:

Sample Copies
Sample copies are available to institutions considering a subscription.

Back Volumes
Back volumes are available in print, microfilm or microfiche.

Microform
Journals marked with an asterisk are available on microfilm and microfiche.

Special Discount Rates
Reduced rates are available for a variety of combination subscriptions. For details, contact AIP Circulation and Fulfillment.

Document Delivery
Obtain full-text copies of individual articles from core journals in physics – plus AIP and Member Society books and conference proceedings – through **Articles in Physics.** Documents are sent to you within 24 hours of your order via fax, mail or overnight express. For more information or to order call 1-800-480-PHYS or 415-259-5002. FAX: 415-259-5044. E-Mail: articles@aip.org

Online Access
Abstracts of journals published by AIP and Member Societies are available online in the SPIN database via the commercial service Dialog as well as on PINET, the AIP online information service. PINET also offers a current awareness database, Advance Abstracts, offering abstracts up to three months prior to their journal publication dates. Please call 516-576-2262 for additional information.

Book Program
AIP publishes a full line of monographs, proceedings, texts, and references. For further information in the U.S. and Canada contact William Phillips, Books Customer Service, at (516) 576-2411. Elsewhere, contact Susan Harrison, Oxford University Press, at +44 865-56767
